According to Sabin,[2] the cardinal characteristics of Toxoplasma are (1) typical morphology and staining characteristics of extracellular and intracellular forms in impression films of fresh tissue or exudate; (2) pathogenicity for mice, guinea pigs, rabbits, chicks, etc.; (3) obligate intracellular parasitism; (4) immunologic relationship with established strains.

Unequivocal proof that toxoplasmas are the cause of certain disease conditions in human beings was first obtained in 1939. The toxoplasmic etiology of certain types of congenital encephalomyelitis and ocular damage, of certain types of acute encephalitis in older children, of a spotted-fever-like disease and pneumonitis in adults now rests on the firm foundation of demonstration of the organisms in the tissues.

---

[2] Am. J. Trop. Med. & Hyg. 2: 360, 1953.

Although toxoplasmosis has been suggested as a possible cause of spontaneous abortions of unknown etiology, it is probably not a common cause. Feldman and Eichenwald together performed serologic tests on 95 women with spontaneous abortions of unknown etiology and found no evidence of current toxoplasmosis.

Studies by Siim in Denmark revealed that among patients with unexplained febrile illnesses associated with lymphadenopathy, a certain number exhibited serologic evidence of recent infection with Toxoplasma. Pinkerton found morphologically typical toxoplasmas in the lymph node of an American woman with a high titer of dye test antibody. Feldman, Eichenwald, and Jacobs found no evidence of active or recent infection with Toxoplasma in more than 100 patients with acute, active, or recurring chorioretinitis tested by the new serologic methods.

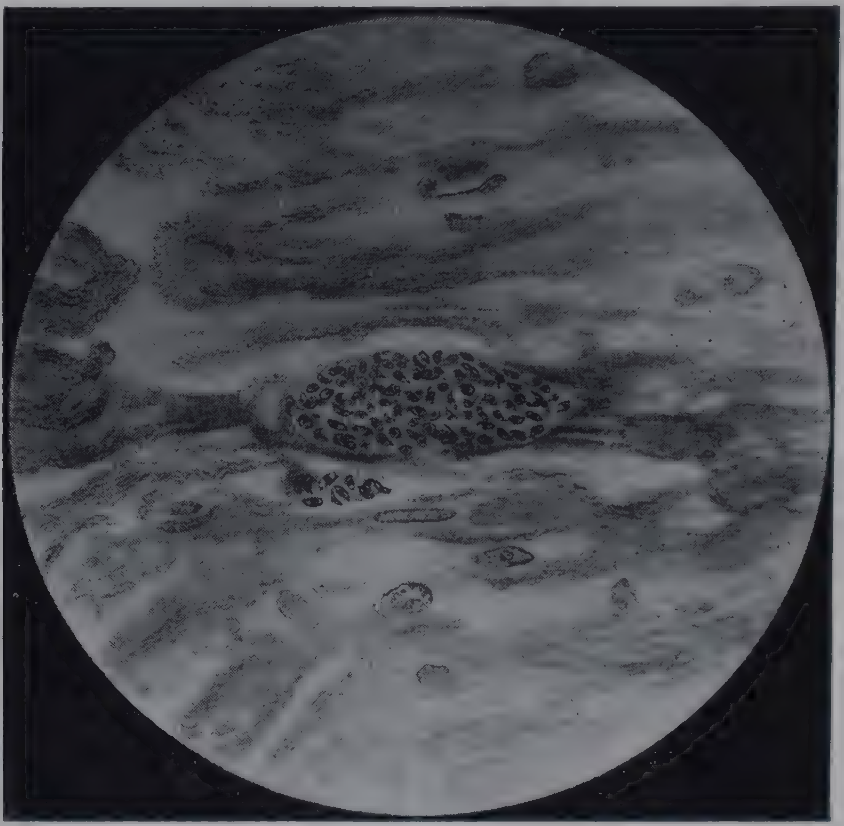

Fig. 478.—Toxoplasma in section of cardiac muscle of a dog. Drawing by David Eichelson of the N.I.H. staff. (Courtesy Leon Jacobs, Laboratory of Tropical Diseases, National Microbiological Institute, National Institutes of Health. Am. J. Trop. Med. & Hyg. 2: 365, 1953.)

It seems to be a fact that countless millions of people in various parts of the world become infected with toxoplasmas during their lifetimes. If this is true, perhaps the clinically recognizable disease associated with such widespread infection might not be as rare as it now seems to be; future awareness and intelligent application of appropriate diagnostic tests might supply us with clues to clinical syndromes of toxoplasmosis which are now lost in the vast mass of undiagnosable human disease.

MALARIA

Order **HAEMOSPORIDIA** Danilewsky

The order Haemosporidia includes small sporozoa and usually intracellular parasites of erythrocytes as well as those found in the endothelial cells of the vertebrate host.

Family **PLASMODIDAE** Mesnil 1903

The Family Plasmodidae includes species which produce pigment within erythrocytes of vertebrates and also produce gametocytes. Species of the genus Plasmodium cause human malaria.

Malaria is a disease caused by protozoa belonging to the genus **Plasmodium.** The parasite is found in the red blood cells of the circulating blood. Malaria produces periodic febrile attacks leading later to high-grade anemia, swelling of the spleen, and severe cachexia.

The geographic distribution is very extensive. An area of about 30° latitude on each side of the equator may be considered as the malarial belt which encircles the earth. Malaria is found in tropical and temperate zones and as far north as 65° latitude in Europe and Asia and about 40° north latitude in North America. Where malaria is not found it is due to the absence of the insect vector or to a mean temperature not greater than 15° C. (59° F.). Approximately 10,000,000 cases have been reported in India, and possibly that number abounds in Africa. It is not definitely settled whether the disease was brought to the New World from Africa in slave ships or whether it was found in the Americas at the time of the discovery by Columbus.

The cause of malaria was discovered in 1880 by Laveran, in Algiers. Richard, in 1882, was the first to confirm Laveran's discovery.

Malaria and Mosquito

In 1896, Manson announced his theory that mosquitoes die within a few days after they have laid their eggs upon the surface of the water. He thought then that the drinking of such water by man resulted in infection, but earlier attempts to infect man by drinking water from swamps absolutely failed. The true story of the sexual development of this parasite in the mosquito was theoretically worked out by Manson and actually proved by Ross in 1897, later confirmed by Grassi. Manson communicated his theoretical idea to Ronald Ross, who, at that time, was a young officer in the medical corps of the British Army. Ross had a long service with the Colonial Forces in India and was a student of mosquitoes even before he had any idea of their role in malaria. While on a visit to England, he was instructed by Manson in the appearance of the malarial parasite and returned to India determined to put Manson's theory into practice. He definitely proved Manson's ideas to be correct. He returned to India in 1895. In 1897 he had successfully proved the role of the mosquito as the intermediary infecting agent in malaria. Four years of hard work followed, studying mosquitoes. He noted the two varieties, the "gray" (Culex) and the "black-striped winged" variety (Stegomyia). On Aug. 20, 1897, in Secundcarabad, India, Ross demonstrated that the sporozoites of the malarial parasites were seen in the stomach wall of "large dapple-winged mosquitoes," and that these were undoubtedly of the Anopheles variety. These mosquitoes were cultivated from larvae and were inoculated with crescent parasites found in blood.

In the same year MacCallum (1897-1898) observed the fertilization of the female gametocytes by the male.

Ross noted that five days after the initial infection the pigmented cells in the mosquito stomach wall were filled with partially developed sporozoites.

This constituted the beginning of the development of the malarial parasite in the mosquito. In 1898 Ross showed the whole process of development of the organism, using bird malaria, or Proteosoma, in the Culex mosquito. He also proved the carrying over of malaria of birds from an infected mosquito to healthy birds.

Fig. 479.—Differentiation of mosquitoes. (Chart planned and drawn by Dr. Alfonso Bonilla Naar, of Bogotá, Colombia, and published through his courtesy by permission of copyright owner, General Biological Supply House, Chicago, Illinois.)

Grassi, Bignami, and Bastianelli in 1898 confirmed this work. Bignami in 1898 was the first to carry over true malaria through an infected Anopheles mosquito. Grassi, Bignami and Bastianelli, toward the end of 1898, showed the full development of the tropical as well as the tertian and quartan parasites in the blood of the *Anopheles claviger*. Ross in 1899 showed further that all three parasitic varieties could be developed in *Pyretophorous costalis* or *Myzomyia funesta* like the proteosoma in *Culex fatigans*. Grassi in 1899 and other Italian workers, and Ziemann in 1900, showed that the Anopheles is the only type of mosquito to carry the human parasites.

Attempts were made by Mesnil and Rouband in 1917 to carry over the malarial parasite to chimpanzees. Reichenow in 1917 and 1920 in the Cameroon attempted the inoculation of anthropoid apes with human malarial parasites. These attempts were unsuccessful.

Malaria is transmitted through the bite of the anopheline mosquito. The known vectors in North America are *Anopheles quadrimaculatus* (a good vector), *A. crucians* (probably a good vector in some sections), *A. maculipennis* (principal vector in Europe and probably also in California), *A. punctipennis* (not known to be a vector till 1916, undoubtedly a poor vector), and *A. pseudopunctipennis* (not known positively to be a vector in North America, but recently shown to be the main vector in parts of Argentina).

It has been proved by Rozeboom and Laird[1] that the *A. bellator* is a vector of malaria. This work was carried out during the 1942 military emergency in Trinidad, in connection with the control of malaria incident to the construction of an Army base at that point. In Trinidad, the control problem had been complicated by the fact that the distribution of malaria could not be explained on the basis of the two known vectors, *A. albimanus* and *A. aquasalis*. It was found that the *A. bellator* breeds in water which collects in the air plants which grow in the Immortelle trees, used locally on plantations as shade for the cocoa trees. It has been suspected that this mosquito was an important vector of malaria on epidemiologic grounds but this was not supported by experimental evidence until the work of Rozeboom and Laird was completed. They showed that the *A. bellator* attacked man viciously, literally swarming about people during the hours when the females became active, and that it attacked man throughout the afternoon, especially on dark days and in the shade of the forest. Experimental infections of *A. bellator* were obtained twice, and proved that the species was very susceptible to at least one of the species of Plasmodium causing human malaria. Oöcysts were found in two of four *A. oswaldoi* that fed on a *P. vivax* gametocyte carrier. Three of 725 ''wild'' *A. bellator* were found to be naturally infected with Plasmodium. The evidence collected by Rozeboom and Laird confirmed the conclusions of DeVerteuil[2] that *A. bellator* is the vector of malaria in the interior cocoa growing districts of Trinidad.

The Anopheles belong to the subfamily Culcinae. The Culcinae are divided into two tribes—Anophelini and Culicini. The tribe Anophelini has been divided into a large number of genera (about thirty-eight) but it has been proposed to recognize only one genus, Anopheles. It is important to distinguish between the Anopheles and the Culex, which is the ordinary nonmalaria-carrying mosquito. All the anophelines can be distinguished by the palpi, which in both the females and males are as long as the proboscis. The female of no other species of mosquitoes has such long palpi. The larvae, when feeding, float parallel to the surface of the water and do not possess a respiratory siphon.

BLOOD PICTURE OF MALARIA SHOWING PHAGOCYTOSIS

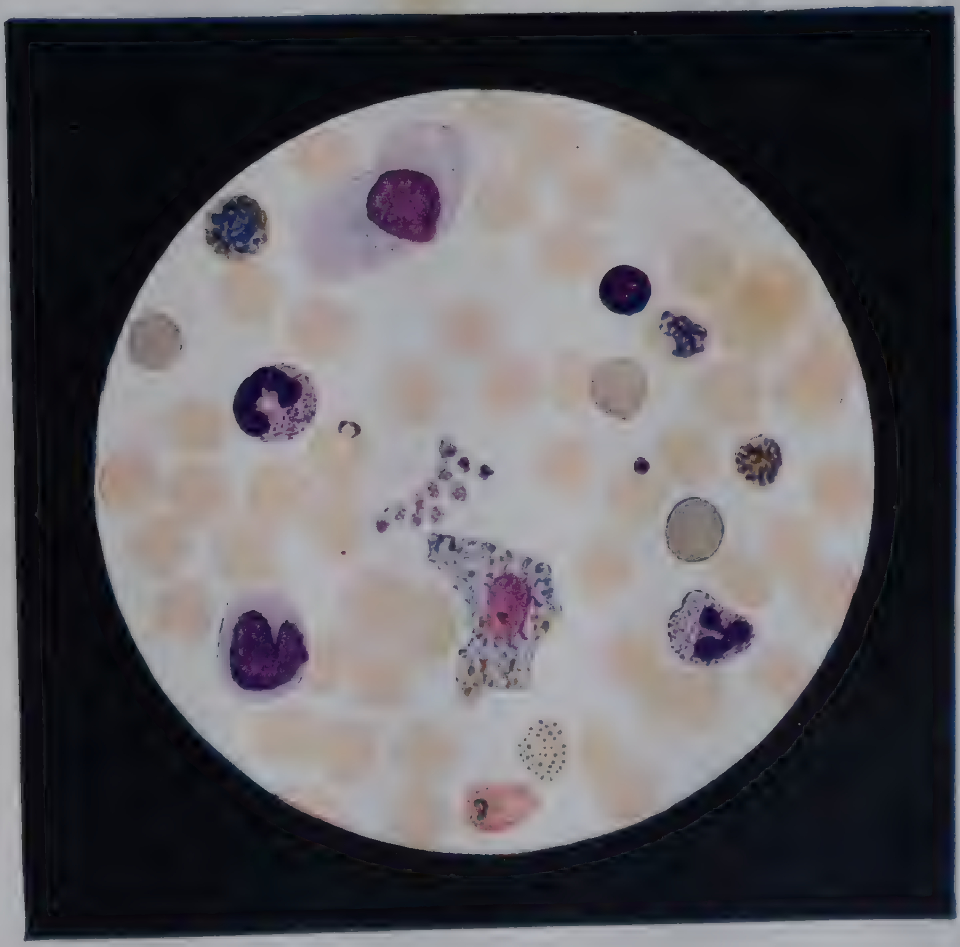

PLATE XLIX.

(See legend on opposite page.)

The winged mosquitoes, Anopheles and Culex, differ from each other in their positions upon the wall. The female Culex sits on the wall with its abdomen parallel and close so that there is a very slight angle. The Anopheles sits with a very acute angle, 50 to 80°.

The female Anopheles have palpi which are long as their stickers, while the Culex have very short palpi. The male mosquitoes of both types have feathery antennae, which readily identify them as males.

The differences in appearance of the two varieties are well seen in Fig. 479.

A. walkeri (Theobald) may confuse malariologists, according to Bellamy and Andrews,[1] who record that more than 80 larval *A. walkeri* were identified in the collections made between Sept. 15 and Nov. 11, 1937, from seven different permanent or semipermanent shallow ponds in southeastern Sumter County, Ga. All the ponds supported heavy growths of emergent vegetation, supplemented in several instances by submerged and floating vegetation and considerable debris.

Twenty adult female *A. walkeri* were taken with collecting tubes while biting between 9:30 and 11:30 P.M., October 5, within 50 feet of a productive breeding place. They found that all of the wild-caught females, plus five raised from larvae, resembled the Florida specimens, having quite distinct bands of white scales on the palpi. Two males which were reared appeared to be similar to *A. quadrimaculatus*, though they were perhaps somewhat darker.

Habits of the Anopheles.—Anopheles are all night-flying insects. The *A. maculipennis* begin to swarm and bite when the sun goes down. With the rise of the sun, they seek dark places. They are most active during twilight. In the tropics, they are very prevalent in cloudy weather with no wind. During the day, they are in the grass and in the dark corners of buildings or in the stables. They avoid wind and rain. A severe rain will throw most of them down and kill them. As soon as it begins to rain, they fly to the houses and huts.

Malarial Parasites

Genus **Plasmodium** Marchiafava and Celli 1885

There are four different varieties of plasmodia which not only are morphologically different, but also produce different and distinct clinical symptoms. There are, however, mixed infections in the same individual. The four species are: (1) *Plasmodium vivax,* the cause of tertian malaria; (2) *Plasmodium malariae,* the cause of quartan malaria; (3) *Plasmodium falciparum,* the cause of tropical or estivo-autumnal, or falciparum malaria; (4) *Plasmodium ovale,* the cause of a benign malaria.

Life Cycle of Malarial Parasites

There are two hosts concerned with the development of the Plasmodium of malaria. One is the vertebrate host in which the cycle is asexual, the other is the invertebrate host, a mosquito, in which the cycle is sexual. The vertebrate and invertebrate hosts have been referred to, respectively, as "intermediate" and "definitive." Some believe that the use of these terms is erroneous. The sexual cycle is initiated in the vertebrate host by the forming of gamete-producing cells. The aggregate of the parasites living within the vertebrate host more nearly corresponds with the adult sexual individual among higher animals since they produce the gametes. A large portion of sporogony appears to be an asexual reproduction. It appears unjustifiable to continue in use the common practice of making alternation of generation strictly parallel without alternation of hosts. Some authors regard the use of the terms "intermediate" and "definitive" hosts for the vertebrate and invertebrate hosts, respectively, as highly questionable. It would seem that the terms "vertebrate phase" and "mosquito or invertebrate phase" for these portions of the cycle would be more appropriate in the present state of our knowledge.

---

[1] South. M. J., p. 797. July, 1938.

The great ease with which the parasites can be studied in the mosquito has led to a much more complete understanding of the morphologic development or stages of the parasites in that host than the stages in the vertebrate hosts. At the present time, a connected story of the development of malarial parasites is known only in a few of the species parasitizing birds, but it is known that the development of the parasites of man in the anophelene mosquito, of those of birds in the culicine mosquitoes, of Haemoplotus in the hippoboscid flies, and of Leucocytozoon in simuliids are similar to general outline.

The Invertebrate Phase.—In the Anopheles, when *P. falciparum* is ingested, the blood from the vertebrate host may contain asexual stages of the parasite in addition to sexually differentiated gametocytes. The former are digested in the stomach or midgut of the mosquito. The **gametocytes** undergo gametogenesis in the lumen of the stomach, resulting in transformation into or production of large **macrogametes** and threadlike **microgametes**. These gametes fuse in fertilization, which results in a **zygote,** which is a vermicular **oökinete,** which migrates through the stomach wall and rounds up to form an **oöcyst.**

Lying between the columnar epithelium and the membrane, these oöcysts grow rapidly, increase in size, and undergo complex internal change. These changes involve the repeated division of the nucleus, the formation of many vacuoles which become confluent, the migration of the nuclei to the cytoplasmic surface next to the vacuoles, and the budding off of small portions of cytoplasm, each containing a nucleus.

These budded portions are called "**sporozoites.**" They fill the oöcyst and become arranged in a haphazard manner prior to the bursting of the oöcysts. When this happens, that is, when the oöcyst bursts, the sporozoites enter the hemocele of the mosquito and circulate. No further development occurs in the mosquito. Many of these sporozoites reach the salivary gland, the cells of which they penetrate. Some disappear. The sporozoites then enter the salivary ducts of the mosquito and are deposited in the subcutaneous tissues of man when saliva is injected during the blood-sucking process.

The Vertebrate Phase.—Following Schaudinn's claim in 1903, it has generally been believed that sporozoites of Plasmodia enter directly into red blood cells. It was, for a long time, assumed that all of the schizogony was confined to circulating cells in species belonging to this genus. It is now known that some species of plasmodium have **exoerythrocytic stages of schizogony.** Schizogonic development and metagonic development occur in all types of plasmodia infecting man. This schizogony is characterized by repeated nuclear division, by extensive vacuolization, and by eventual production of merozoites. In most species, schizogony must be repeated many times. This schizogony may take place in an individual host for as long as eight years. In the case of one strain of avian malaria, it has continued without intervention of sexual reproduction for 32 years.

With **erythrocytic schizogony,** the best known stages of malarial parasites which develop in the vertebrate host are of those that live in the erythrocytes. The youngest stage found in the erythrocyte is the uninucleate trophozoite which consists of cytoplasm and a nucleus. In the youngest stage, it is most frequently round or oval. No pigment is visable at this stage. The trophozoite grows at the expense of the erythrocyte and assumes a more variable form which differs widely with the species, but in most cases the formation of pseudopodia is seen, and when observed in the living stage, granules, which vary according to the species, appear soon after the first perceptible growth has occurred. These granules consist of hematin which is formed as the result of digestion of the hemoglobin of the erythrocyte.

The growing parasite is destined to produce either a schizont or a gametocyte. Parasites destined to grow into segmenting forms are schizonts from the beginning of their development. As the parasite grows, further division of the nucleus takes place, a process termed ‘‘**schizogony.**’’ After the last nuclear division has occurred, the cytoplasm fragments into as many portions as there are nuclei and the parasite in this stage is known as the ‘‘segmented’’ or ‘‘mature’’ **schizont.** The uninucleate progeny are known as ‘‘**merozoites.**’’

The erythrocyte ruptures, releasing the merozoites, and accumulated pigment, into the plasma of the blood. The individual merozoites usually enter other erythrocytes. The terms ‘‘schizont’’ and ‘‘trophozoite’’ are not mutually exclusive. A **trophozoite** is the actively growing asexual stage regardless of its nuclear condition. As stated before, after Schaudinn’s work, published in 1903, for twenty years there was a generally accepted belief that schizogony was exclusively erythocytic. It is obvious from the work of James that intermediate stages exist between sporozoites and erythrocytic stages. Warren and Coggeshall in 1937 proved that during the ‘‘negative’’ phase of the blood, *P. cathemerium* parasites actually existed in the spleen, liver, bone marrow, and the site at which the sporozoites had been inoculated. These results were confirmed and extended to other species.

In the stages of the avian malarial parasites, two types have been recognized as exoerythrocytic, the *P. circumflexum* and *P. elongatum.*

Different terms are now used for the two categories: **exoerythrocytic stage** and the **pre-erythrocytic stage,** which comprise all forms of the first line of development between sporozoites and the first erythrocytic trophozoites. This includes the first generation **cryptozoites,** stemming directly from the sporozoites, and **metacryptozoites,** which follow the cryptozoites. The term ‘‘exoerythrocytic’’ cell means the stages in the cells other than the erythrocytes which are seen in blood-induced infections, and late enough in sporozoite-induced infections so as not to be thought of as pre-erythrocytic stages. Huff and Coulston have proposed the term ‘‘phanereozoites,’’ or ‘‘phanerozoic’’ stages for this category.

PLATE L.

Summary.—Sporozoites of *P. vivax* and *P. falciparum*, and presumably those of the other parasites, leave the blood after a few hours and undergo a pre-erythrocytic phase in the parenchyma cells of the liver. The ripe forms produce a group of young sporelike formed merozoites which seek blood corpuscles for further cyclical development. It must be remembered that there are two forms of development: one asexual, which is called "schizogony"; and the other, the sexual form, which develops gametes, called "sporogony."

The mosquito picks up the malarial parasite by biting a malarial subject. The male and female elements combine and produce their offspring in the stomach of the mosquito. In other words, the adult males, or microgametocytes, fertilize the adult females, or macrogametocytes. This occurs from twenty minutes to two hours after the bite. From this fertilization, the oökinete is formed. This pierces the wall of the stomach of the mosquito and starts an oöcyst under the outer epithelial area of the stomach. This occurs in about forty-eight hours. The oöcysts develop slowly, forming a large sporoblast with many thousands of sporozoites in the form of a large cystic mass on the wall of the stomach. Rupture of this cystic mass permits the sporozoites to enter the salivary gland of the mosquito. The entire development, provided the proper temperature prevails, takes place in from eight to ten days. By proper temperature is meant between 24 and 30° C. Sharp cooling hinders this development. From the salivary gland, the free sporozoite is inoculated into the next human subject and the next cycle of development in man begins.

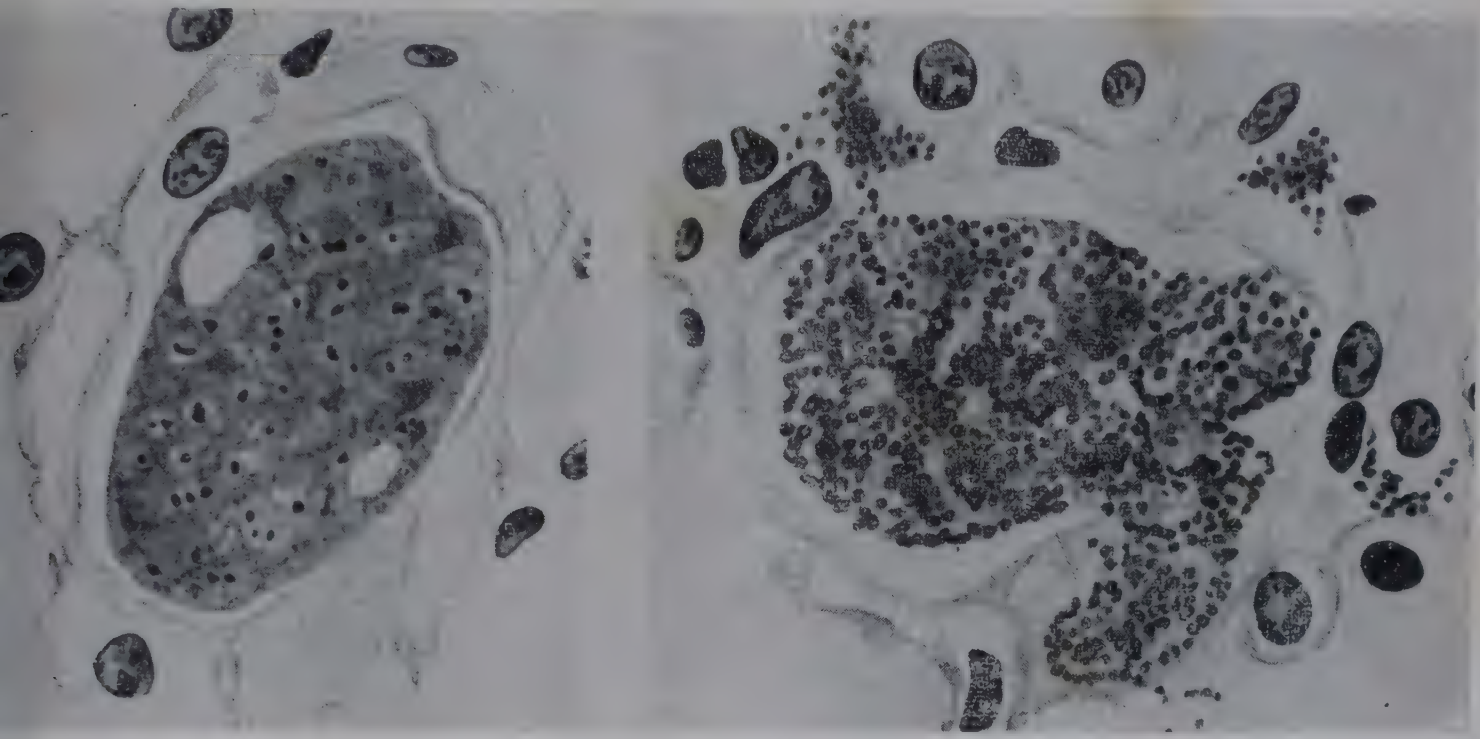

Fig. 480.—Pre-erythrocytic phase. Schizonts of *Plasmodium vivax* showing development in the human liver on the seventh day after experimental sporozoite infection. (After Shortt and Garnham: Tr. Roy. Soc. Trop. Med. & Hyg. **41**: No. 6, 1948.)

1. Plasmodium Vivax (Grassi and Feletti 1890) (Malaria Tertiana)

In the Giemsa-stained specimen, the youngest asexual form appears as a blue ring with a small red dot. The free interpretation of the ring is, according to Schaudinn, that it is a nutritional vacuole. In the youngest forms of the parasite may be seen distinct pigment (melanin) as fine granular brown or black irregular masses. The asexual forms may reach the full size of the red blood corpuscle. It is in this form of malaria, therefore, that the corpuscle seems to be increased in size by the presence of the parasite. The nucleus of this parasite divides into 12 to 22 very small nuclei, while the pigment is distributed usually into two large clumps. After a parasite reaches the stage of division, there is a destruction of the blood cells and a new cycle of development occurs. In the case of tertian malaria this takes about forty-eight hours and is responsible for the absence of fever during this time. The name ''tertian'' is used because the fever occurs every third day. If, however, there are two parasitic varieties in the same blood at the same time, development takes place on the third day, but every day or so paroxysms may occur, which is called ''tertiana duplicata,'' also known clinically as ''tertian fever.''

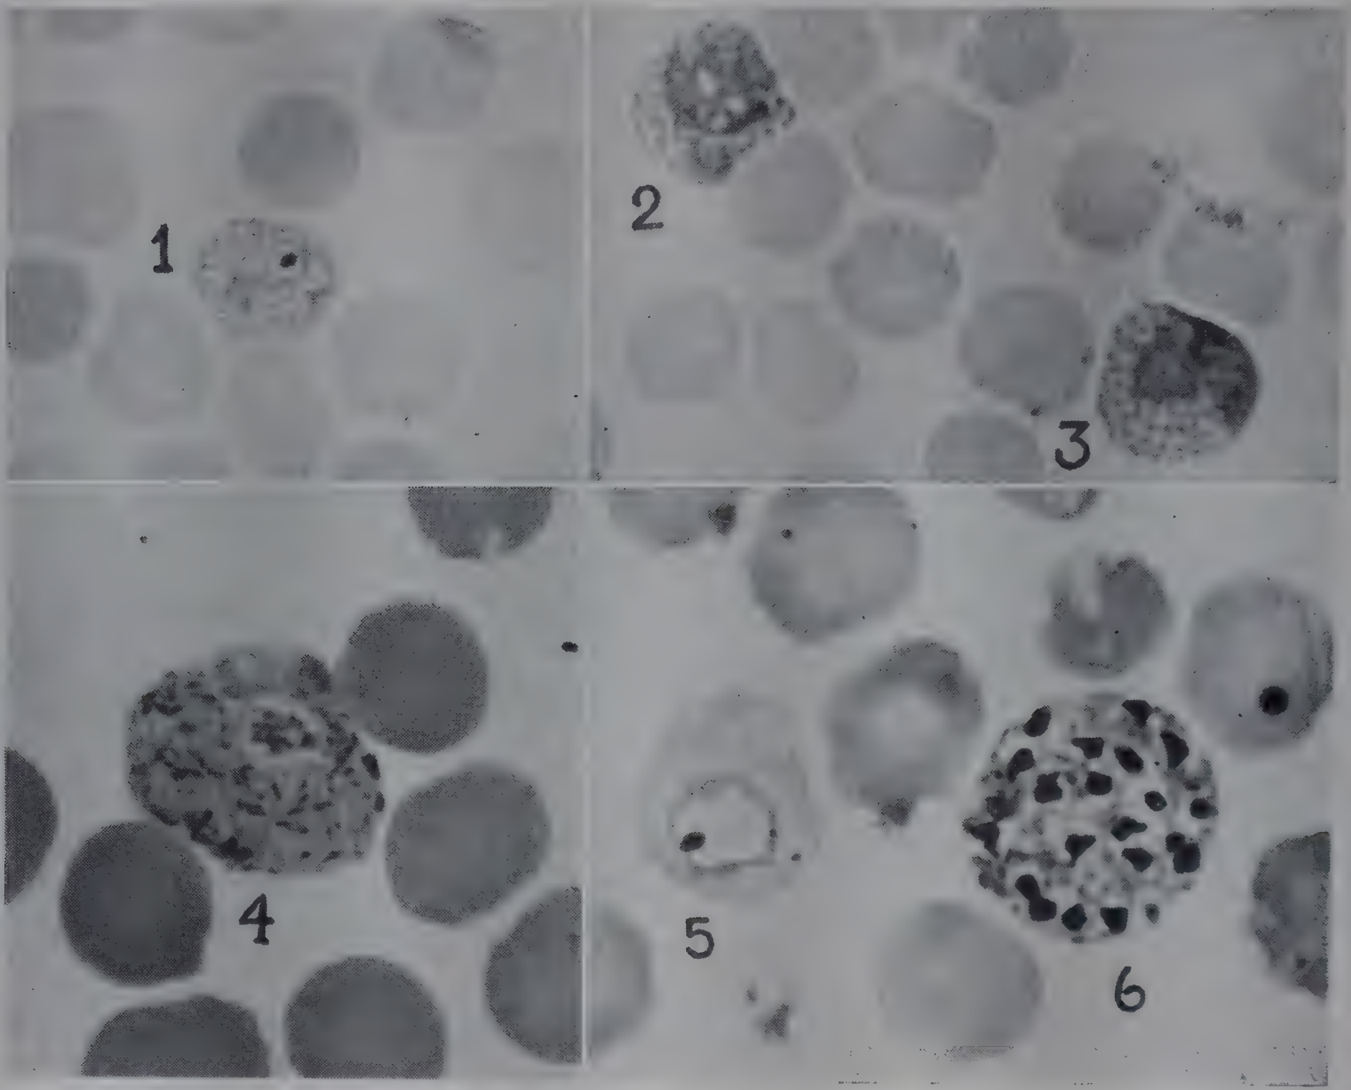

Fig. 481.—*Plasmodium vivax.* Film of peripheral blood stained with Giemsa. *1,* Young schizont, ameboid form, showing Schüffner punctation; *2* and *3,* two schizonts, ameboid form, in a further stage of development, each parasitizing one erythrocyte with Schüffner punctation; *4,* spherical gametocyte occupying the entire enlarged erythrocyte; *5,* young trophozoite, ring form, parasitizing a pale, enlarged erythrocyte; *6,* completed schizogonous division, numerous merozoites, which fill the entire enlarged erythrocyte. Compare the size of the parasitized erythrocytes with those without parasites. (Original photomicrograph of Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

The sexual forms, microgametocytes and macrogametocytes, in their youngest stage, form round or oval blue bodies with chromatin granules in the center or on the side. They retain their round form for a long time, but they do not show any ameboid movement. In the older stages, the cytoplasmic-rich female gametes are stained intensive blue. The chromatin-rich nucleus is at one side and often shows a light aureola. They can attain twice the size of the blood corpuscle. The male sexual forms show the same figure, but remain small. They are poor in cytoplasm and therefore show more nuclear substance. They also stain a lighter blue and often are reddish. The nucleus is lobulated and shows red chromatin lines. Fully developed ripe male forms show a rich fine granular brown black pigment which is distributed all over the parasite. In the unstained specimen this shows active Brownian molecular movement. The sexual forms can be distinguished from the asexual parasites by this pigment in the fresh specimen as well as in the thick drop preparation. We have observed double infection of asexual and sexual forms in the same specimen of blood.

The asexual forms show clumping of the pigment; the sexual forms show no clumping but a generally scattered pigmentation.

The red blood cells in tertian infection are very pale and are increased in size by virtue of the presence of the parasite. They show in the Giemsa stain very fine, later coarser, so-called Schüffner stippling. Alkalinizing the stain makes the Schüffner stippling more distinct, whereas neutralizing the water makes the parasite stand out more distinctly. The schizogony or asexual division of *P. vivax* shows 12 to 22 nuclei, while that of *P. malariae* shows no more than 12. This is a very important point of differentiation.

The rings of *P. falciparum* are small and represent about one-fifth of the diameter of the cell, whereas the rings of *P. vivax* are large, representing one-third of the diameter of the cell. The rings of *P. falciparum* also show two or more nuclei, while those of *P. vivax* show but one, rarely two. Also it must be remembered that the rings of *P. malariae* are larger, but the red blood cell itself is not enlarged.

2. Plasmodium Malariae (Grassi and Feletti 1890) (Malaria Quartana)

The quartan parasite resembles the tertian parasite but it is smaller and not as actively motile. The youngest asexual forms are rings. Older forms always appear as bands. Dependent upon the age, there are either small or wide band forms. The chromatin appears near the edge; there is an elongated nucleus. There is a very fine and light golden yellow pigment (melanin) close to the edge. A completely developed parasite has wide bands with divided nuclei. The divisions are between 8 and 12 but seldom up to 16, as is seen in *P. vivax*. These forms attain about the normal size of the red cell. The cycle of the development period for *P. malariae* is seventy-two hours. Several varieties, however, may exist in the same individual so that there is a double infection with daily fever or two days of fever in succession, the so-called "quartana duplicata" or "quartana triplicata." The sexual forms show the same form and staining as the *P. vivax* but are never larger than a normal red cell. The red cells in quartan malaria are not enlarged, not blown up, and not stippled, but are more globular. In quartan malaria, the parasites are rather scarce in peripheral blood.

3. Plasmodium Falciparum (Welch 1897) (Malaria Tropica) (Estivo-Autumnal Malaria)

The youngest asexual forms are very small rings. Older stages show more protoplasm and appear as large rings, the so-called "cycle" ring forms. They usually show two chromatin granules which lie close together. The ripe asexual forms, especially in comatose cases, are found in the peripheral blood.

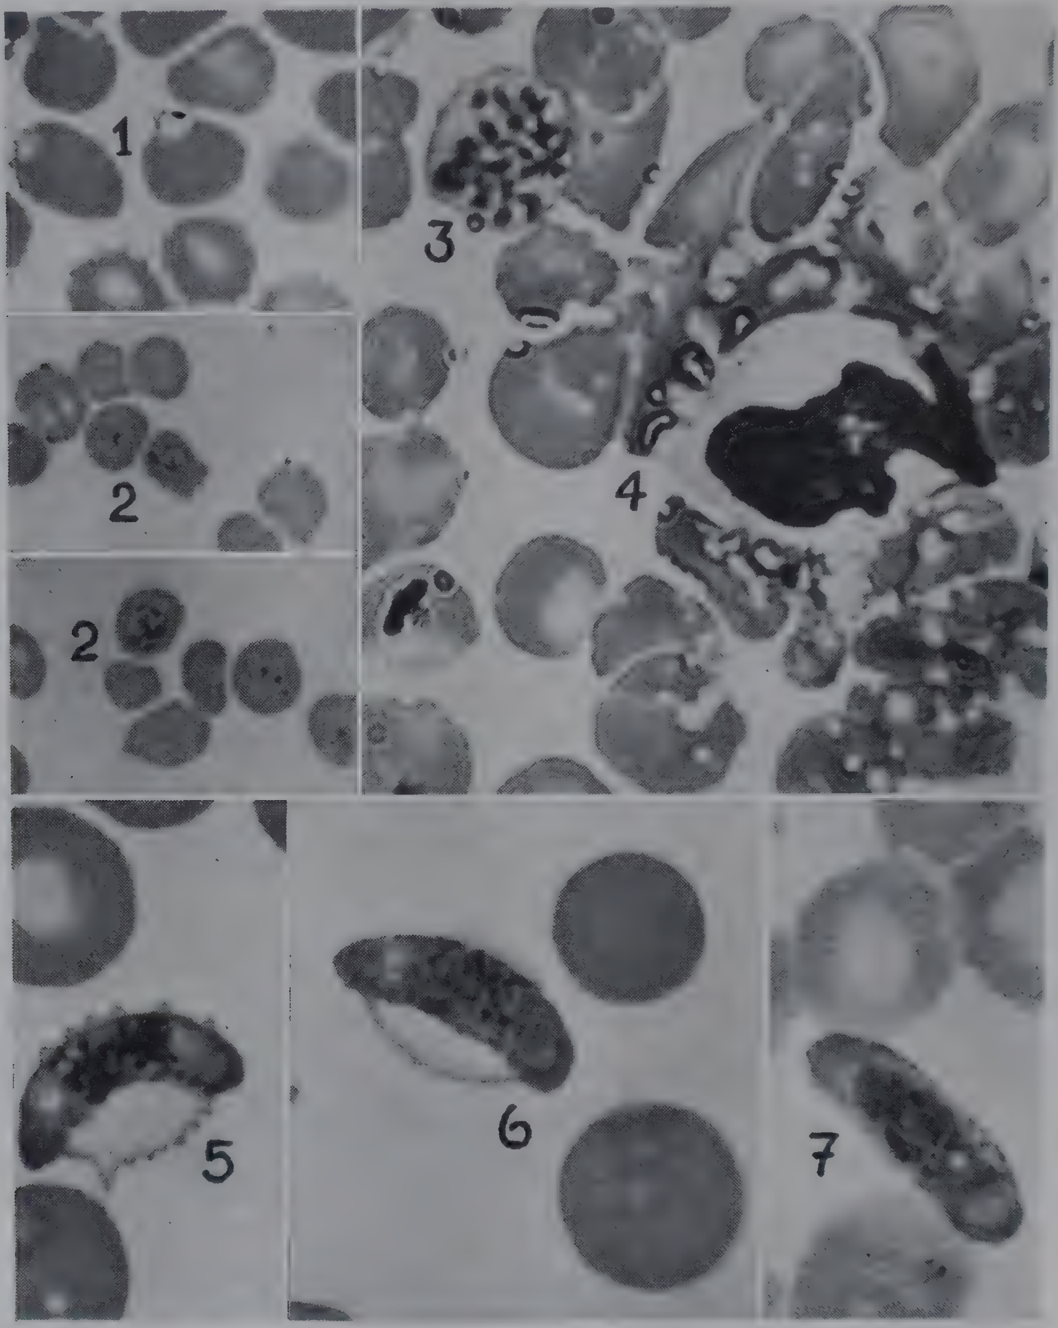

Fig. 482.—*Plasmodium falciparum.* Blood film stained with Giemsa stain. *1,* Young trophozoite, ring form; *2,* fully developed schizont; *3,* schizont divided into numerous merozoites, rosette form; *4,* an endothelial cell in peripheral blood; *5, 6,* and *7,* typical crescent form, banana, bean, or kindey shaped, of the gametocyte. Note in *5* the arch of the denticulated border which encloses the cavity of the gametocyte, as well as the festooned edges, representing the remnants of the parasitzed red cell; and in *6,* note the smooth edge of the arch which incloses the cavity of the gametocyte, representing the rest of the parasitized red cell. (Original photomicrographs of Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

The dividing form shows 8 to 12 to 32 nuclei. Development takes forty-eight hours. Sexual forms of the tropical parasite are roundish, often long oval. The riper forms are long, light, concave-convex pictures called the "crescent" form. The female forms, with Giemsa, stain an intensive blue. They lie squarely in the middle of the red blood cell or near one peripheral border. The male forms are lighter, often reddish, with a lobulated nucleus with pigment.

The red blood cells in this form with asexual parasites present are not enlarged. They show a deep red spotting in the typical chromatin stain, the so-called "Maurer or Christopher pernicious spotting." They show irregular spots.

Plasmodium Ovale (Stephens 1942)

P. ovale has sufficient morphologic characteristics to differentiate it from the *P. vivax* and from the *P. malariae*. It is round or oval with exceptionally ameboid schizonts, and fewer merozoites than the vivax, 8, which compose the rosette form. These rosettes are very small by comparison with those of *P. malariae*. The gametocytes of *P. ovale* are spherical and smaller than those of the *P. vivax* and are found in the red cells in oval form, with slightly decolorized and indented borders, at times hypertrophic, and presenting heavy Schüffner punctation in red cells parasitized by the young trophozoites. At times the parasitized erythrocyte is weakly stained and seems almost free of Schüffner punctation. The *P. ovale* increases the size of the erythrocyte. The rosettes have few merozoites. It is in this particular that it resembles *P. malariae*, but it differs from that form by its oval shape and indented borders and by the abundant and frequent Schüffner punctation, observed so often in erythrocytes containing the *P. ovale* and not in those parasitized by *P. malariae*.

TABLE 183.—DIFFERENTIAL POINTS OF THREE TYPES OF MALARIAL PARASITES

	PLASMODIUM VIVAX	PLASMODIUM MALARIAE	PLASMODIUM FALCIPARUM
Type of Malaria	Tertian	Quartan	Tropical (Estivo-Autumnal), Falciparum
Effect on Size of Red Blood Cell	Enlarged	Reduced	No change
Effect on Color of Red Cells	Pale	Intensified	No change
Stippling of Red Blood Cell	Schueffner punctation may be observed	None	Pernicious maculation may be seen
Size of Ring	Large (⅓ diameter of red blood cell)	Medium or small	Very small (⅕ diameter of red blood cell)
Number of Nuclei in Each Ring	1, rarely 2	1, sometimes 2	2 or more
Number of Nuclei in Division Forms	12-22	Never more than 12	8-12-32
Shape of Asexual Forms	Very many different forms	Usually band	Not seen (ring)
Shape of Mature Forms	Oval or round	Oval or round	--
Chromatin of Mature Forms	At one side	Elongated forms near edge	--
Shape of Sexual Forms	Round or oval	Round or oval	Crescent
Size of Sexual Forms	Usually slightly larger than red blood cell	Smaller than red blood cell	Diameter: about ½ red blood cell; length: slightly longer than red blood cell
Pigment of Sexual Forms	Scattered	Clumped	Centralized
Cycle of Asexual Development	48 hr.	72 hr.	48 hr.
Yellow Pigment in Asexual Forms	None	Always present	Occasional

Irregular, Relapsing, and Recurring Malaria

Irregular, relapsing, and recurring malaria are rather frequent, especially in treated patients. The parasites may be difficult to find in the peripheral blood stream. Sternal puncture can be helpful in such cases.

Diagnosis of Malaria by Laboratory Methods

Methods of Examination.—

The parasites may be recognized in *unstained preparations* by observing small brown or black granules within them. They show a distinct dancing motion. The unstained specimen is made by simply placing a drop of blood between a cover glass and slide.[1]

The fully developed parasite can be well seen in the stained specimen, the Giemsa, the Romanowsky, the Giemsa-Romanowsky stains combined, or Wright stain. With these stains, the protoplasm is stained blue and the chromatin of the nucleus red. (See Plates XLIX and L.)

1. Take a drop of blood from the ear with the usual precautions, place it on a clean slide, superimpose a cover glass, ring with petroleum jelly, and examine at once with a high dry lens and then with the oil immersion lens.
2. Stain margin-free films with Giemsa or Wright stain.
3. Stain thick drop specimens in the usual way.
4. Use the Barber-Komp method.

This diagnosis can best be made by finding the plasmodia in direct blood examinations, thin or thick films, or by thick drop. For the thick drop method for the diagnosis of malaria use the method of Barber and Komp. Staining with Giemsa, or Wright and Giemsa combined, affords an admirable method of diagnosis. Most cases of symptomatic malaria without treatment will show plasmodia. Even if the infection is latent, thick films or thick drops will reveal them. If this fails, then resort must be had to methods of driving the plasmodia from their hiding places in the body out into the peripheral blood stream. For this purpose, the subcutaneous injection of 1 mg. of Adrenalin serves quite well. At the same time one may expose the splenic area to x-rays, followed by physical exercise. Plasmodia usually appear in the blood shortly after the administration of Adrenalin. Others use strychnine nitrate, 2 mg., subcutaneously administered, for the same purpose.

Concentration Methods.—Some years ago, the author had an opportunity to witness Bass and Johns' excellent method of concentration of malarial plasmodia in their laboratories in New Orleans.

Their method advises 5 to 10 c.c. of blood withdrawal from an arm vein. Receive it into a syringe containing a small amount of sodium citrate solution. Eject the blood into a 50 c.c. centrifuge tube and rotate at 2,500 r.p.m. Pipette off the upper column of red cells and transfer to a smaller test tube, centrifugalize at the same rate of speed until the cells are deposited at the bottom of the tube. Make thin film preparations by means of a pipette which takes off a small amount of this sediment, place it on glass slide, place another slide on top and push it along to make a film that is rather thin. Dry and stain at once.

Malarial Forms Found in Blood Films

In cases of single infection with *P. vivax* or *P. malariae*, one will find, in the blood films of such patients, schizonts which practically fill the structure of

---

[1] For technic of staining, refer to pages 615 ff. and 650 ff.

the red blood cells; mature and segmenting schizonts; free merozoites, and gametocytes. In the case of infection with *P. falciparum*, only ring forms are found in the blood at the time of the paroxysm, but if the infection has existed several days, crescents will be found. Shortly after paroxysms of *P. vivax* and *P. malariae* infections, ring forms of trophozoites and young gametocytes are found together with young pigmented forms. The day following the paroxysms in infections with *P. vivax,* we find young gametocytes. In the case of *P. malariae,* the next day one finds partly developed schizonts and gametocytes. With *P. falciparum,* only ringlike trophozoites and gametocytes are found at the end of 24 hours. When 36 hours have elapsed, in *P. vivax* infections, pre-segmenting schizonts, ring forms and gametocytes are found. At such a time *P. malariae* cases show half grown and fully grown schizonts and gametocytes. With *P. falciparum,* there are ring forms of gametocytes. In double infections there will be seen the same forms already described plus many half grown schizonts.

HUMAN HELMINTHOLOGY[1]—NEMATHELMINTHES

The animal kingdom is divided into Protozoa and Metazoa. Metazoa are further divided as follows:

Metazoa	Vertebrates	Bilaterally symmetrical	Artiozoa
	Invertebrates	Bilaterally symmetrical	
		Radically symmetrical	Phytozoa

The Artiozoa, which comprise all those animals bilaterally symmetrical, are divided into two large groups: vertebrates and invertebrates. Of the invertebrates, the Helminths and the Arthropods are of interest here.

Helminthology, as the word indicates, is the study of worm parasites, or helminths. Helminths include the roundworms, the flatworms, and the tapeworms.

The Helminths are divided into two phyla of importance: phylum Nemathelminthes and phylum Platyhelminthes. The first phylum is divided into three classes: Nematoda, Acanthocephala, and Gordiacea; the second into five classes, of which only two are of interest to us: Cestoidea and Trematoda. The following diagram gives the characteristics of each:

		Phyla		**Classes**
Helminths or Worms	Round body, chitinous integument, coelomic cavity present, usually dioecious	Nemathelminthes	Usually with complete digestive tract	Nematoda
			Posterior part of the digestive tract atrophied in the adult	Gordiacea
			Digestive tract absent	Acanthocephala
	Flat body, soft integument, without coelomic cavity, usually hermaphrodites	Platyhelminthes	Digestive tract absent; segmented body	Cestoidea
			Incomplete digestive tract, without anus	Trematoda

---

[1] In the preparation of the preceding edition we wish to acknowledge with appreciation the excellent translation work by one of our assistants, Mr. Rubin Marshosky, of Panama City, R.P.

Although this classification of the Helminths does not exactly follow the Zoological Classification, we have adopted it for its simplicity and practical value in clinical work.

PHYLUM NEMATHELMINTHES

The most important Nemathelminthes which habitually parasitize man belong to the class Nematoda.

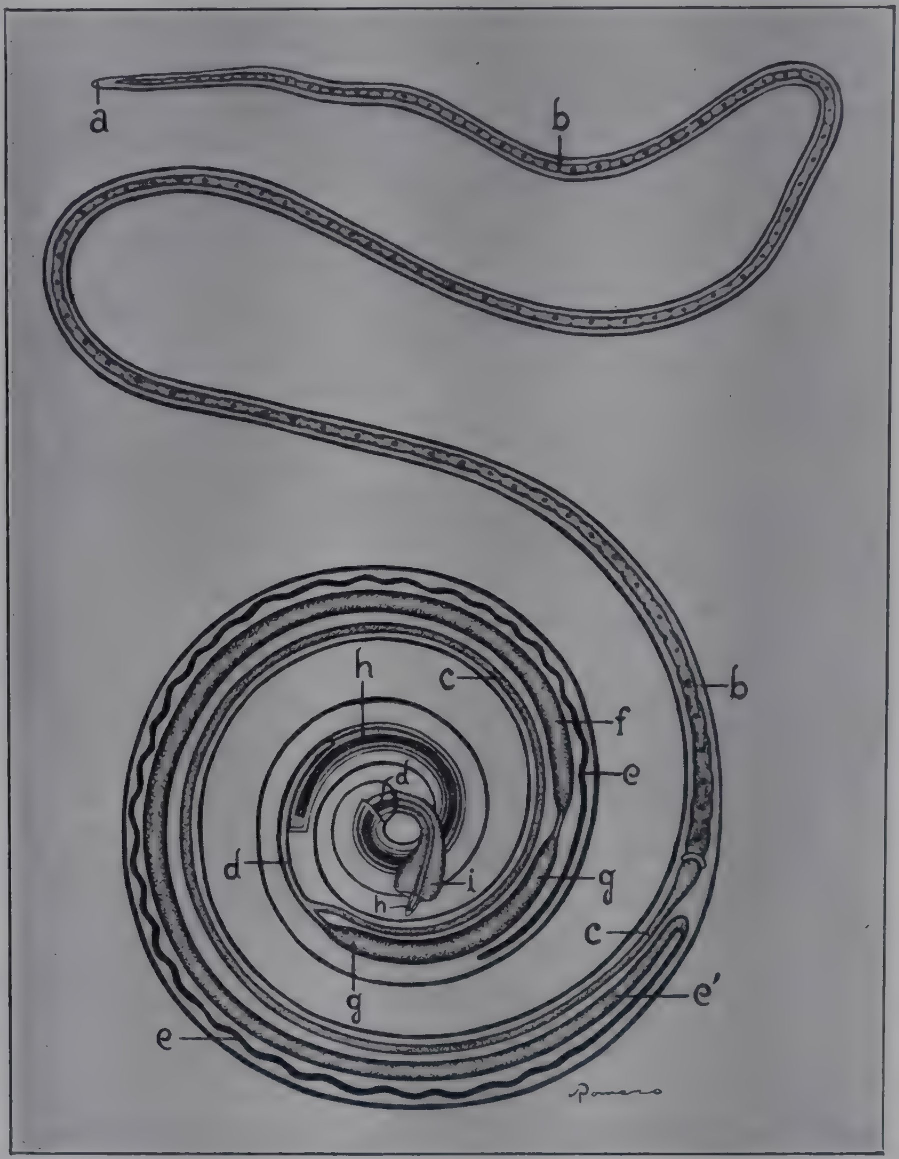

Fig. 483.—Male *Trichuris trichiura*. *a, b, c, d,* Digestive tract; *a,* mouth in the anterior end of the parasite; *b, b,* esophagus occupying the entire length of the thin portion of the parasite and formed by a fine duct which passes through a single layer of cells; *c, c,* intestine; *d, d,* cloaca; *e, e′, f, g, h, i,* male genitalia; *e, e,* testicle; *e′* vas deferens; *f,* seminal vesicle; *g, g,* ejaculatory duct; *h, h,* spicule; *i,* sheath or thorny prepuce. (After Guiart, modified by Kourí: Lecciones de Parasitología y Medicina Tropical. Courtesy of Editorial Profilaxis S.A., Havana, Cuba.)

Class **Nematoda**

Nematodes are roundworms, vermiform, elongated, and cylindrical, whitish or pink, at times with dark bands.

Order **TRICHURATA**

TRICHURIASIS

Family **Trichuridae** Railliet 1915

The type species of this family is *Trichuris trichiura*, a parasite of man.

Trichuris Trichiura (Linnaeus 1771)

Trichuris trichiura, the whipworm, is usually found clinging to the intestinal mucosa, with the thin anterior portion buried in the chorium beneath the epithelium. It lies superficially parallel to the mucosa. It is a hematophagus parasite.

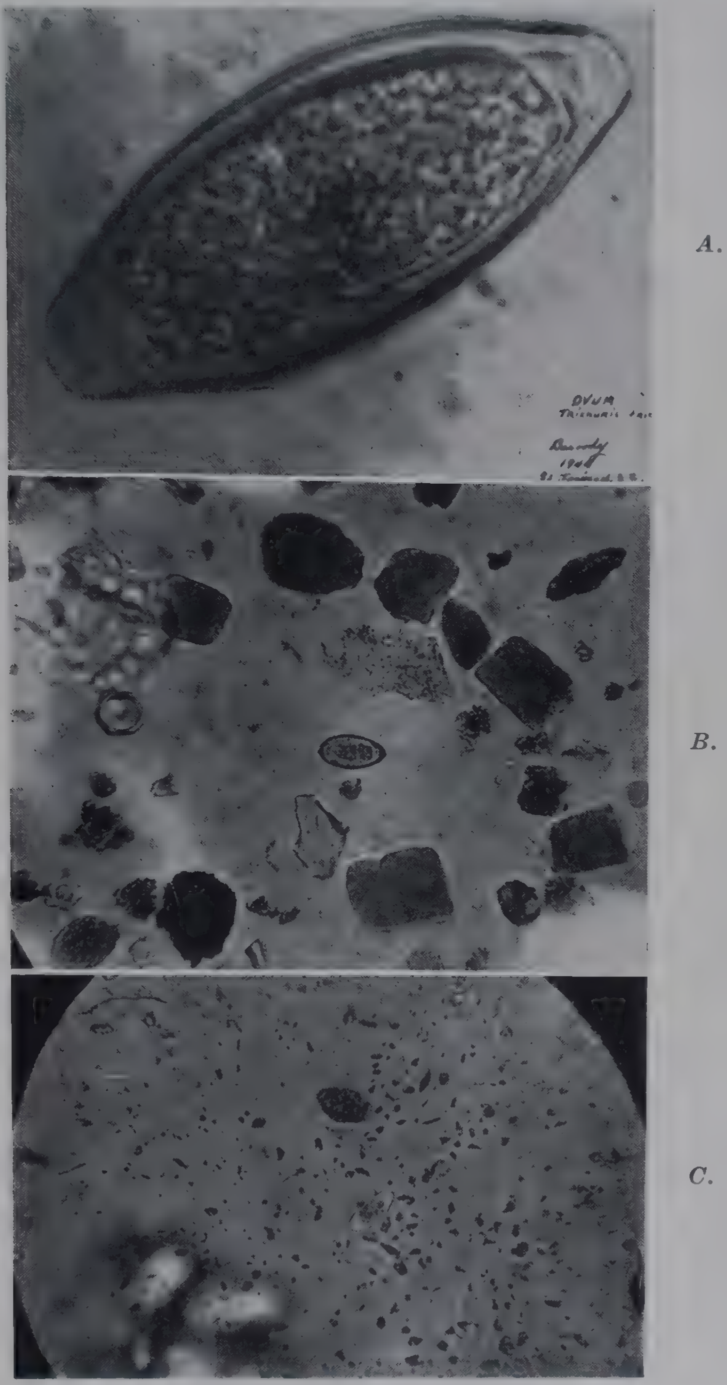

Fig. 484.—*A*, Egg of *Trichuris trichiura* (greatly enlarged). *B*, Egg of *Clonorchis sinensis*. *C*, Cyst of *Isospora hominis*. Water centrifugal sedimentation concentration method of Baroody and Most. (Original photomicrographs of Dr. B. J. Baroody.)

Eggs.—Eggs are very characteristic. They are approximately 50 microns long by 25 microns wide, symmetrically narrowed at the poles. They are brown due to the presence of bile. The shell is thick and is perforated at the poles. Each orifice contains a refractive, hyaline, colorless albuminous plug.

Parasites.—The female is approximately 4 to 5 cm. long. The thick portion is approximately half as long as the thin portion and describes an arc, the concave side facing the ventral part of the body. The esophagus is a thin

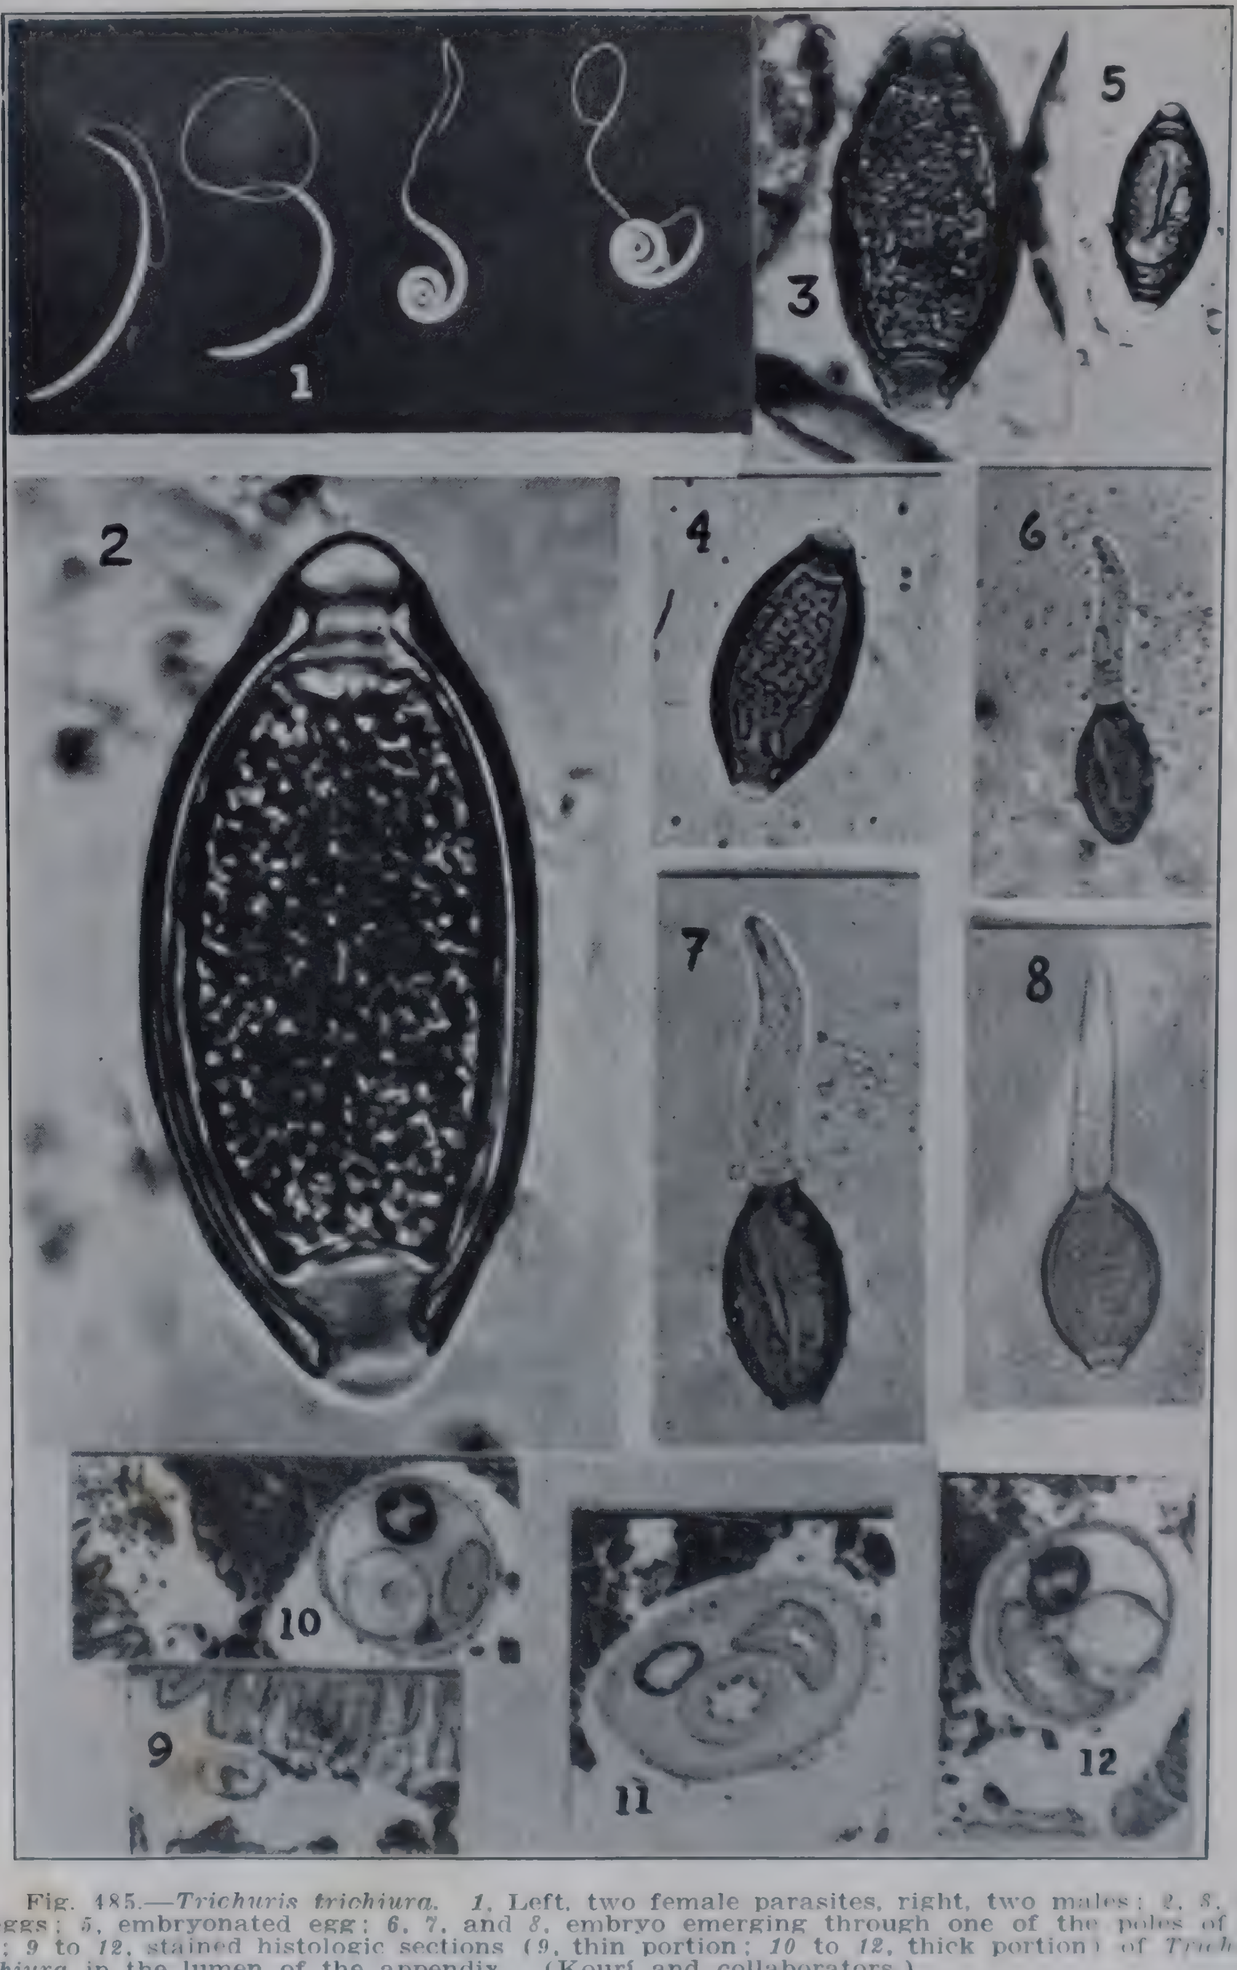

Fig. 485.—*Trichuris trichiura.* *1*, Left, two female parasites, right, two males; *2*, *3*, and *4*, eggs; *5*, embryonated egg; *6*, *7*, and *8*, embryo emerging through one of the poles of the egg; *9* to *12*, stained histologic sections (*9*, thin portion; *10* to *12*, thick portion) of *Trichuris trichiura* in the lumen of the appendix. (Kourí and collaborators.)

tube extending throughout the thick portion, ending in the anus. The genital organs lie in the thick portion. The uterus is broad and packed with eggs.

The male is smaller than the female, 3 to 4 cm. long with the thicker end spirally coiled, the convex surface lying ventrally. From the cloaca, in the thicker portion, extends a spicule, 2.5 mm. long, which bears a sheath or prepuce beset with spines.

The parasites are pink when alive, white in Formalin.

Life Cycle.—The life cycle is given in Fig. 486.

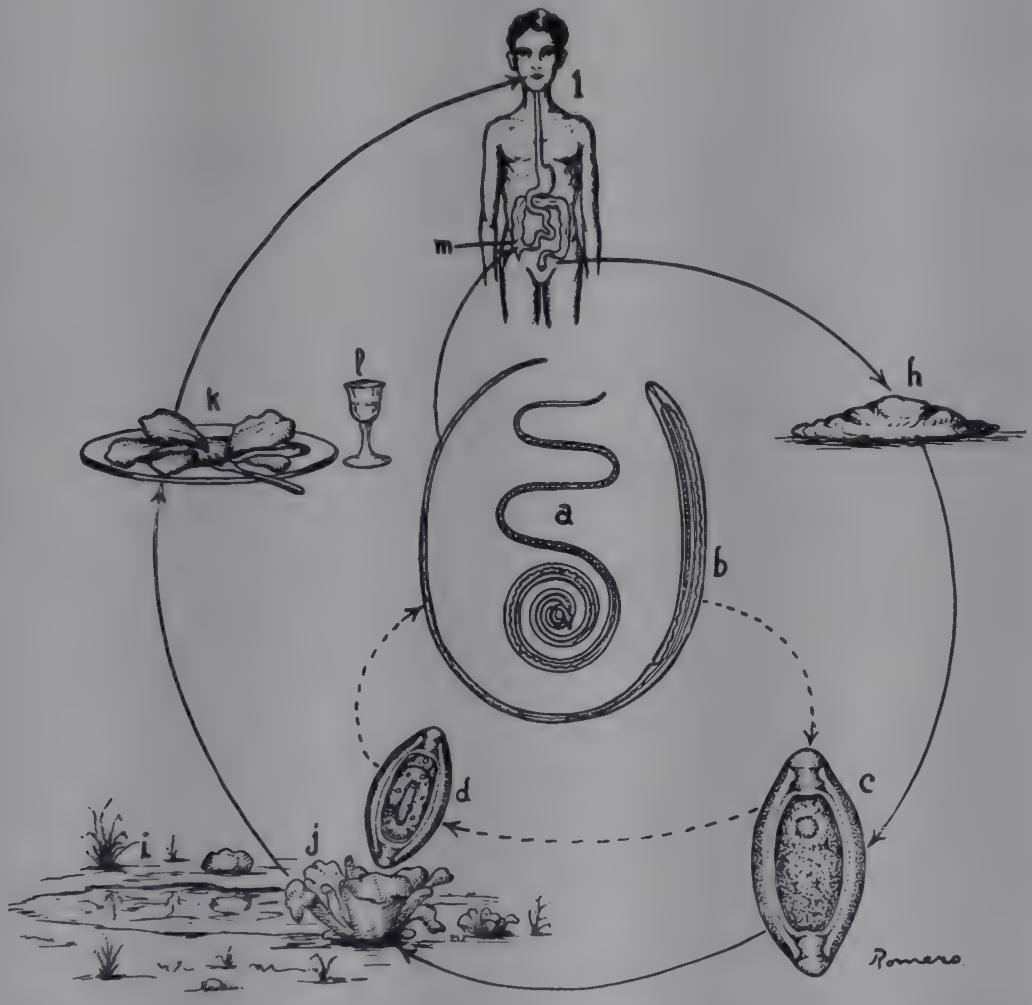

Fig. 486.—*Trichuris trichiura.* Life cycle. The male and female (*a* and *b*) localize primarily in the cecum of man (*1*). The female lays eggs (*c*) which are passed in the feces (*h*). Shortly after, they are embryonated (*d*), becoming the infective form. When ingested in contaminated food (*k*, *l*), the embryo is set free in the intestines and develops into the adult male (*a*) or female (*b*) parasite. After copulation, the female lays fertilized eggs (*c*) which are passed in the feces (*h*), beginning a new cycle. (Original drawing of Drs. Kourí and Basnuevo.)

Life Span.—The life span is unknown and is very difficult to calculate. Premunition is not believed to exist. For this reason, reinfestation is possible, and thus it is very difficult to calculate the life span, the more so because this parasite is cosmopolitan.

Epidemiology.—The infesting form is the embryonated egg, which is very resistant to adverse environmental conditions. This explains the frequency of parasitism since the opportunities of infestation are numerous in man. Eating vegetables containing embryonated eggs and putting the contaminated hands in contact with the mouth are two important modes of infestation.

Diagnosis.—Accurate diagnosis can be made only by thorough microscopic examination of the feces. The presence of the characteristic eggs is sufficient evidence.

In massive parasitism, presence of eggs is constant in fecal material, but in mild parasitism, negative phases exist, during which eggs are not found even with concentration methods.

In order to judge the efficacy of an antitrichuric drug it is necessary to submit it to parasitic control:

1. Count the eggs microscopically in the stools before treatment, taking an average of two or three serial examinations.
2. Count adult parasites expelled during treatment.
3. Count eggs microscopically after treatment and take the average of two or three serial examinations.

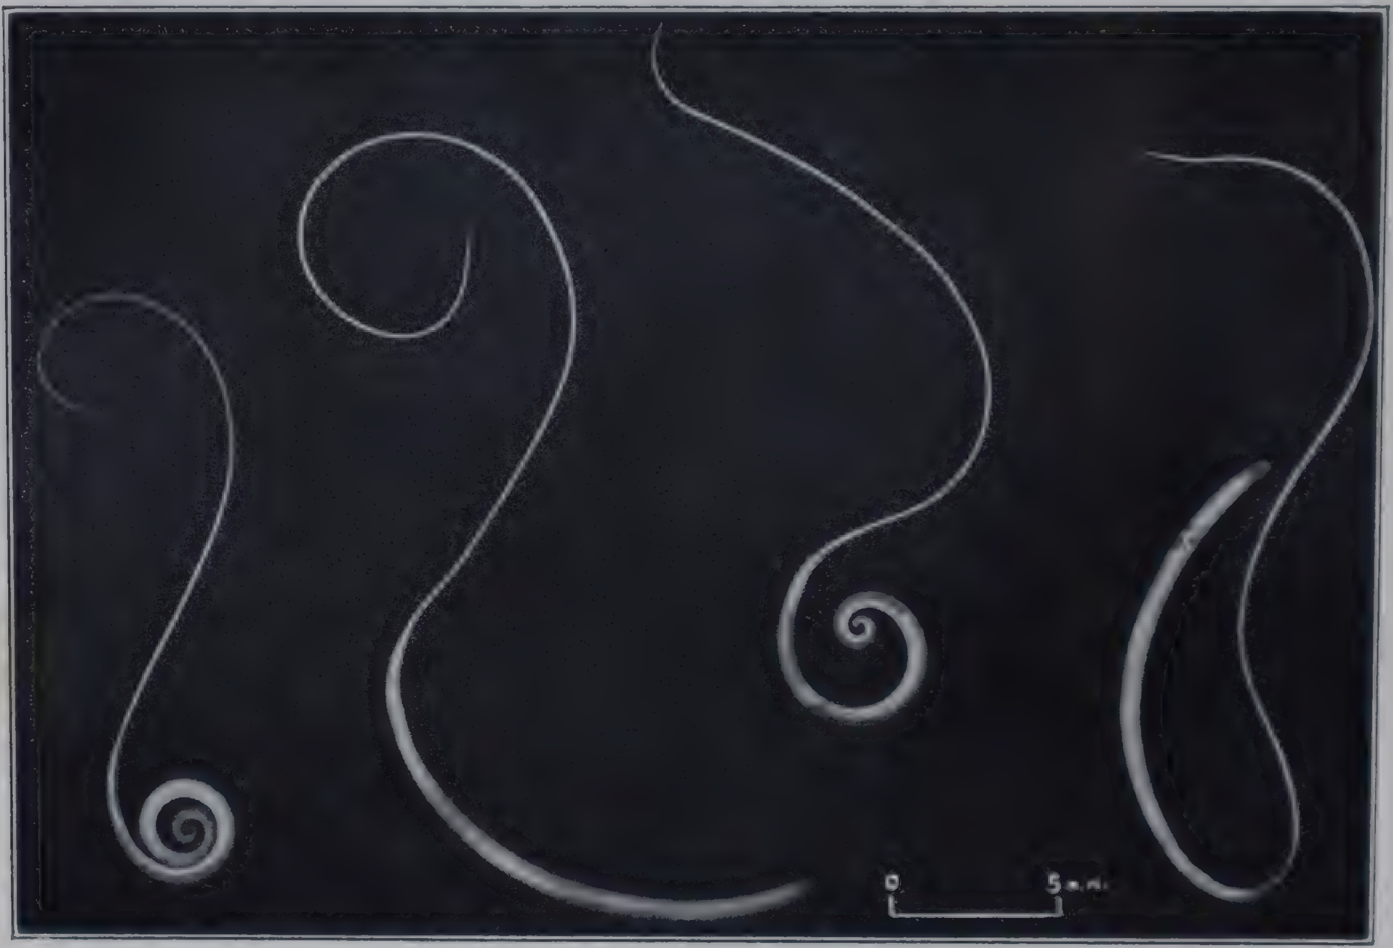

Fig. 487.—*Trichuris trichiura.* Photograph of male and female *Trichuris trichiura.* Millimeter scale. (Original photograph of Kourí.)

Absence of Trichocephalus eggs from the stools after treatment does not necessarily imply complete cure of the parasitism, since it is known that negative phases exist in mild infestations. Nor does the persistence of the eggs after treatment necessarily mean that the drug is ineffective, because if the eggs have not been counted one cannot ascertain whether or not the number of parasites has decreased, or how much the decrease has been. Counting the number of parasites expelled during treatment, however, gives an index of the efficacy of the drug used.

TRICHINOSIS

Trichinella Spiralis (Owen 1835) Railliet 1895

Geographical Distribution.—The parasite is cosmopolitan except in the Philippines, Puerto Rico, and Australia. Trichinosis is particularly prevalent where pork is eaten raw or insufficiently cooked; more frequent in the Northern Hemisphere than in the tropics. It is common in Europe and in the United States, but is relatively rare in Africa and South America. To date this parasite has not been observed in Cuba, either in humans or in animals.

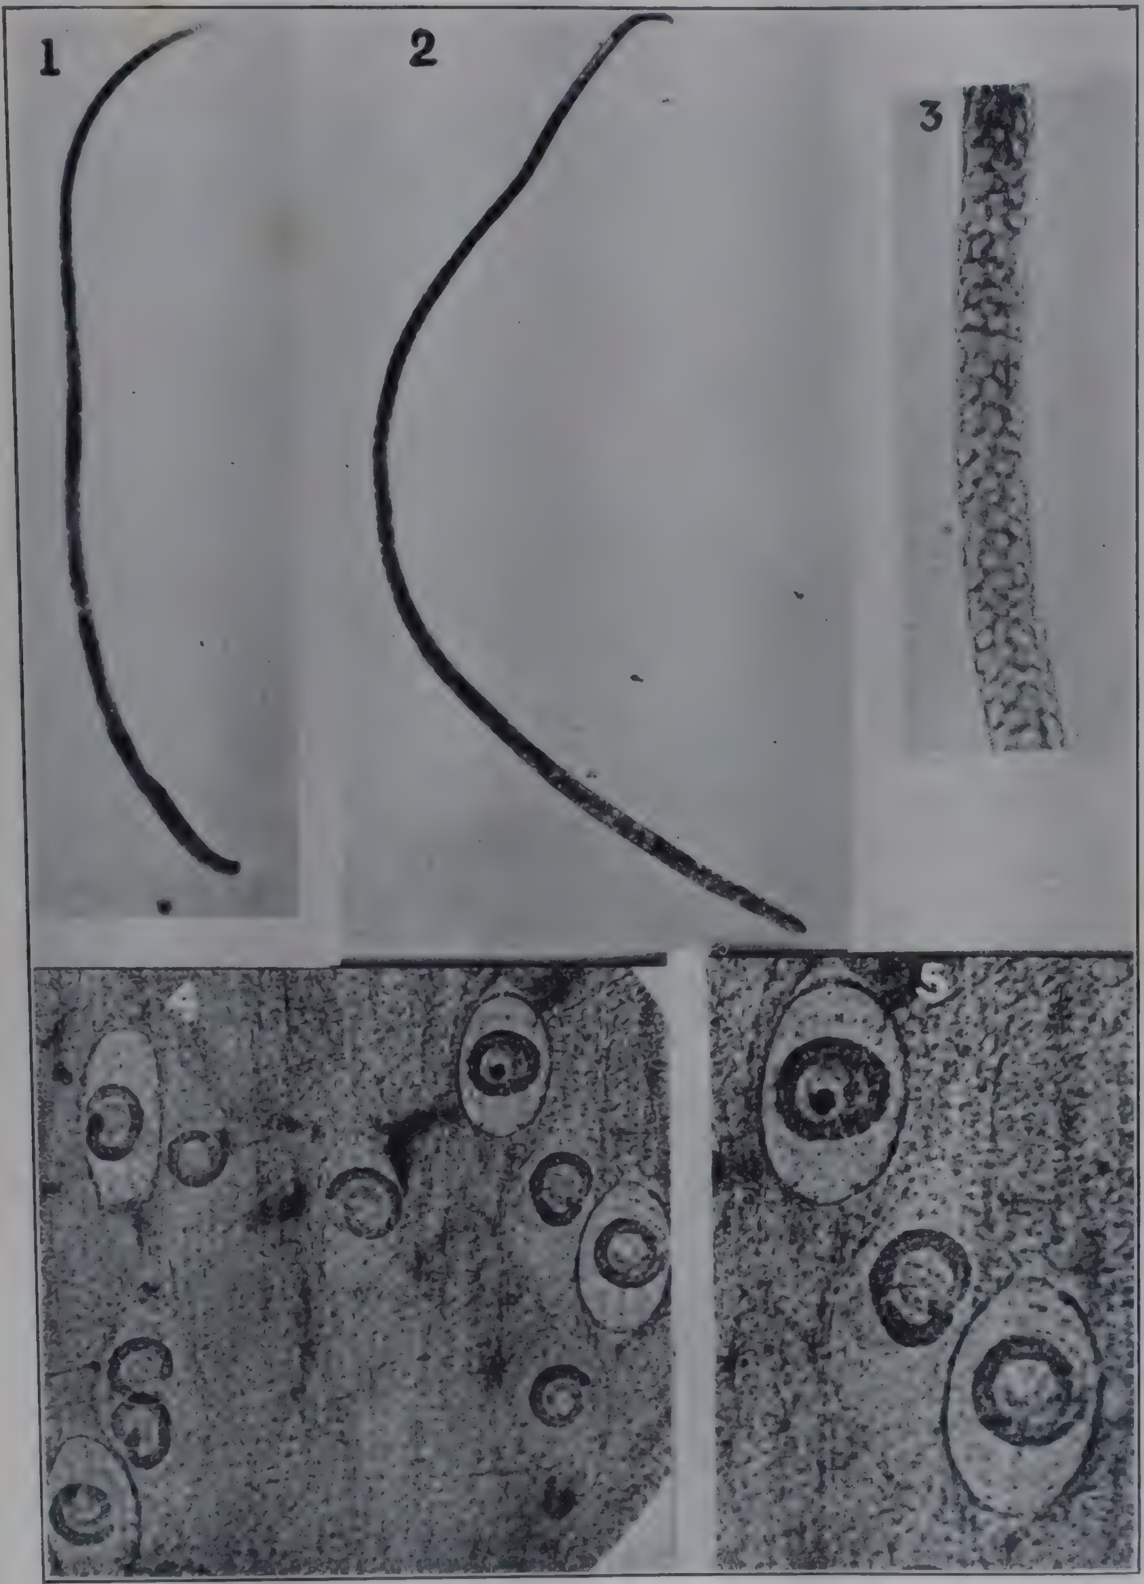

Fig. 488.—*Trichinella spiralis.* *1,* Male; *2,* female; *3,* magnified body of female. (Experimental infestation of swine. Material supplied by Dr. G. Bachman.) *4* and *5,* Larva in diaphragm of an experimentally infested white rat. (Originals of Kourí.)

Etiology.—The disease is caused by encystment of the larval forms in the striated muscles. The adult forms live in the small intestine.

Characteristics of the Parasite.—The male measures 1.4 to 1.6 mm. in length and 0.04 mm. in diameter. The anterior part of the body is narrowed; the orifice of the cloaca is terminal and lies between the two caudal appendages;

the two pairs of papillae are internal and dorsal, one behind the other. The cloaca is evertible for copulation. The female measures 3 to 4 mm. in length and 0.06 mm. in diameter; its anus is terminal.

This worm in its adult stage inhabits the small intestines of man, pig, wild boar, rat. The young do not leave the body of the host but become encysted in the muscles.

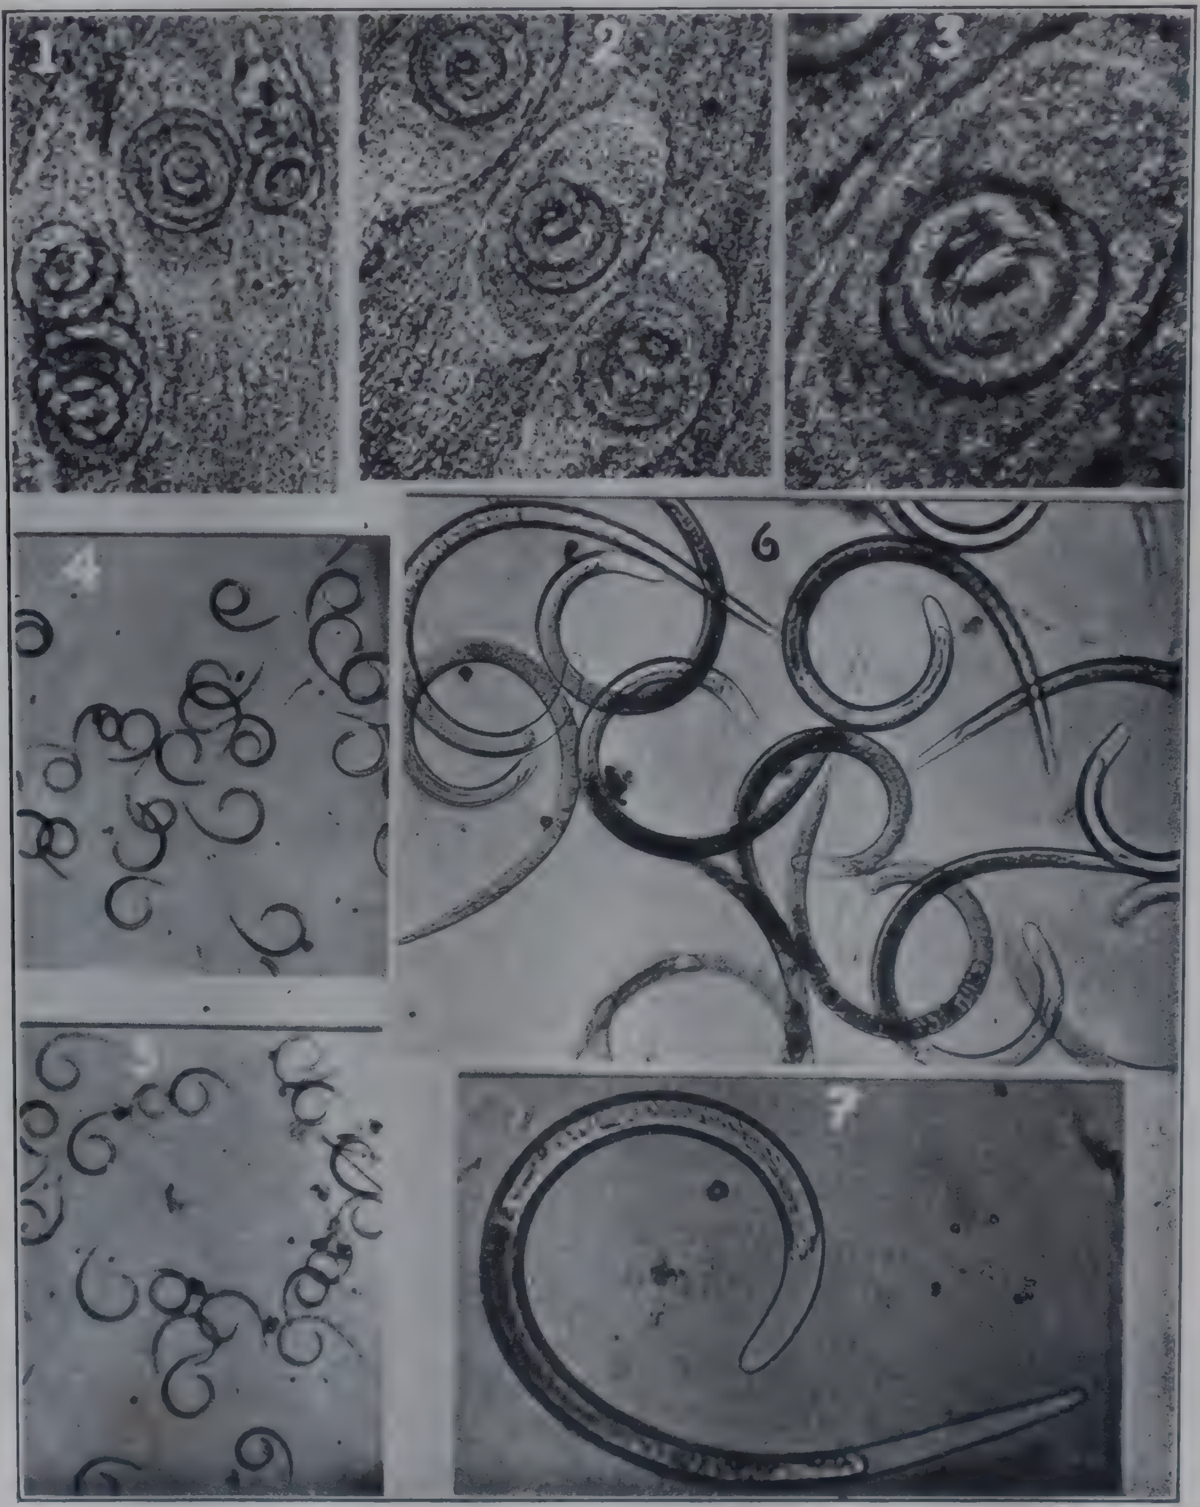

Fig. 489.—*Trichinella spiralis.* (Experimental infestation of white rat. Material supplied by Dr. G. Bachman, Puerto Rico.) *1* to *3*, Larvae in diaphragm muscle; *4* to *7*, larvae freed by artificial digestion of muscle. Various magnifications. (Original of Kouri.)

Development of *Trichinella spiralis* takes place in the intestines of experimental animals. The encysted trichinellae escape from their capsules, which are destroyed by the gastric juices. They then enter the duodenum and jejunum, where they mature. Soon after copulation, the males die and the females bore more or less deeply into the villi or into the mucous membrane and thus reach the lymph spaces. Some pierce the intestinal wall and are found in the mesentery and glands. The eggs are deposited in the lymph spaces. The larvae are carried along by the lymph stream to the heart. The young brood is distributed from the heart throughout the entire body, but the conditions necessary to their further development are found only in striated muscles; the young nematodes penetrate the capillaries, reach the intramuscular connective tissue, and then enter the fibers. On the ninth or tenth day after infestation the first worms have reached their destination; but further invasions are constantly taking place because the intestinal worms live from five to seven weeks, and continue to produce their young. Trichinae in their encysted condition may remain alive and capable of development for years.

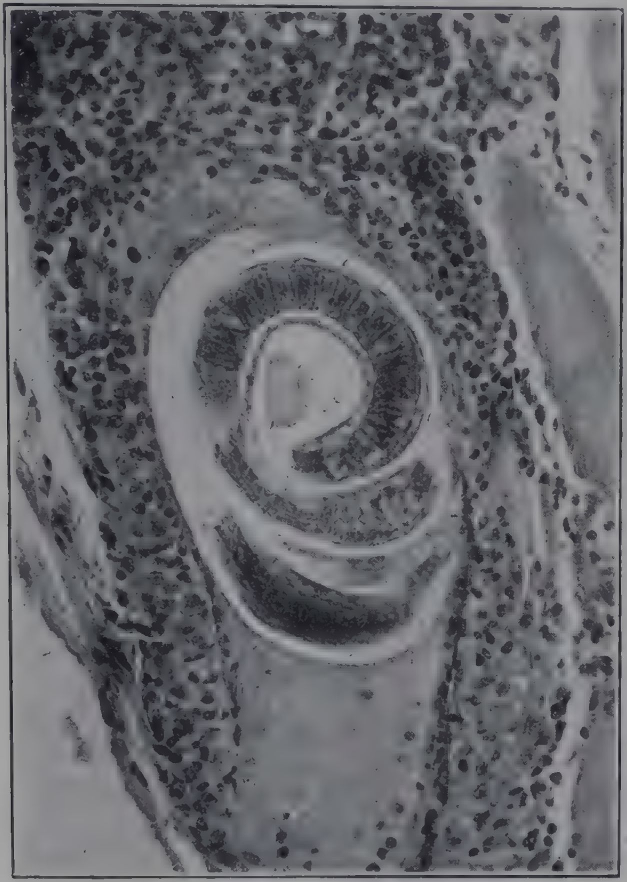

Fig. 490.—Section of *Trichinella spiralis* in muscle.

Symptomatology.—Infested patients have symptoms of gastrointestinal disturbance, nausea, vomiting, etc. Muscular pains occur with recurrent abdominal pains and a temporary edema. In the second week, inflammation of the muscle is the predominant symptom. Temperature may be 104° F. In several cases which we have observed, the symptoms are very suggestive of typhoid fever. A last period of encystment takes place with symptoms of marked cachexia, and edema of the face occurs. Delirium, somnolence, and lung affections take place. Either the patient dies at this time or the symptoms gradually subside. It is noteworthy that in all cases there is a marked eosinophilia. In a case observed (Gradwohl) eosinophilia was 90 per cent.

The disease occurs in nearly all countries of Europe and in America. There were widespread outbreaks in the old Kingdom of Prussia and some other parts of the German Empire. Here in the United States the incidence of this disease has been underestimated. Investigation during recent years has shown an increasing number of cases as determined by serial autopsies on cadavers as well as by clinical experiences.

"Regarding* meat inspection in this country, in reference to control of trichina infection in pork, microscopic inspection of pork for trichinae was discontinued in 1906. This inspection had been carried on in this country only on pork destined for the export trade and never done on any pork designed for domestic consumption. The inspection was inaugurated in 1891 because of certain restrictions placed on the importation of American pork by Germany and some other European countries. These restrictions had been largely removed by the year 1906 and this inspection was discontinued at that time. As a matter of fact, there never has been any microscopic inspection of pork intended for consumption within the United States. The Federal Meat Inspection Regulations provide for processing for the destruction of trichinae of products customarily eaten without cooking by the consumer. Such products include salami, mettwurst, Italian style hams, etc. This portion of the regulations therefore definitely provides protection against the acquisition of trichinosis from products of this sort which are produced in packing houses operating under these regulations. It may be said, however, that heretofore only about 70 per cent of the meat consumed in the United States has been packed under Federal inspection."

Riley and Scheifley examined the diaphragms of all cadavers in the dissecting room of the University of Minnesota and found evidences of trichinosis in 20 out of 117 cadavers. The most important means of communication from hog to man is through ingestion of pork products infested with this worm. Trichina infection in the hog depends almost entirely on the practice of feeding the swine garbage of raw or inadequately cooked pork scraps. Since human trichinosis is based almost entirely on feeding hogs raw garbage containing trichina-infested pork scraps, solution of the problem is clear. Garbage used in feeding hogs must be boiled for at least one-half hour, and all pork products must be properly processed before being offered for sale.

"Of their flesh shall ye not eat, and their carcass shall ye not touch; they are unclean to you."—Leviticus 11:8.

The earliest clue to the existence of trichinosis is the Mosaic injunction against eating pork.

Thorough cooking of pork constitutes the best method of prevention. Much would be gained in preventing the spread of this disease by an extension to small plants of the federal regulations regarding the preparation of sausages and other pork products which are ordinarily consumed without being cooked. It must be borne in mind that the usual process of pickling and smoking, even when long continued, does not destroy the Trichinellae contained in meat. Unless roasting is accompanied by thorough distribution of heat throughout the middle of the joint, the worm will not be killed. Naturally, all meat found infested on inspection should be condemned.

The autopsy findings in cases of trichinosis show definite cysts in the muscle. The muscles of the calves of the legs should be searched very carefully as well as other muscular parts where symptoms during life have suggested the presence of the cysts.

---

*Personal communication. We are indebted for these precise facts to the courtesy of Dr. W. H. Wright, Chief, Division of Zoology, National Institutes of Health, Bethesda, Maryland.

It is necessary and advisable for the public not to purchase pork or pork products from any independent source unless the independent source has actual knowledge of freedom from infestation with this worm. A knowledge of this, of course, can be obtained only by a careful inspection of the slaughtered animals by an expert veterinarian.

Life Cycle.—The life cycle is given in Fig. 491. See page 1910.

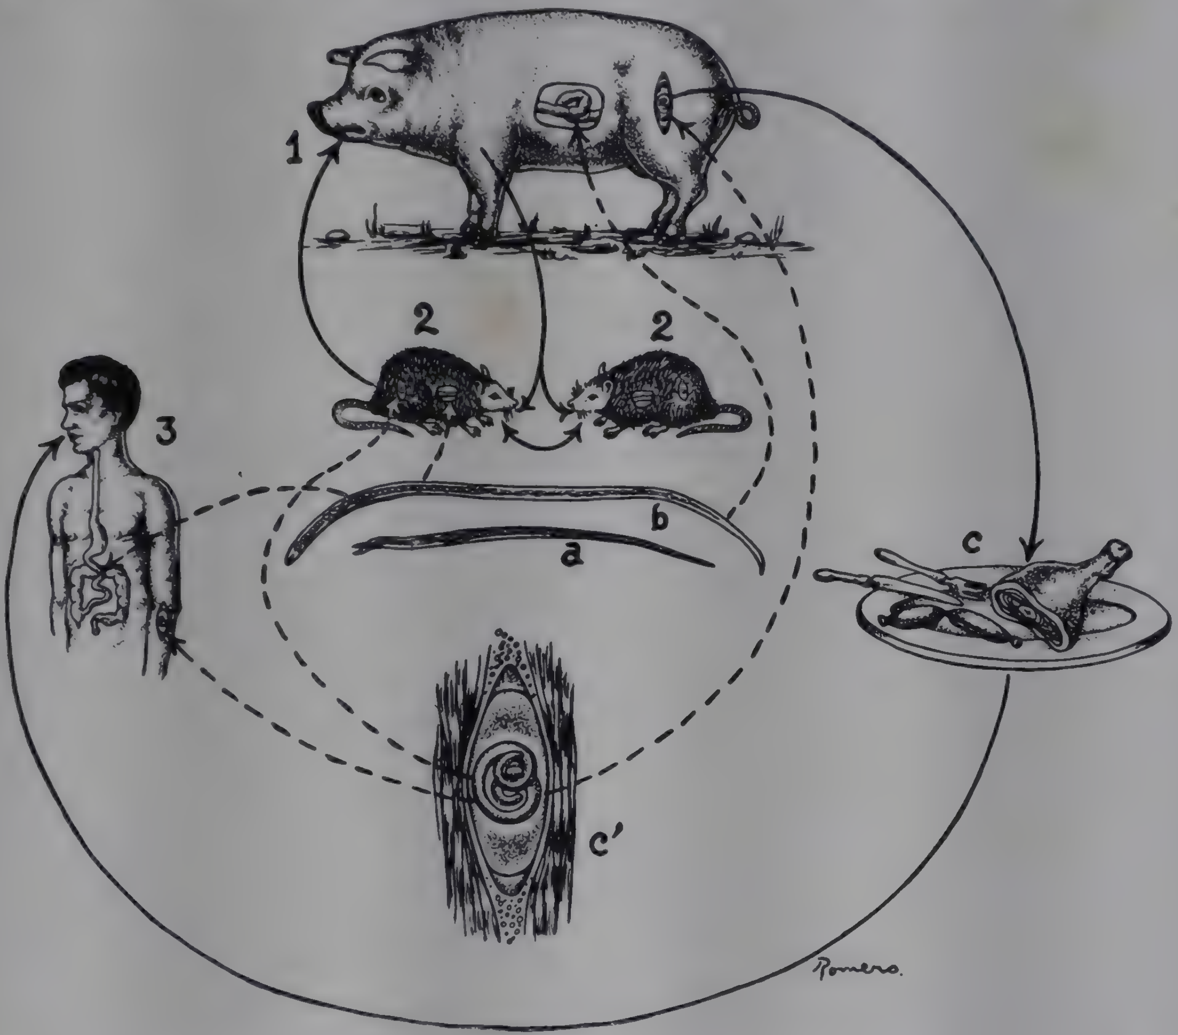

Fig. 491.—*Trichinella spiralis.* Life cycle. Numerous mammals may act both as definitive and intermediate hosts at the same time. The adult parasite, male (*a*) and female (*b*) live, normally, in the small intestine of the host; *1*, swine; *2*, *2*, rat; *3*, man; and others. After copulation, the female burrows in the intestinal mucosa, where it deposits the embryos which reach the circulatory system and migrate to the muscles where they encyst and develop into larvae (*c′*). Man (*3*) becomes infected when he ingests pork or its by-products (*c*), raw, poorly cooked, salted or smoked, contaminated with larval forms. Swine (*1*) usually become infected by ingestion of contaminated waste from other pigs, infected rats (*2*, *2*), or other contaminated animals. Rats become contaminated when they eat each other or when ingesting meat from another animal contaminated with the larval forms (*c′*). (Original drawing of Kourí and Basnuevo.)

Laboratory Diagnosis

Blood Picture.—The blood picture in the majority of cases shows definite leukocytosis, from 10,000 to 20,000. In some cases there is leukopenia. It is the presence of an eosinophilia that wakens the thought of trichinosis or some other worm disease. The eosinophilia may rise as high as 80 per cent; Gradwohl has seen a case with a percentage of 90.

Examination for Larvae.—Examination of the blood, spinal fluid, and feces for trichina larvae may be made. Positive findings are important although negative findings do not rule out trichinosis. Isolation of larvae is accomplished in only a small percentage of cases.

Biopsy is an inconvenient and painful procedure but not a dangerous one. By this is meant biopsy of muscle. Biopsies made before the twenty-first day after infection will be negative because the larvae will not have reached the muscles in sufficient concentration to be easily detected. Examinations are made by pressed preparations rather than by sections.

Intradermal and Precipitin Tests.—As well stated by Wright and Brady,[1] the development and refinement of these tests have provided additional valuable aids in the diagnosis of trichinosis. The antigen is prepared from powdered trichina larvae. As produced in the National Institutes of Health, the powder is extracted with neutral physiologic saline solution, the resulting material is sterilized fractionally by heat, and is dispensed in 2 c.c. hermetically sealed vials each containing 0.10 c.c., an amount more than sufficient for one intradermal test. Samples of this antigen exposed to sunlight and room temperature for a period of 6 months have shown no loss of potency when tested by the precipitin method, and presumably the antigen will retain its potency for even longer periods of time if stored in a refrigerator.

Tests with this antigen have indicated to date its species specificity in that it usually elicits positive reactions in patients infected with *Trichinella spiralis* but does not produce positive reactions in patients harboring such common intestinal parasites as *Ascaris lumbricoides, Necator americanus, Enterobius vermicularis,* and *Trichuris trichiura.* However, in using the antigen in suspected cases of trichinosis, it should be borne in mind that examinations made in the National Institutes of Health on approximately 4,900 diaphragms from unselected necropsies in various sections of the United States indicated that 16.4 per cent were positive for trichinae. If one person in six is infected with the parasite, it may be expected that some infected individuals will give a positive reaction to the intradermal test with trichina antigen even though their illness may not be related to clinical trichinosis. In fact, experimental evidence indicates the validity of this assumption. Furthermore, it should be borne in mind that tissue sensitivity to *T. spiralis* antigen may be present for years after a person has suffered from an attack of trichinosis and such persons may react positively to the intradermal test for relatively long periods of time. Under these circumstances, a positive reaction may mean that the patient is suffering from clinical trichinosis at the time of the test; that the patient has had in the past a trichina infection of a degree sufficient to produce persistent tissue sensitivity; or that the patient has at the time of the test a nonclinical trichina infection to which his present illness is unrelated etiologically. Considerable care should therefore be exercised in interpreting the results of the intradermal test. Due cognizance should be taken also of the fact that the test is usually not positive until after the second week of infection; if the test is applied earlier than this, the patient may fail to react. Positive reactions are usually of the immediate type and appear within 15 to 20 minutes after injection of the antigen. However, in exceptional cases, particularly in early stages of infection, there may occur a delayed type of reaction which does not reach its height before 24 hours.

---

[1] Wright, W. H., and Brady, Frederick J., respectively Chief and Passed Assistant Surgeon, Division of Zoology, National Institutes of Health, United States Public Health Service. Monograph of August, 1940.

The precipitin test has the disadvantage of eliciting a positive response even later in the infection than does the intradermal test, since positive reactions are usually not obtained until after the third week of infection. However, circulating antibodies disappear before tissue sensitivity, and positive precipitin reactions are usually not obtained for longer than 1 to 2 years after infection. When possible, it is of advantage to make use of both tests in suspected cases, since every infected individual does not always react positively to each test. However, too much reliance should not be placed on these tests but rather the results should be given due consideration in connection with the clinical syndrome, the differential blood picture, the case history, and other factors. Occasionally individuals not infected with trichinae may react positively to these tests for reasons not apparent at the present time. It is possible that drugs and certain malignancies may influence the reaction.

In the past, many samples of serum submitted for this test have been unsuitable for use because they contained bacterial growth or hemolyzed blood, or were extremely chylous. If possible, the directions given below should be followed in obtaining and supplying samples of serum for this test.

1. Serum for the precipitin test should be secured either before, or 24 hours after, the application of the intradermal test.
2. The patient should be bled before breakfast in order to avoid chylous specimens and prevent deterioration of the sample en route.
3. All apparatus used for collecting specimens should be washed free of alkali and acid before sterilization.
4. Only sterile apparatus should be used.
5. The syringe used in withdrawing the blood should be rinsed with physiologic saline solution to prevent hemolysis.
6. The serum should be separated from the clot before hemolysis begins to take place, and rendered perfectly free from red cells and particles by centrifuging.
7. At least 2 c.c. of perfectly clear serum should be submitted; about 5 c.c. of blood will provide this amount of serum.
8. Do not heat or add preservative of any nature.

Complement Fixation Test.—The complement fixation test for trichinosis is considered quite reliable. The method of conducting the test for trichinosis is identical with that originated by Bozicevich for conducting a complement fixation test for amebiasis (see page 1831). The only difference is in the antigen. Wright[1] states that this complement fixation test for trichinosis is now used in his Department exclusively.

Preparation and Use of Trichina Antigen.—Bozicevich[2] has given full details for the preparation and use of an improved trichina antigen. This antigen is the same antigen recommended for diagnosis of trichinosis by precipitin and intradermal tests.

Obtain trichina larvae in the usual manner by infecting rats with trichinous meat and killing the rats 4 to 6 weeks after infection. Skin and eviscerate the rats, and grind the remainder of the carcasses in the meat grinder. The ground trichinous meat is then ready for digestion.

Hobmaier and Meyer[3] described a modification of the Baermann apparatus for the recovery of trichina larvae. For this purpose, the author prefers a funnel of 3-liter capacity, to the stem of which a centrifuge tube is attached by means of a short piece of rubber tubing. Place a pinchcock on the tubing to permit closing when the centrifuge tube containing the larvae is removed after digestion of the infested meat. Place a 6-inch perforated porcelain plate, such as is used in a desiccator, in the funnel, and over this plate lay 4 or 5 layers of cheesecloth having 40 to 44 mesh apertures to the inch.

---

[1] Wright, W. H., Chief, Division of Tropical Diseases, National Institute of Health: Personal communication.

[2] Pub. Health Rep. 53: 2130, 1938.

[3] Science 86: 568, 1937.

Prepare the **digestive fluid** as follows:

Add 15 grams of pepsin to 3 liters of warm tap water. This amount is sufficient to digest approximately 70 grams of infested meat.

Stir until the pepsin dissolves.

Add 21 c.c. of hydrochloric acid, sp. gr. 1.10 to 1.19.

Place the digestive fluid in the modified Baermann apparatus (Fig. 492).

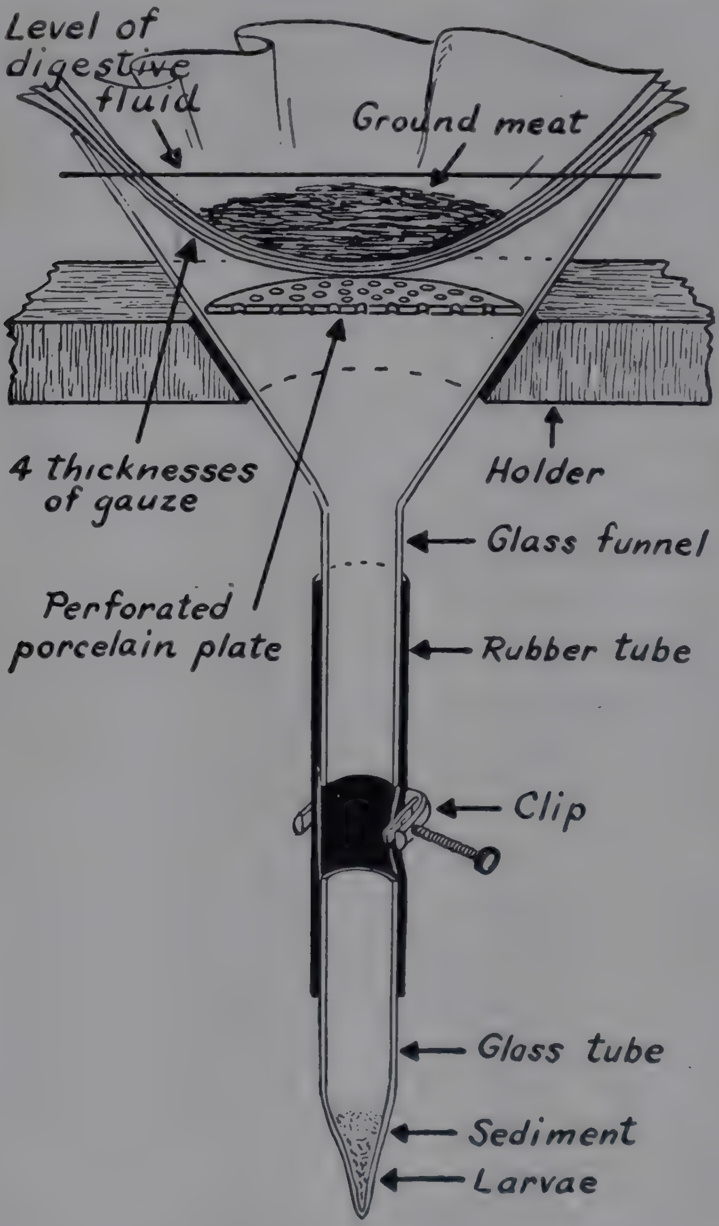

Fig. 492.—Modified Baermann apparatus.

Add the meat carefully, without agitation, on top of the cheesecloth.

Place the funnel containing these materials in an incubator at 37° C. for 15 to 18 hours. As the larvae are liberated from their cysts by the digestive fluid, they gravitate to the bottom of the centrifuge tube and, by means of their constant agitation, set in motion the fine sediment which settles over them when they become static. As a result, a clean, concentrated collection of larvae may be obtained, thus necessitating only a minimum amount of manipulation in removing rat protein.

At the end of the incubation period, close the pinchcock on the rubber tubing and remove the centrifuge tube.

Remove the supernatant fluid, along with the layer of sediment, by means of a pipette.

In order to neutralize the acid adsorbed from the digestive fluid, use a washing solution of pH 7.5. Wash the larvae three times with this washing solution over a 2-hour period. After each washing, allow the larvae to settle and draw off the supernatant fluid. After this, use neutral physiologic saline. At the end of this fourth washing, perform a biuret test on the supernatant fluid and, if the test is negative, the larvae are ready to be dried.

Place the larvae, with a minimum amount of fluid, in a sausage dialyzing skin 12 inches long and ½ inch in diameter. Place this in front of an electric fan. Evaporation is completed within 2 to 3 hours, depending upon the amount of fluid in the skin.

Then grind the larvae in an agate mortar. Since there is still considerable moisture remaining, place the mortar containing the material in a vacuum desiccator containing sulphuric acid or phosphorus pentoxide. After evacuation of the air, continue the drying overnight, and, when thoroughly dried, pulverize the mass and weigh it.

Calculate the extraction strength on the basis of the dried powder in a neutral 0.85 per cent solution of sodium chloride. A 1:20 dilution is usually the basic dilution used for precipitin work. After an extraction period of 3 to 4 hours at room temperature, adjust the reaction of the suspension to pH 7.0, if necessary, and continue the extraction in the refrigerator for 15 to 18 hours. Then centrifuge the suspension for one-half hour at the highest available speed. Discard the sediment.

Place the supernatant fluid in a water bath at 58° C. for 1 hour. Again centrifuge it and discard the sediment. Check and adjust the reaction, if necessary.

Set aside a portion of this fraction to be used in making **precipitin tests**, and dilute the remainder for **skin testing** in concentrations of 1:8,000 or 1:10,000, depending on the antigenic strength as determined by the precipitin titer given by a high titered antiserum. A high titered antiserum will give a good positive reaction with a 1:3,000 dilution of antigen. The solution used for skin testing is diluted to approximately three times the precipitin titer.

Distribute the antigen to be used for skin testing in 2 c.c. vials in quantities of 0.10 c.c., which is more than suffiicent for one intradermal test. Seal the vials hermetically in an oxygen flame. When they have cooled to room temperature, place them, sealed end down, in a beaker containing water stained with eosin or any suitable dye. Place the beaker containing the vials in a vacuum desiccator and apply house vacuum of 500 to 600 mm. In this manner, any defective seal will be detected readily when air is readmitted to the desiccator, since the stained water will enter any inadequately sealed tubes; such tubes should be discarded.

Check the seals, place the tubes in a water bath at 58° C. for one hour. Allow to stand at room temperature for 12 to 15 hours and place again in a water bath at 58° C. for one hour. Continue this fractional sterilization until sample tubes show no aerobic growth. Label and store the sterile tubes in a refrigerator.

Order **ASCARIDATA** Railliet and Henry 1915

Family **ASCARIDAE** Baird 1853

ASCARIASIS

Ascaris Lumbricoides Linnaeus 1758

Ascariasis is parasitism produced by *Ascaris lumbricoides*. It is found in every part of the world, but is more abundant in tropical countries because the high temperatures aid in the development of the parasite, and poor hygienic conditions of certain regions promote infestation.

Ascariasis is also known as ascaridiasis or roundworm infestation.

Morphologic Characteristics.—*Ascaris lumbricoides* is a large cylindrical worm tapering to pointed ends, the anterior end being thinner than the posterior. Pink while alive, it turns whitish when fixed with Formalin and yellowish if fixed with alcohol.

Females are usually 20 to 35 cm. long, sometimes 40 cm., by about 5 mm. in breadth. Males are smaller, from 15 to 30 cm. in length and 2 to 4 mm. in the widest portion.

Fig. 495.

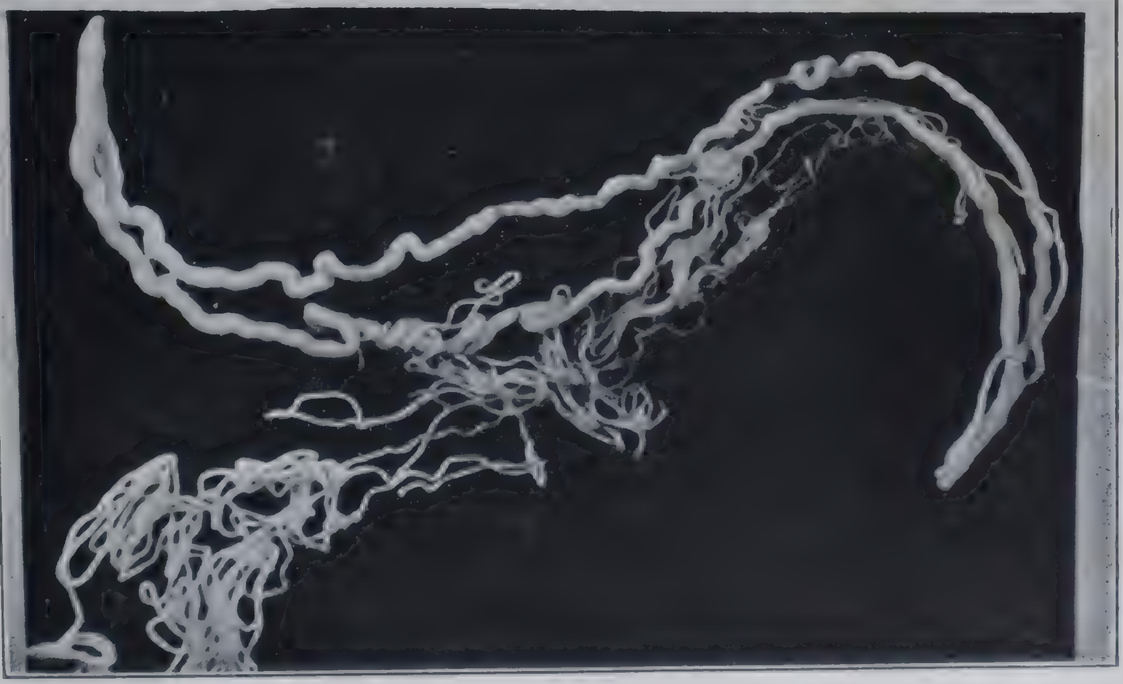

Fig. 496.

Fig. 495.—Posterior extremities of male and female *Ascaris lumbricoides*, drawn from life. (Original work of Prof. Kourí.)

Fig. 496.—Photograph of female genitalia. (Original work of Prof. Kourí.)

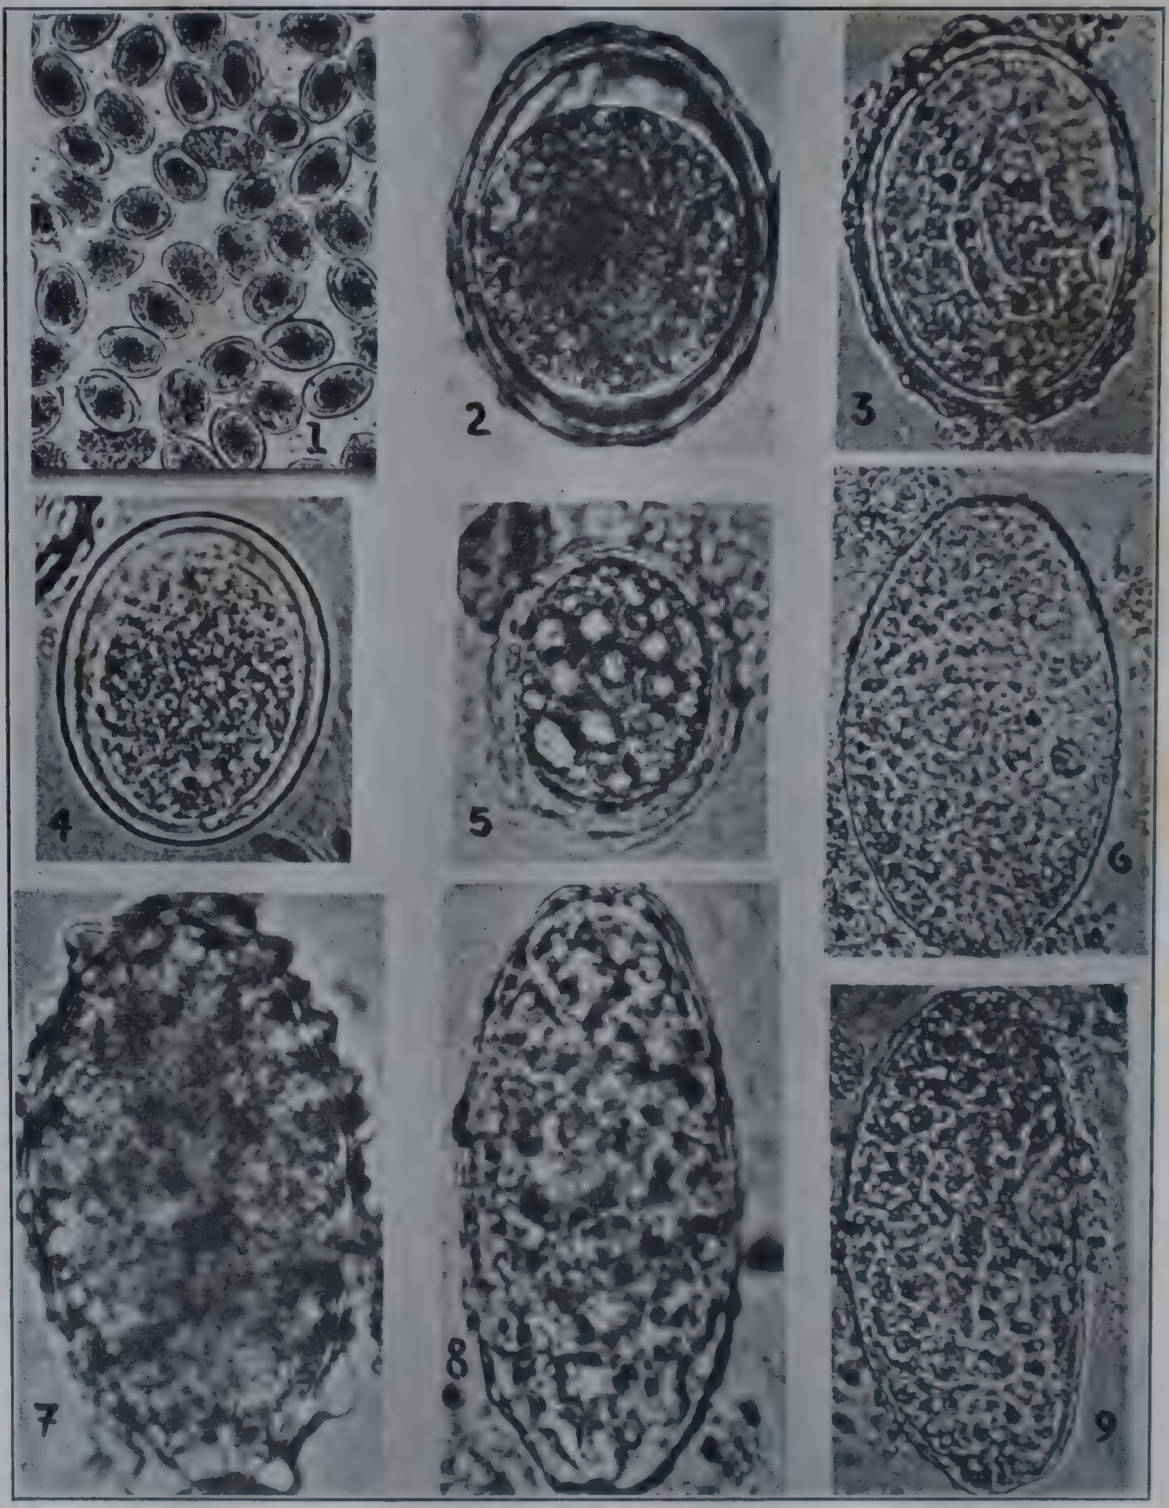

Fig. 497.—Photomicrograph of eggs of *Ascaris lumbricoides: 1*, Group of eggs removed from uterus; *2*, typical, or fertilized egg; *3* and *4*, eggs which have lost their external layer, *3* in part, and *4*, entirely; *5* to *9*, various unfertilized (atypical) eggs. (After Kourí.)

They are provided with a chitinous and resistant outer layer, transversely striated, and with two lateral narrow streaks running along the entire body length; these longitudinal lines correspond to the lateral fields. Female reproductive organs are often observed through the transparent parasite when viewed before a light.

A distinguishing characteristic of the male is the appearance of the posterior end, which curves ventrically.

Fertilized Eggs.—Eggs are ovoid with the longitudinal diameter longer than the transverse. They are 50 to 75 microns by 40 to 60 microns. Two membranes form the shell, the outer, festooned or mammillated, albuminous, stained more or less dark yellow with bile; and an inner smooth, stout, colorless, and refractive membrane. The two membranes are more in evidence when the egg is pressed between slide and cover glass, when it loses the mammillated outer covering.

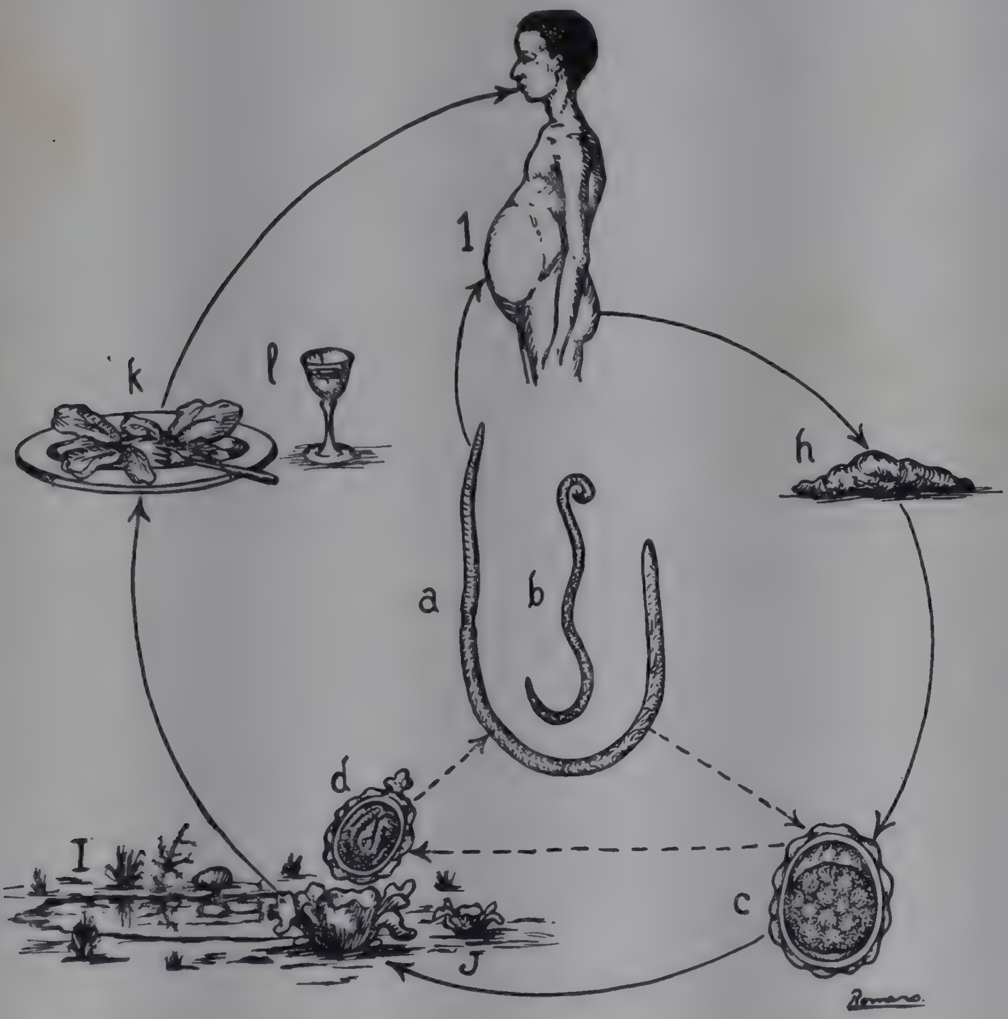

Fig. 498.—*Ascaris lumbricoides.* Life cycle. The fertilized eggs (*c*) are passed in the feces (*h*) of individuals (*1*) harboring female (*a*) and male (*b*) parasites; in two to three weeks the eggs embryonate (*d*); contaminate food (*i,j,k,l*) are ingested (*d*), develop into female (*a*) or male (*b*) adults in the intestines of their host (*1*), after migrating through the circulatory system; larval stages in the liver, the heart, and the lungs of their host (*1*). (Original drawing of Drs. Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

There is a spherical, sharply defined, granular protoplasm within the egg, but not occupying the entire egg cavity. It has a small, clear, rounded zone corresponding to the nucleus.

Unfertilized Eggs.—These are generally longer than the fertilized eggs although some of them are small. The shell is much thinner. The mammillated shell disappears with slight pressure. The contents consist of large refractile granules resembling fat droplets.

Life Cycle.—The life cycle is seen in Fig. 498.

Habitat, Number, and Life Span.—The usual habitat of this parasite is the small intestine of man. In erratic parasitism it may be found in any other part of the digestive tract. The number of parasites ranges from one to two hundred; in exceptional cases there may be more than one thousand; usually there are only eight or ten.

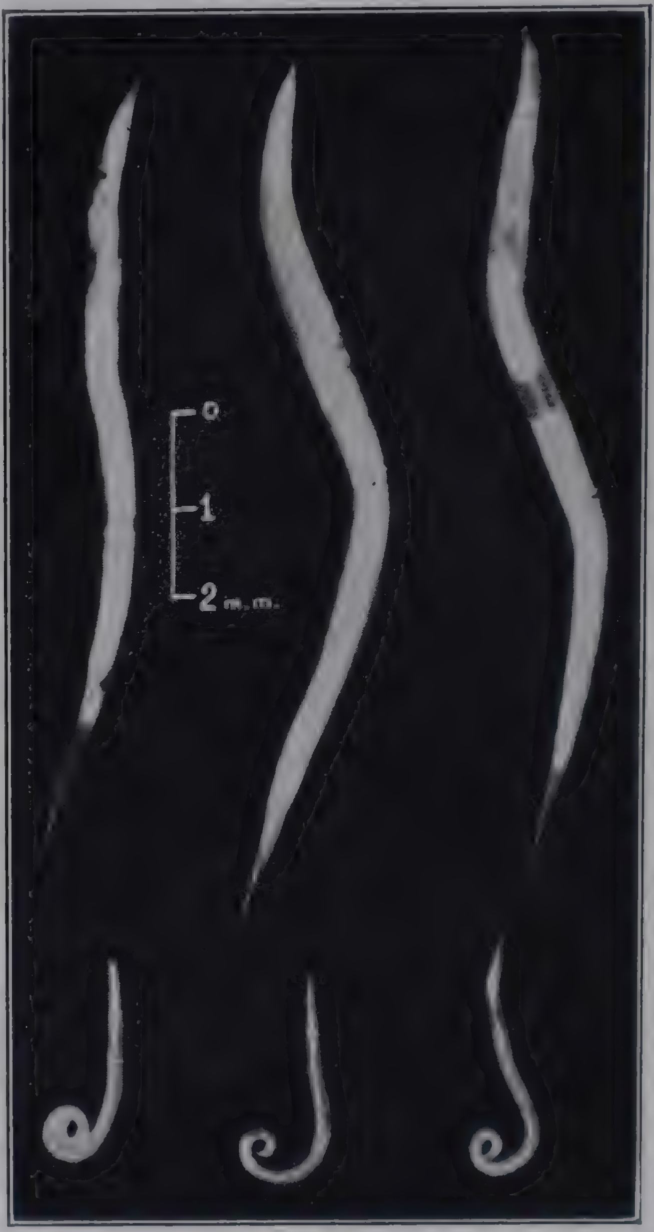

Fig. 499.—*Enterobius vermicularis.* Above, three females, showing the characteristic fine, long tail; below, three males, much smaller, with the posterior extremity coiled upward. (Original figure of Kourí and Basnuevo.)

The life span of this parasite is unknown.

Ascaris lumbricoides which infests man is morphologically identical to *Ascaris suum* of swine; biologically, however, they are different species. Koino, in 1922, and other more recent investigators have demonstrated that the Ascaris which parasitizes man cannot be transmitted to swine, and vice versa.

Diagnosis.—The only definitive diagnosis consists in finding the parasite or its eggs. Direct microscopic examination of feces and the use of concentration methods constitute the usual procedure in the diagnosis of this parasitism. The characteristics of unfertilized eggs are important in avoiding diagnostic errors. Consecutive examinations at several days' intervals should be practiced.

Parasitism by male Ascaris cannot be diagnosed by the microscopic examination of feces alone. Test treatments and occasionally x-ray examinations might prove diagnosis in cases of this type.

In gastroduodenal and biliary localization of the parasite, eggs are found in microscopic examination of fluids obtained through duodenal intubation.

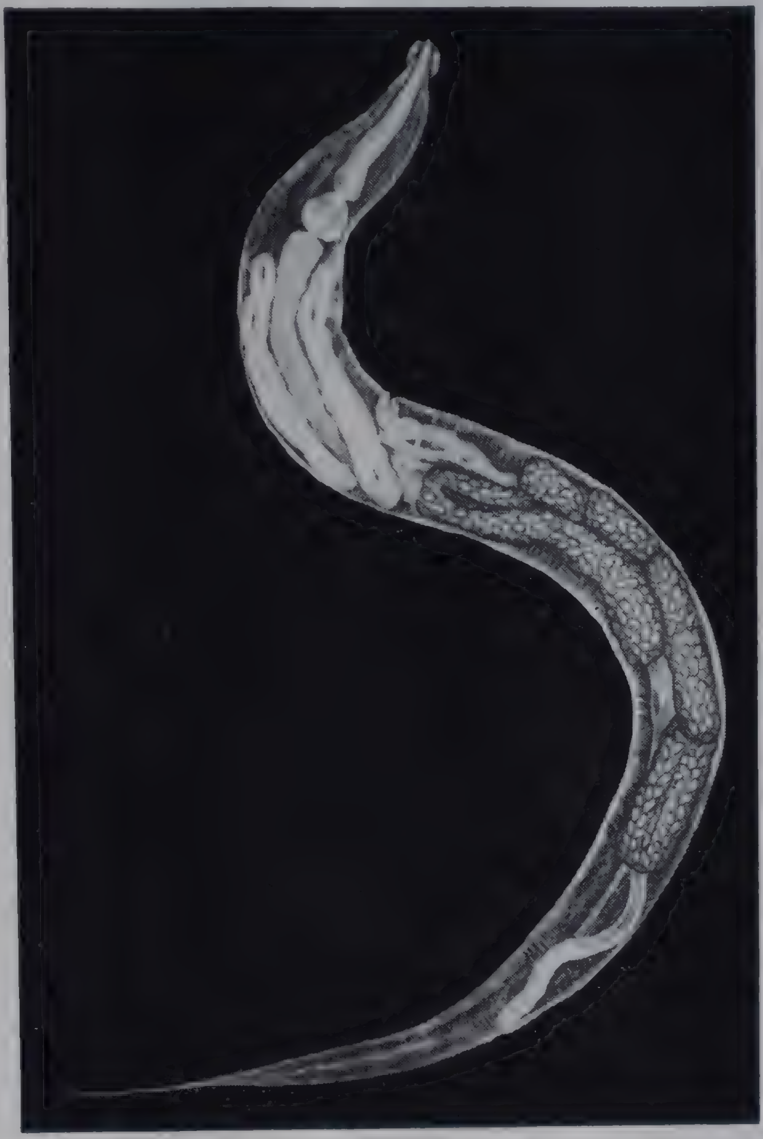

Fig. 500.—*Enterobius vermicularis.* Pregravid female parasite. Observe the cuticular cervical expansions, the muscular esophagus, with its two portions, the intestine, ovaries, uterus, vulva, and anus. (Original figure of Kourí and Basnuevo.)

Family **OXYURIDAE** Cobbold 1864

ENTEROBIASIS (OXYURIASIS)

Enterobius Vermicularis (Linnaeus 1785) Leach 1853

Enterobiasis, or pinworm infestation, is parasitism produced by *Enterobius vermicularis. E. vermicularis* is a very small worm, of a whitish color. The posterior extremity of the female is very long and sharp, that of the male conical and coiled. The male measures 2 to 5 mm. in length and the female 9 to 11 mm. The females characteristically have a fine, long, pointed tail.

The **eggs** are oblong, asymmetrical, flat on one side and convex on the other. They are about 60 microns long and approximately 30 microns wide. In addition to being asymmetrical, they are double-walled, colorless, and contain a tadpole-shaped or worm-shaped embryo. The embryo emerges from the cephalic pole or adherence zone of the egg, the convex end portion. The eggs are embryonated when laid. They often adhere to each other, forming a cluster.

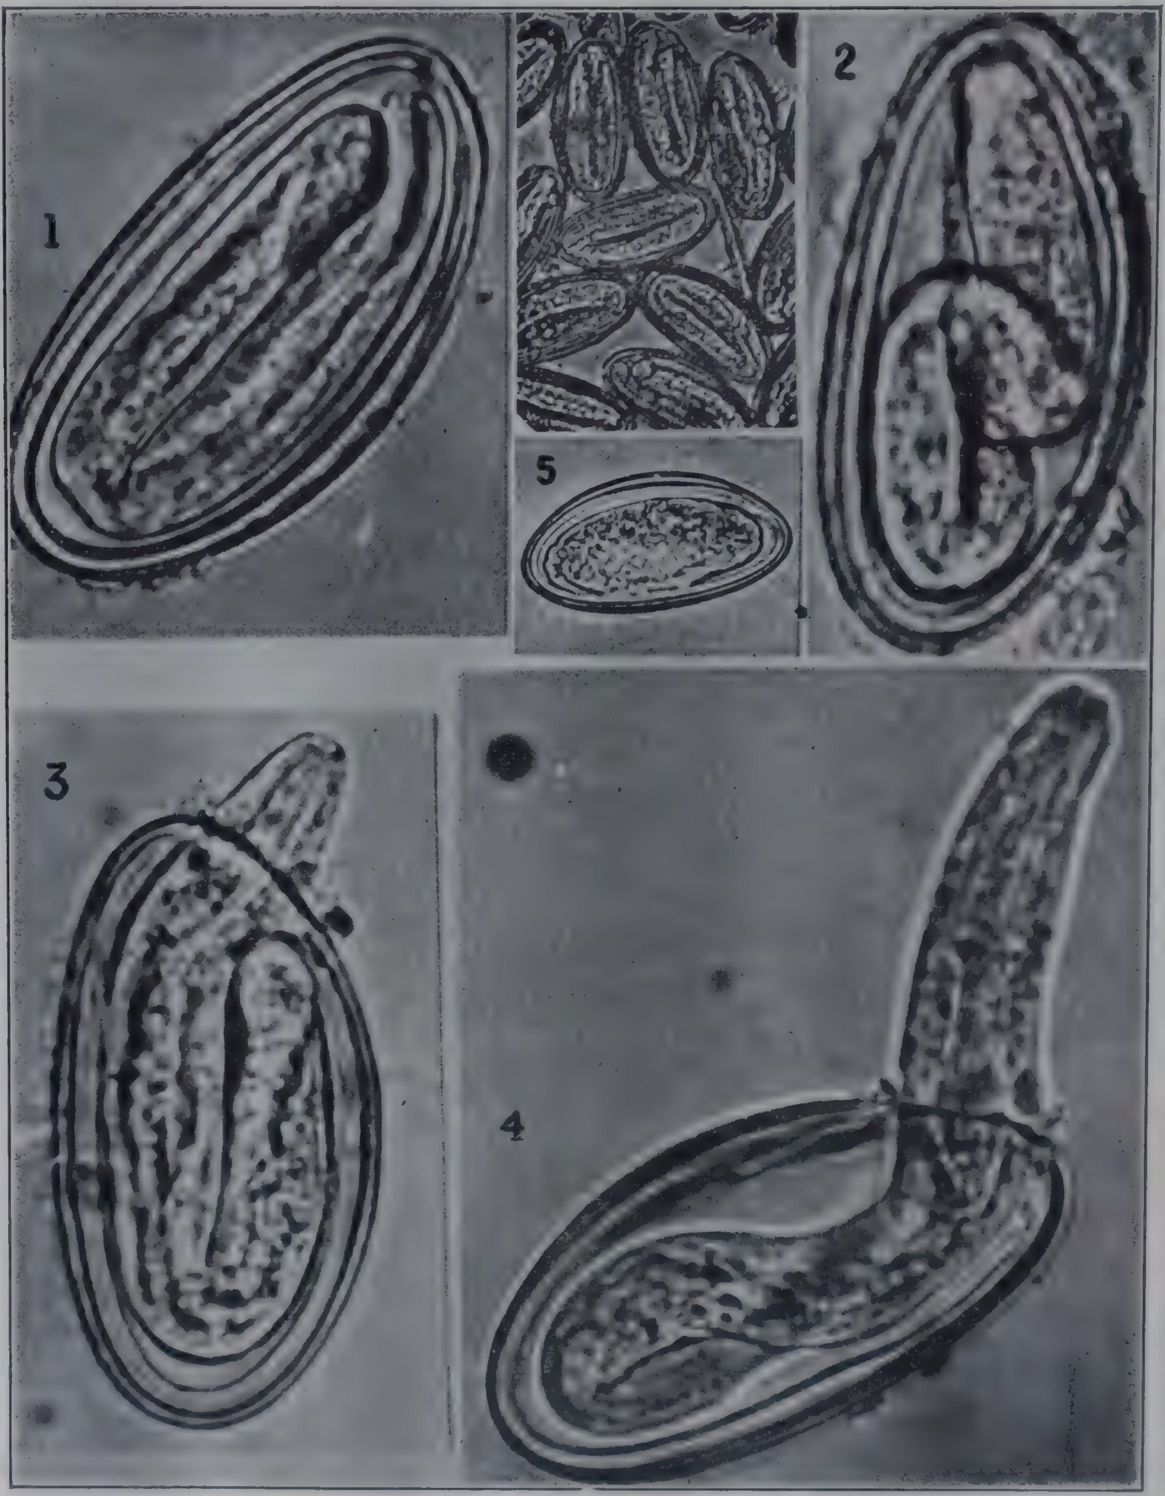

Fig. 501.—Eggs of *Enterobius vermicularis.* *1* and *2*, Egg with vermiform embryo. *3* and *4*, Two stages in the emergence of the vermiform embryo. *5*, Eggs with lower magnification. (Original photomicrographs of Kourí.)

Life Cycle.—The life cycle of this worm is set forth in Fig. 502.

Diagnosis.—When infestation with *E. vermicularis* is suspected, the best diagnostic procedure is to ask the patient if he has noticed any small whitish worms in the feces. If the answer is in the affirmative, direct him to bring a specimen in a small bottle containing water, alcohol, or 10 per cent Formalin. Other methods of diagnosis are parasitologic examination of the feces, microscopic examination of the scrapings of the marginal regions of the anus, examination of the cellophane covering of Hall's anal swab (see page 1813), and microscopic examination of material from the subungual groove.

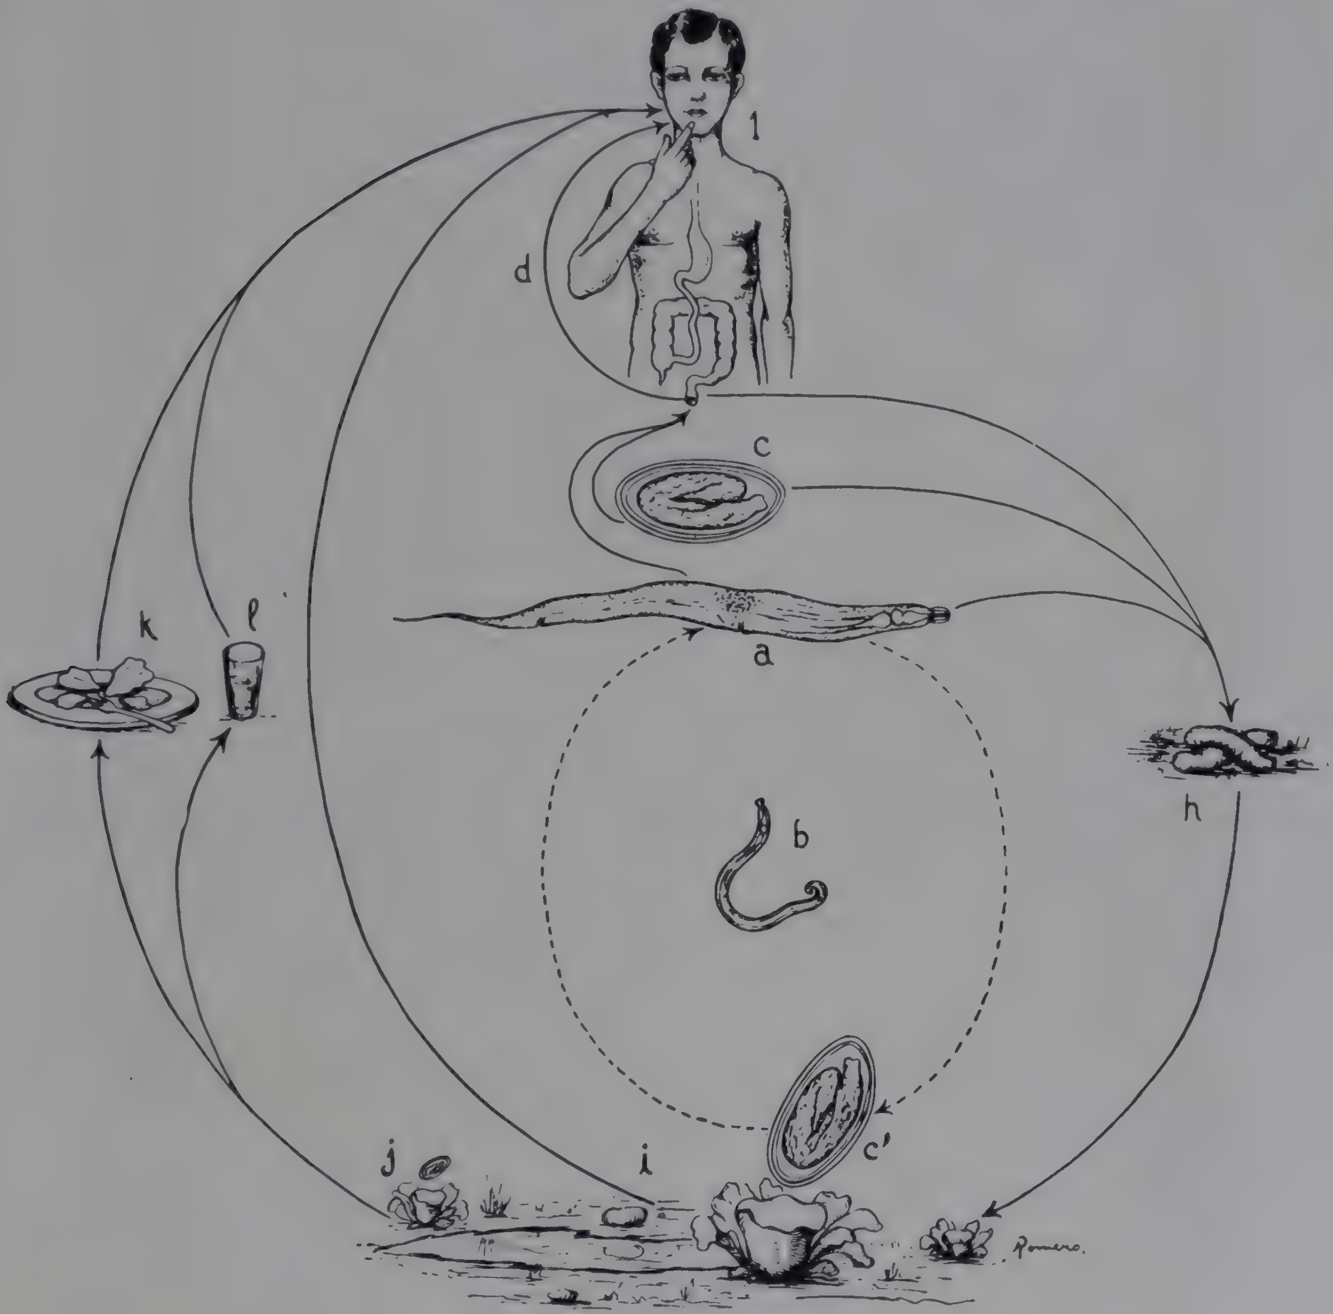

Fig. 502.—*Enterobius vermicularis.* Life cycle. Auto-infestation (*d*) occurs because the egg is embryonated and infestive when first laid in the anal margins or outside the body. *a*, Oviferous female in the anal margins, lays it eggs, *c*, which contaminate the fingers of the host, or, in the feces (*h*), drop on the soil, *c'*, and contaminate foodstuffs, *k,l*. When the eggs are ingested, the intraovular embryo is set free in the intestines, where the adult female *a*, or male, *b*, develops. After copulation the males, *b*, remain in the cecum and die. The oviferous females, *a*, descend to the anal margins of the hosts, *1*, to again begin the cycle. (Original figure of Kourí and Basnuevo.)

Finding the egg is essential for the diagnosis, but eggs are not found constantly in the feces of parasitized individuals, since the female parasite does not lay eggs in the intestine of the host, but migrates to the rectum and anus and lays the eggs there, or empties its uterus after leaving the body of the host. It is for this reason that the Hall anal swab procedure is so important in the diagnosis of this parasitism.

Family **RHABDITIDAE** Micoletzky 1922

STRONGYLOIDIASIS

Strongyloidiasis is parasitism produced by *Strongyloides stercoralis.*

Strongyloides Stercoralis (Bavay 1876) Stiles and Hassal 1902

S. stercoralis has two adult forms and a rather complex cycle of development. There are two types of larvae, one the rhabditiform, the other filariform. The first adult form is called "strongyloid" because of the shape of the esophagus which is cylindrical and long. The second form is called "rhab-

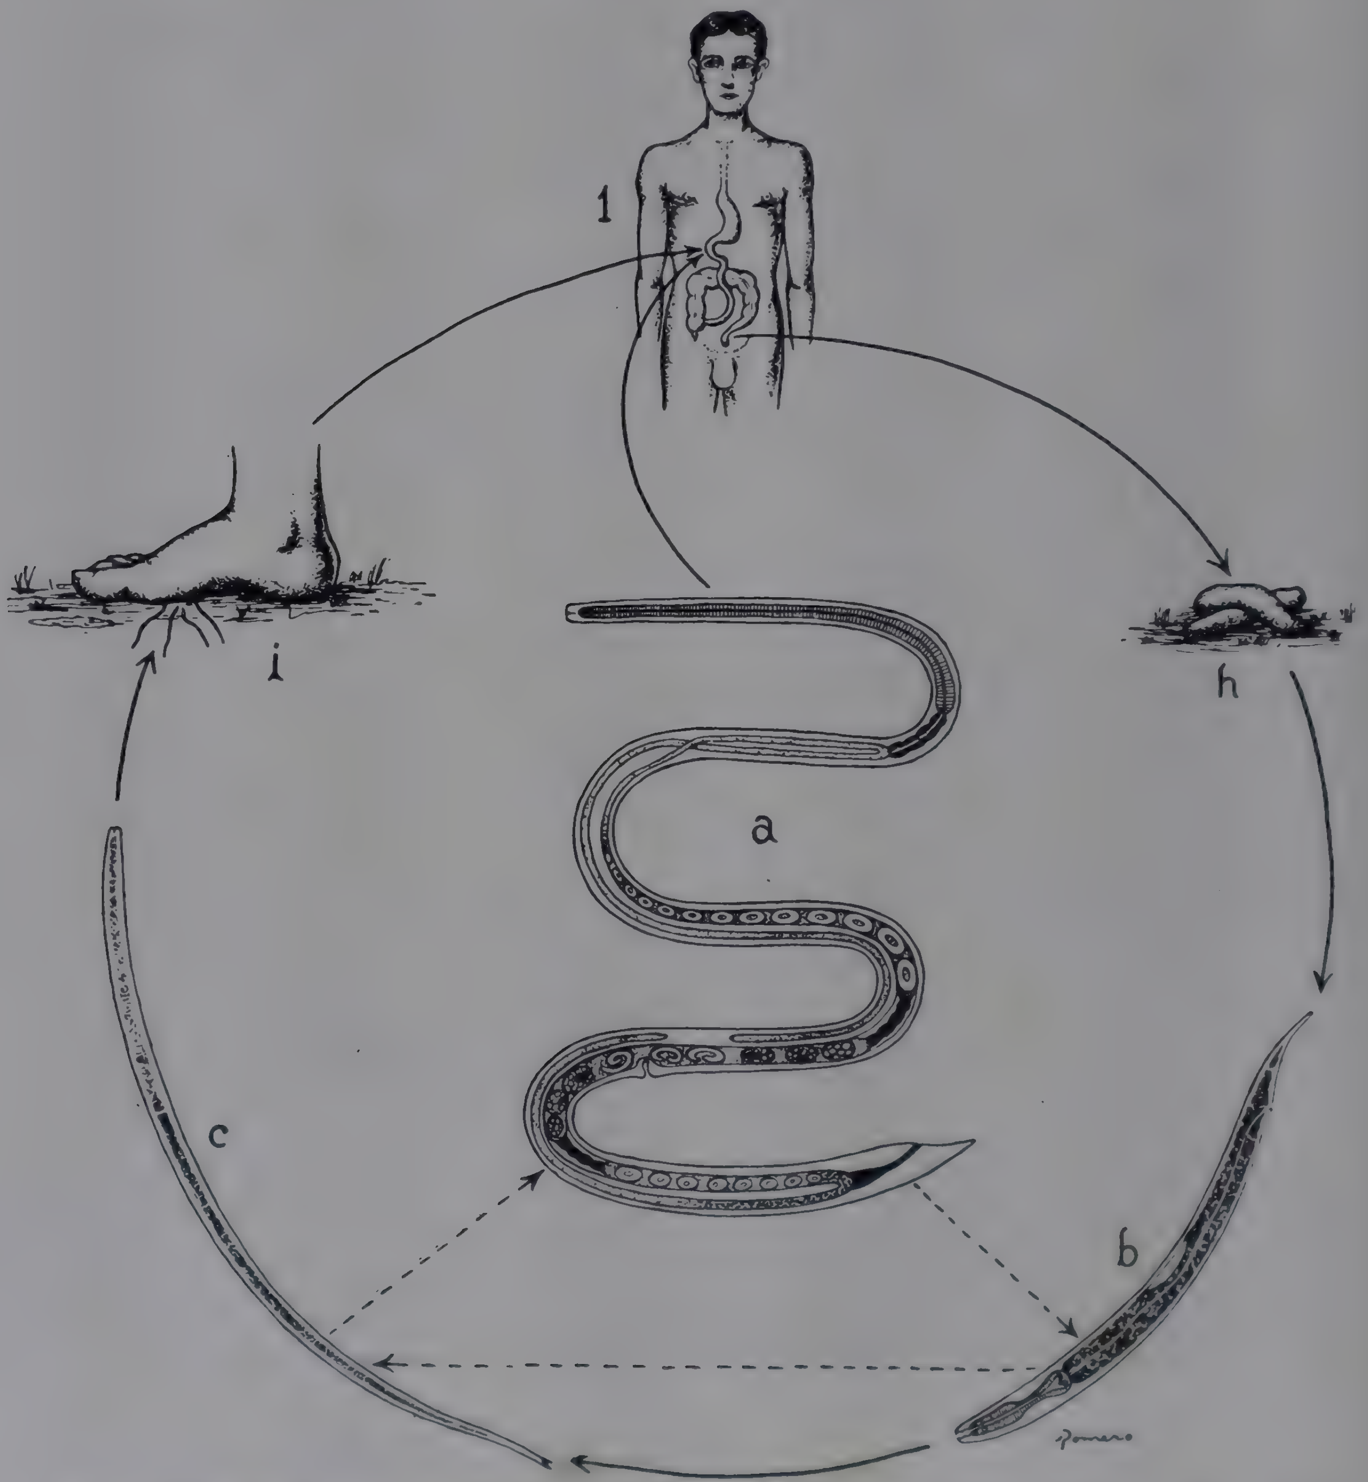

Fig. 503.—*Strongyloides stercoralis.* Life cycle. Direct or short cycle. The female parasite (*a*), in the intestinal mucosa of the host (*1*) lays eggs which burst and free, in the feces (*h*), a rhabditiform larva (*b*) which is transformed directly into a filariform larva (*c*) which bores through the skin (*i*), migrates to the intestines, and is transformed into the parasitic form (*a*), which adheres to the mucosa, lays eggs, and begins anew its cycle with freeing of the rhabditiform larvae (*b*) in the feces (*h*). (Original figure of Kourí and Basnuevo.)

ditiform,'' because of the bulbous shape of the esophagus. At the time of expulsion, the rhabditiform larva is 200 to 300 microns long, and rapidly increases in size as it develops into the filariform larva.

The **rhabditoid female,** fecal or free type, is about 1 mm. long and 50 microns wide, and can be seen with the naked eye. If a drop of coproculture is placed on a slide, it can be seen but is difficult to detect because of its small size.

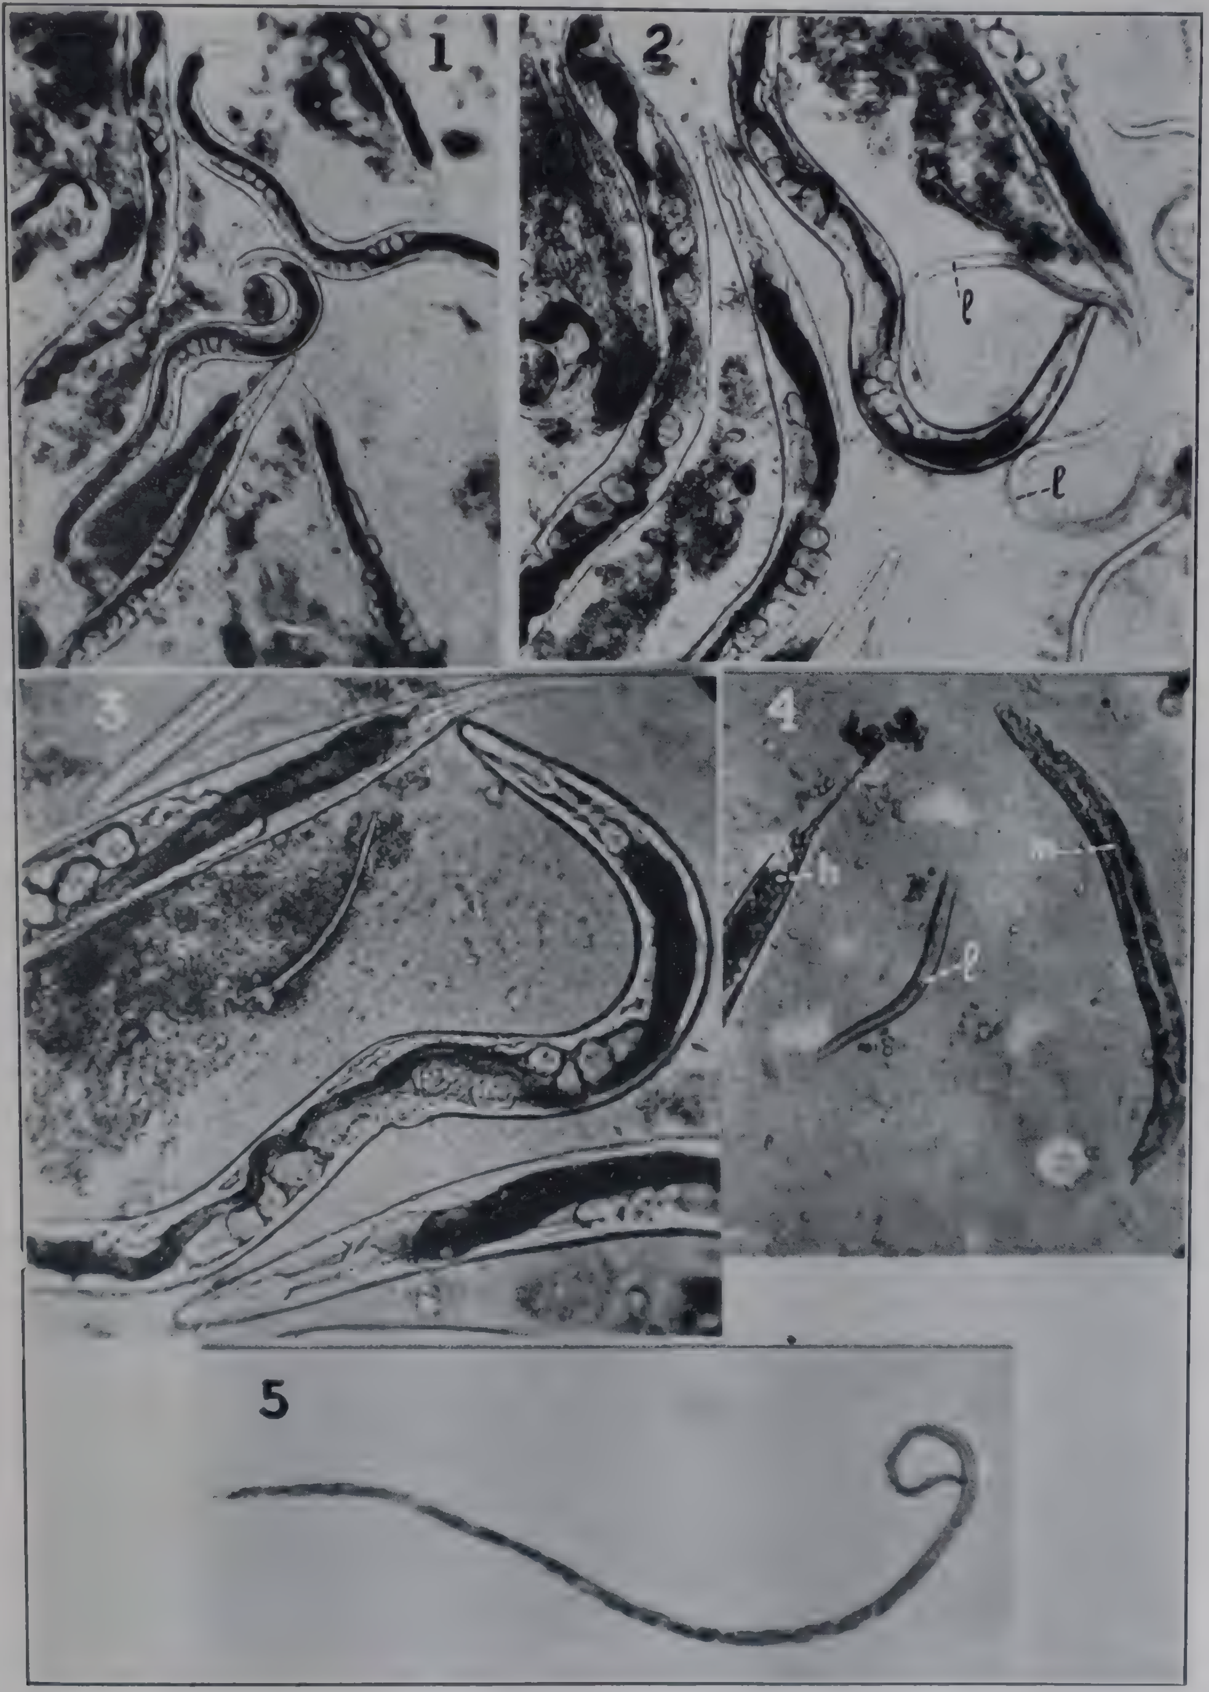

Fig. 504.—*Strongyloides stercoralis.* *1,* Gravid rhabditoid females in fecal cultures *2,* Free-living females and strongyloid larvae in fecal cultures. *3,* Rhabditoid free-living females, higher magnification. *4,* Posterior extremity of female, *h,* rhabditiform larva, *l,* and free-living male, *m.* *5,* Female parasite, Strongyloides, from a rat. (Kourí and collaborators.)

The **eggs** are ellipsoid and measure approximately 50 to 60 microns in length by 30 to 40 microns in width. They have a very thin single, colorless, refractile wall. In fecal cultures, some of these eggs burst, giving rise to rhabditiform larvae within the uterus of the rhabditoid female.

The **life cycle** is shown in Fig. 503.

The **rhabditoid male** is seen in Fig. 504.

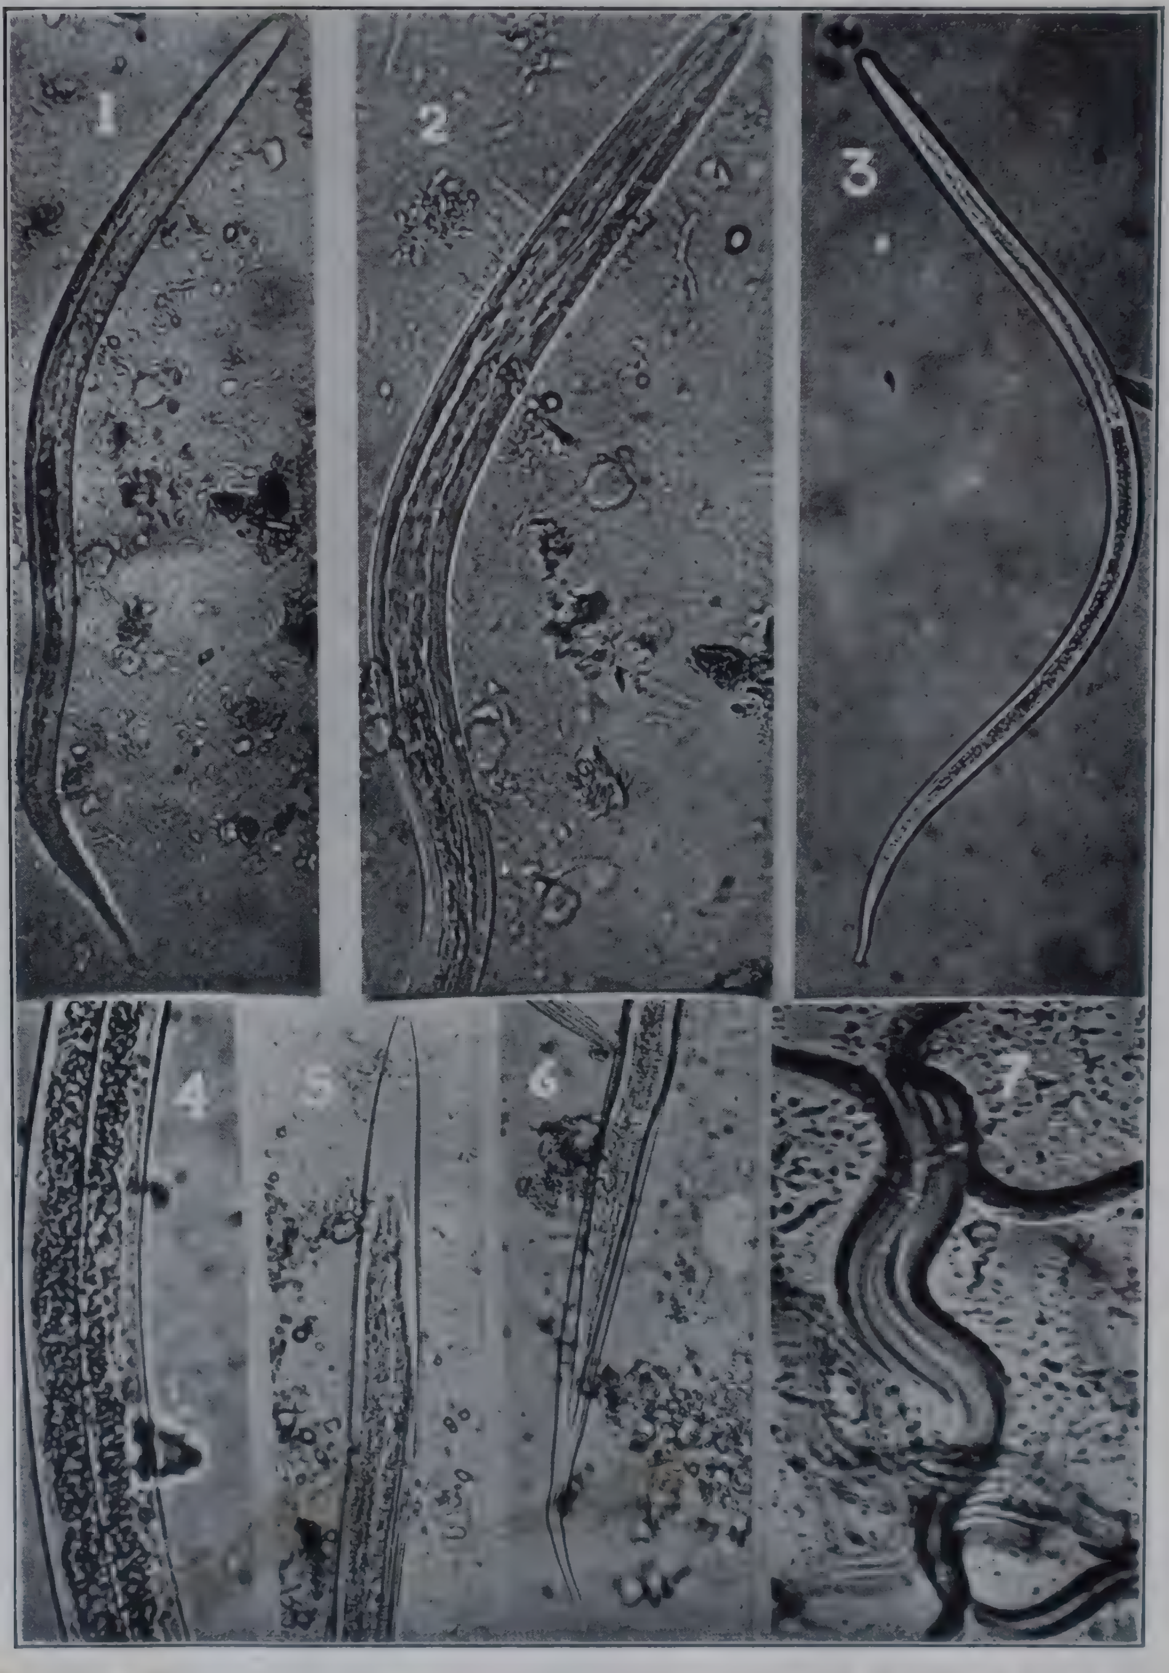

Fig. 505.—*Strongyloides stercoralis*. Developing larva and filariform larva in coprocultures. *1*, Larva developing into filariform larva. The esophagus has become longer and is almost cylindrical; the intestine has become shorter; and the outline of the genital organs has narrowed. *2*, Anterior half of the same larva under high magnification. *3*, Typical filariform larva. *4*, Central portion of body of larva developing into filariform. *5* and *6*, Anterior and posterior portions of larva during molting stage. *7*, Group of filariform larvae (arranged like locks of hair) in the coprocultures. (After Kourí and collaborators.)

Diagnosis.—Diagnosis is established by microscopic examination of the feces, where the rhabditiform larvae are found. If the feces are not examined for some time after they have been passed, the filariform larvae, and even sexual forms, might be seen.

Stools are examined unstained, stained with Lugol solution, concentrated, or by screening. Coproculture is important when parasites are scarce. Examination of bile obtained by duodenal intubation may show rhabditiform larvae or embryonated eggs surrounded by mucus.

Order **STRONGYLATA** Railliet and Henry 1913

Family **ANCYLOSTOMIDAE** Lane 1917

HOOKWORM DISEASE

Hookworm disease is parasitism produced by *Necator americanus* or *Ancylostoma duodenale.*

Necator Americanus (Stiles 1902) Stiles 1903, and **Ancylostoma Duodenale** (Dubini 1843) Creplin 1845

The species *Necator americanus* predominates in the Western Hemisphere, Central South Africa, Southern Asia, East India, Polynesia, Micronesia, and Australia. *Ancylostoma duodenale* predominates along the coastal regions of Northern Africa, the Mediterranean, Southern Europe, Northern India, and China and Japan.

N. americanus is a pinkish-white round worm, frequently stained dark by digested blood. The female is 9 to 11 mm. long and 0.4 mm. wide, the male 7 to 9 mm. long by 0.3 mm. wide. The body of the female describes an arc, the ventral surface on the inner side. The anterior surface curves back over the body with the buccal capsule facing the convex dorsal surface.

TABLE 184

ANCYLOSTOMA DUODENALE	NECATOR AMERICANUS
Buccal Capsule	
Note teeth. Two on each side.	Note absence of teeth. Instead of this, there are liplike pouch-formed plates.
Distal End of Female	
A very fine sharp point or tail.	No tail or point.
Distal End of Male	
Note spicules which come off from the bursa copulatrix diverging from each other and ending in a point. The bursa is spread out in umbrella shape.	The spicules which come from the bursa copulatrix lie near the end and close together and carry a hook. The bursa appears as if it were made of two lobes.
Sexual Opening of the Female	
Sexual opening lies behind the middle of the body in the convexity.	Sexual opening lies in front of the middle of the body in concavity.
Position of the Body in Rigor Mortis	
The head, and in the male the distal end, are bowed in from the ventral side of the body. ("C" position.)	The head, and in the male the distal end, are bent from the dorsal side almost hook shape.
Size	
Somewhat larger and thicker than the Necator.	Somewhat shorter and more slender than the Ancylostoma.

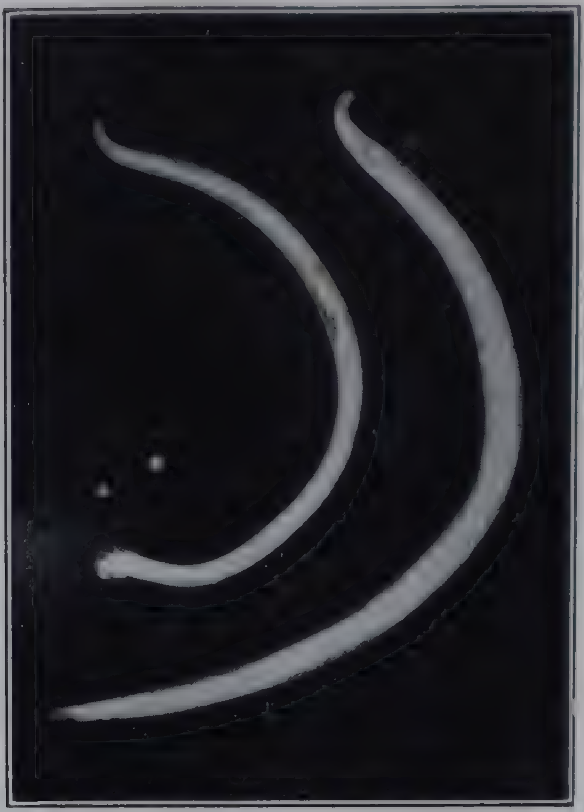

Fig. 506.—*Necator americanus. Left,* male. *Right,* female. (Original figure of Drs. Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

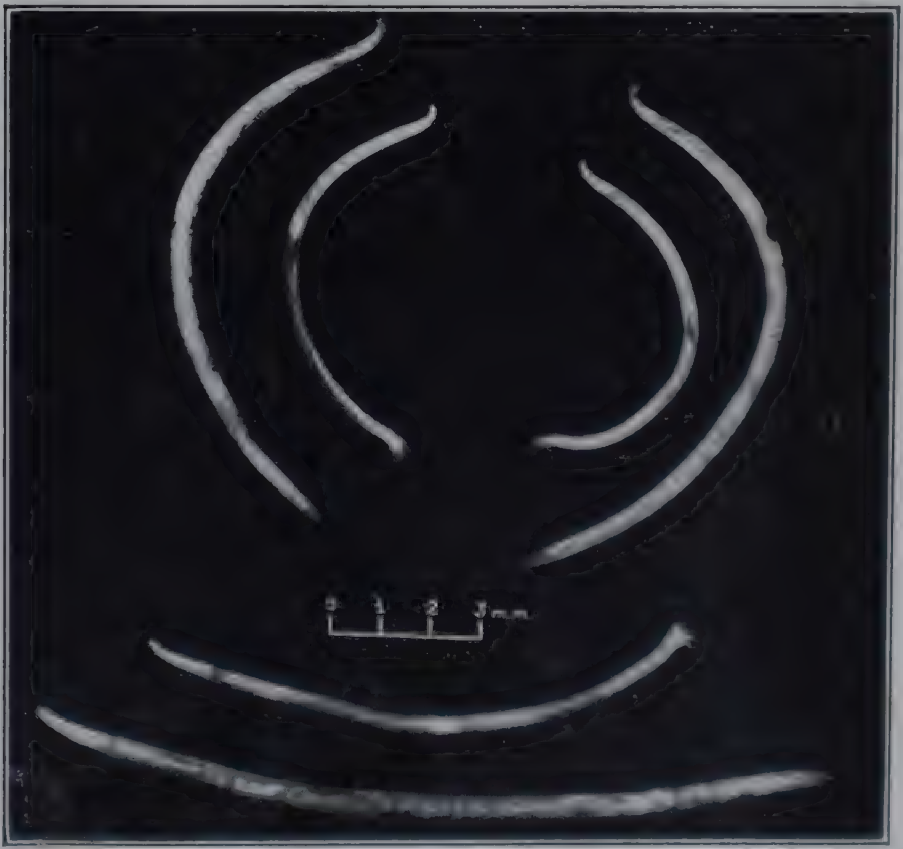

Fig. 507.—Necator and Ancylostoma. *Above, Necator americanus,* male and female (two pairs); *below, Ancylostoma duodenale,* male and female (one pair). Millimeter scale. (Original figure of Kourí.)

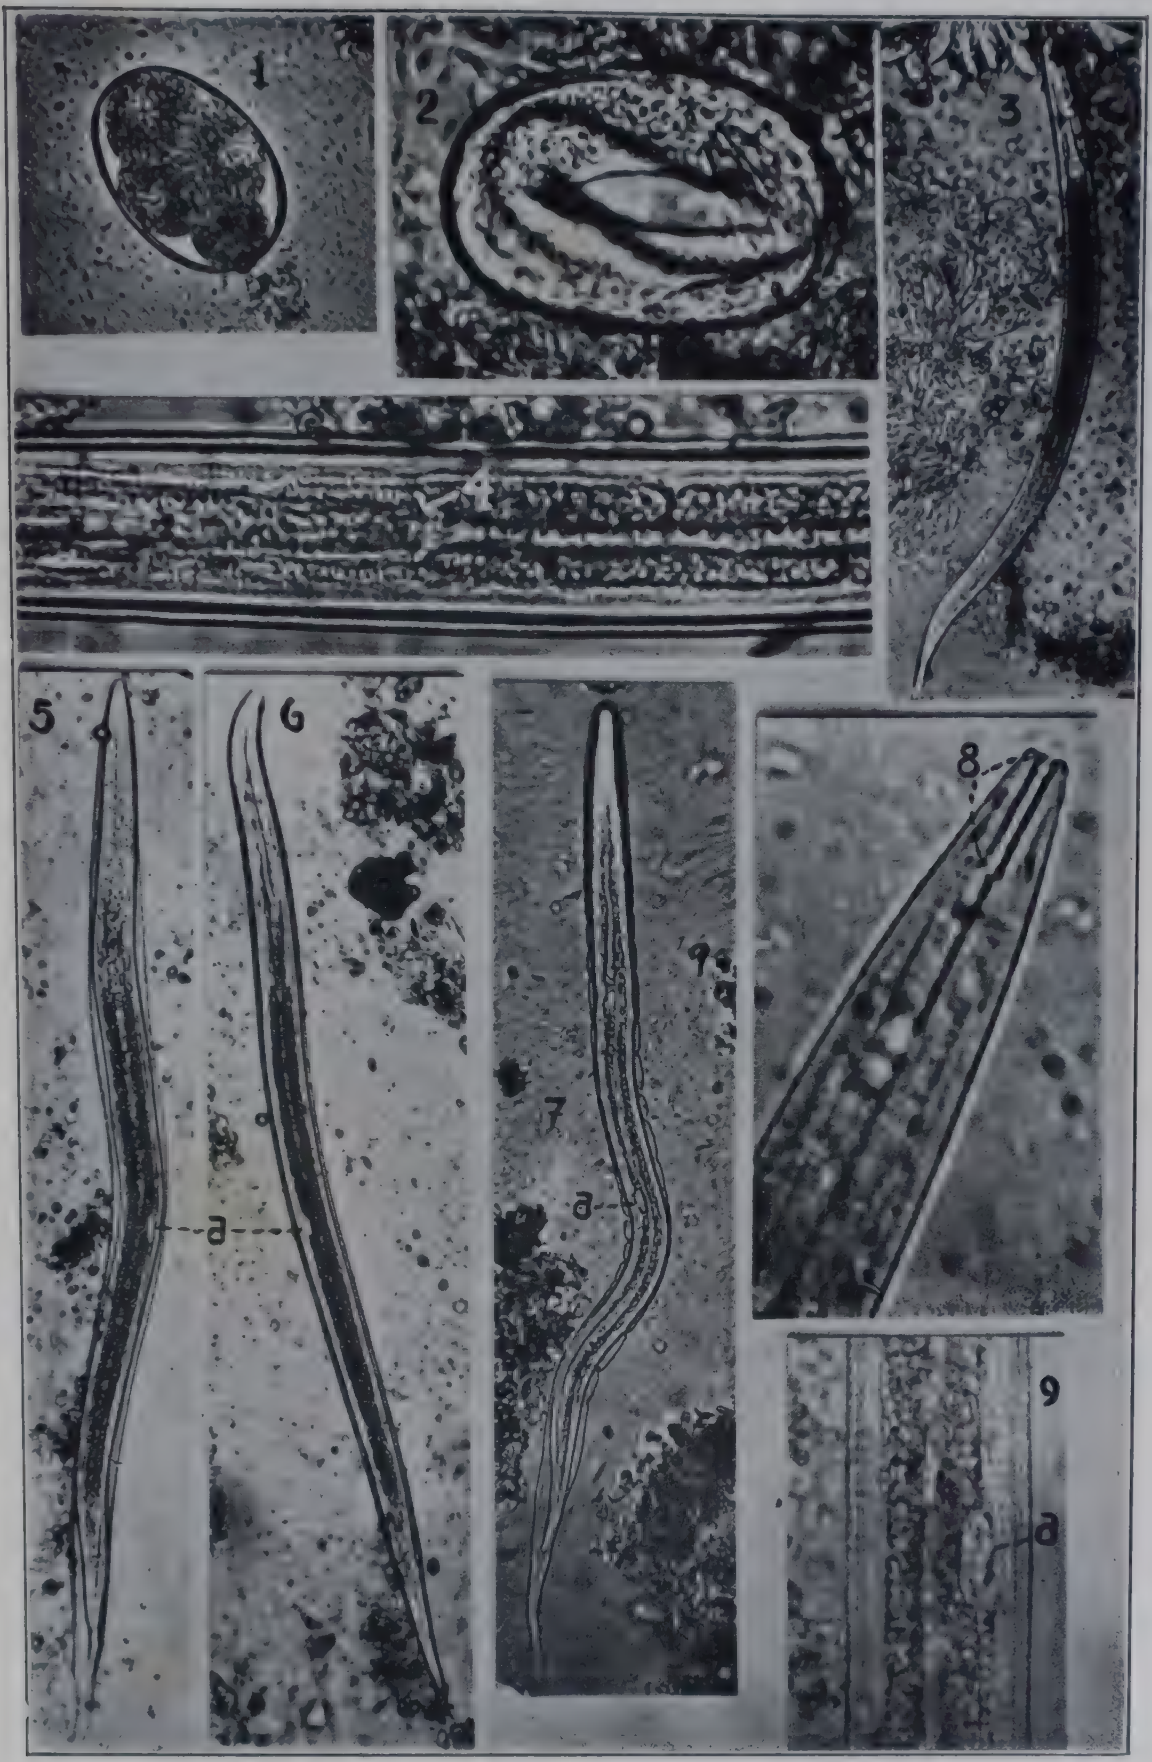

Fig. 508.—*Necator americanus,* eggs and larvae. *1,* Eggs with 4 segments or cells; *2,* embryonated egg with long mouth; *3,* rhabditiform larva, esophagus with 2 dilated portions, rudiments of genital organ not visible; *4,* point of junction of esophagus, left, and intestine, right, of filariform larva; *5, 6,* and *7,* various developmental stages of filariform larva; *7,* sheathed filariform larva, infesting form with (*a*) rudiment of small genital organ; *8,* long mouth of rhabditiform larvae; *9a,* small rudiment of genital organ in rhabditiform larva. In 5 and 7 the sheath is clearly outlined. (Original photomicrographs of Kourí.)

Female *A. duodenale* species are 10 to 18 mm. long by 0.6 mm. wide; males are 8 to 11 mm. long and 0.4 mm. wide. Ancylostoma shows an irregular curvature.

The females of the two worms differ in size and shape, and the buccal capsules. See Table 184. In the *N. americanus,* the vulva is in the median third of the body; in the *A. duodenale,* it is in the posterior third.

Eggs.—Eggs of *N. americanus* are ellipsoidal, and are longer than those of *A. duodenale,* which measure 60 microns by 40 microns. Eggs of *N. americanus* are 70 by 40 microns, the wall is very thin, colorless, refractile. The eggs are composed of a granular grayish substance divided into 4 to 8 cells or metameres (blastomeres), each containing a clear, rounded zone which represents the nucleus.

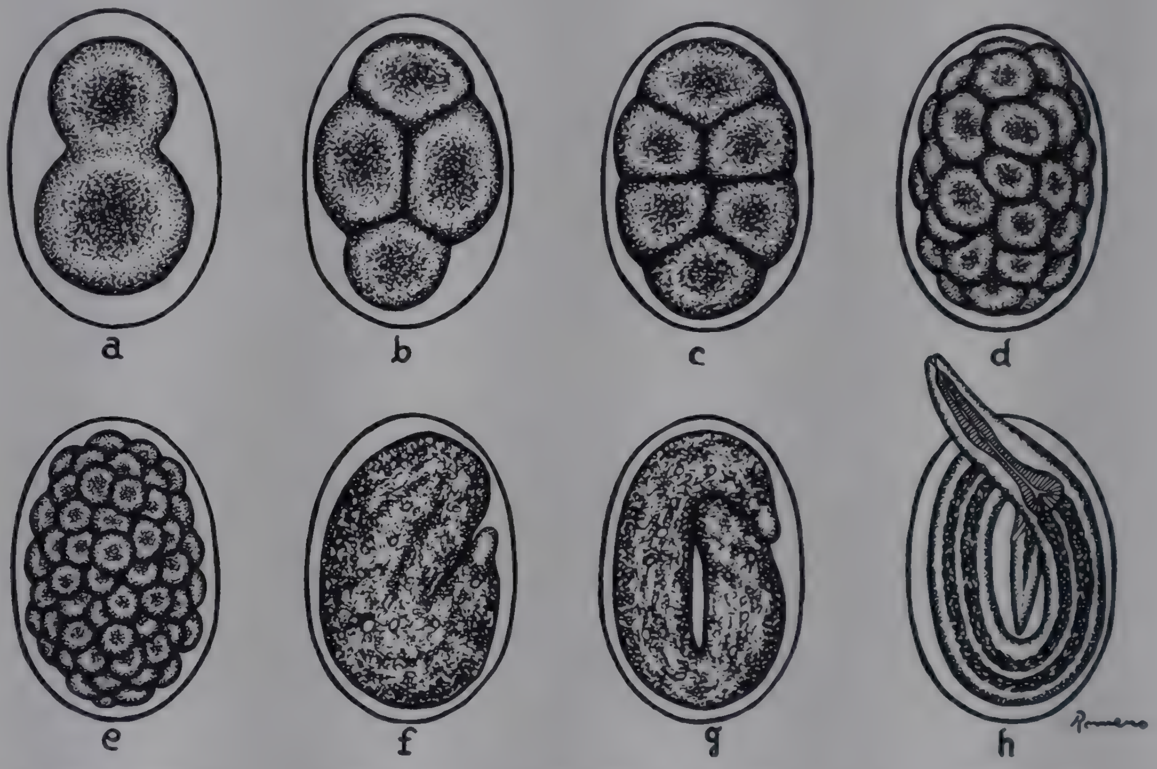

Fig. 509.—*Necator americanus.* Development of the egg. *a, b, c,* Eggs with two, four, and six metameres; *d,* beginning of the morula stage; *e,* morula in a more advanced stage of development; *f,* egg with tadpole-like embryo; *g,* egg with vermiform embryo; *h,* egg with rhabditiform larva. (Original drawing of Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

Life Cycle.—The life cycle is given in Fig. 510.

N. americanus and *A. duodenale* live in the small intestine of man, especially in the upper portion. The number of worms harbored by some patients may be in the thousands in cases with severe anemia. The life span of the parasite is probably from 1 to 5 years.

Hookworm disease shows various symptoms: cutaneous, intestinal, and general. For a description of hookworm anemia, see page 750.

Diagnosis.—Diagnosis is often confused with malarial cachexia or beriberi. Confirmatory diagnosis should be made by examination of the feces, where the eggs are numerous in cases of massive parasitism. Concentration methods are necessary in cases of mild infestation. Study of the duodenal contents obtained by intubation with Lyon's catheter may reveal both eggs and adult forms of the parasite.

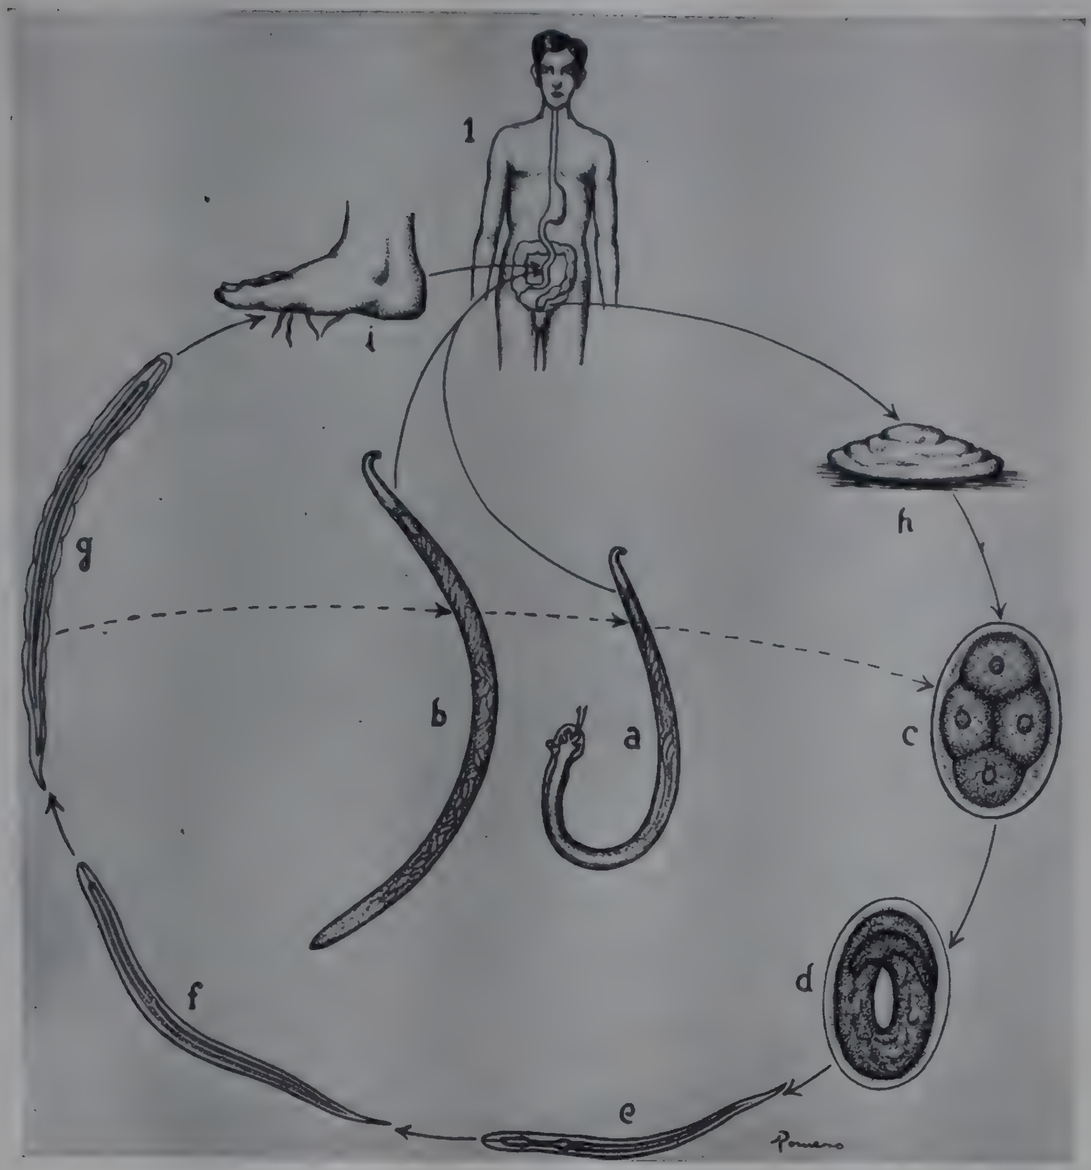

Fig. 510.—*Necator americanus.* Life cycle. *a* and *b,* Male and female adult parasites the habitat of which is the duodenum and jejunum. The eggs are passed in the feces (*h*); develop (*c* and *d*); a rhabditiform larva (*e*) is set free; it molts and becomes a filariform larva (*f*) which molts and becomes surrounded by a sheath; this is the infective larva (*g*) which bores through the skin (*i*), migrates through the heart and lungs, and reaches the intestines where it grows to the adult stage (*a* and *b*) after molting twice.

Extra-human stages (free-living): egg and three larval forms. Intra-human stages: two larval forms and the adult parasite.

(Original drawing of Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

CREEPING ERUPTION (LARVA MIGRANS)

The larvae of certain animal nematodes may occasionally bore through the human skin and live for a period of time in the dermis where they creep or advance, giving rise to an extremely pruriginous dermatitis along that part of the surface of the skin which is covered by the larva in its trajectory. This condition is known as *larva migrans* or creeping eruption. The original dermatitis may be complicated with pyodermatitis and superficial ulcerations following violent scratching.

Infection occurs on beaches when the skin comes in contact with sand that has been contaminated by egg-infested canine fecal material. Most of the cases have been caused by *Ancylostoma braziliense,* but *A. caninum* and others have also been reported. See Fig. 511.

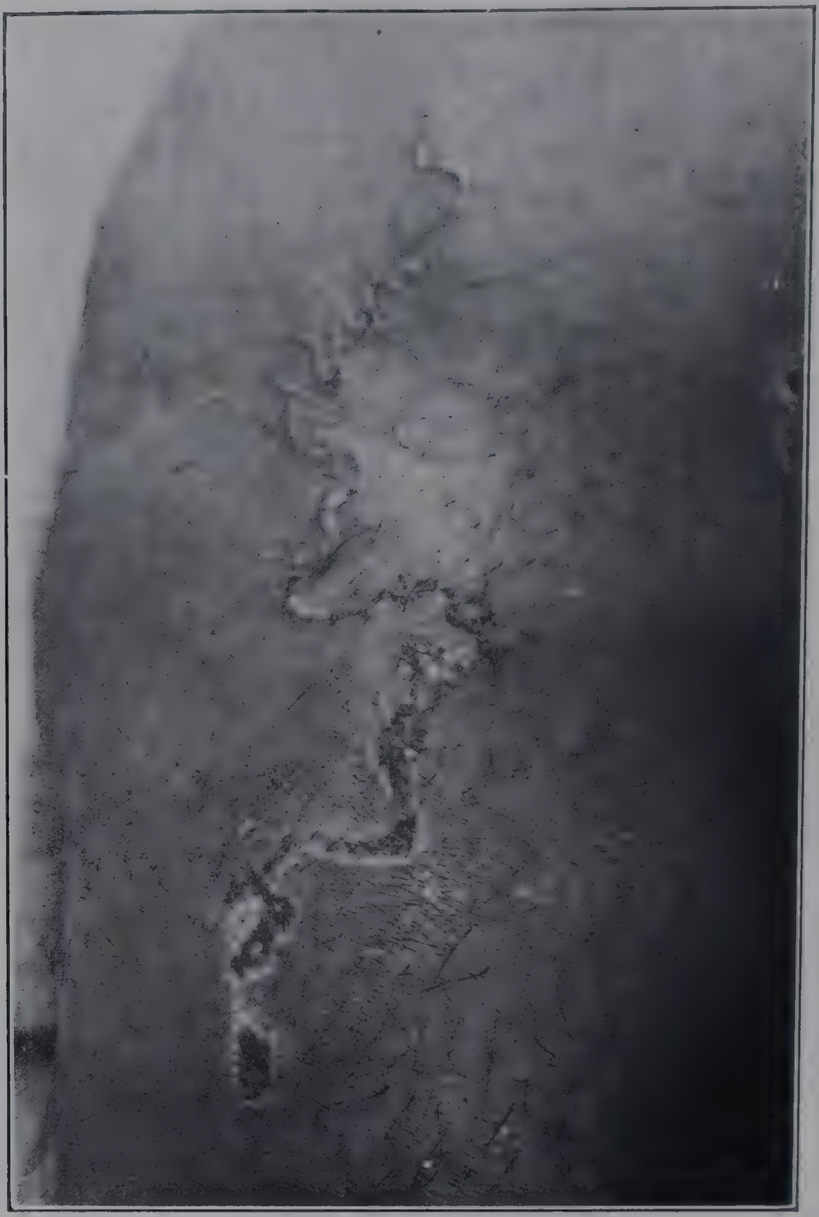

Fig. 511.—Clinical case of *larva migrans* studied by Dr. Kourí. Lesions on the internal surface of the right leg and knee.

Order **FILARIATA** Skrjabin 1915

The most important parasites in the order Filariata in human helminthology are the genera Wuchereria, Loa, Dirofilaria, Onchocerca, Dipetalonema or Ancanthoceilonema, and Mansonella filaria and microfilaria.

Family **FILARIIDAE** Clauss 1885

FILARIASIS BANCROFTI

Wuchereria Bancrofti (Cobbold 1877) da Silva Araujo 1877

Species in the genus Wuchereria are very delicate, with pointed anterior ends, and a broad head which is rounded and followed by a neck.

Filariasis bancrofti is caused by *Wuchereria bancrofti*. See Fig. 512. The adult worms are characterized by their extreme length and thinness, blunt extremities, and transparent opalescent white color. The male is 40 mm. long and 0.1 mm. wide; the female 80 to 100 mm. long and 0.3 mm. wide. The male parasite has a tendency to coil. The parasite is ovoviviparous.

The **eggs** are 40 microns long and 25 microns wide.

The females lay the embryos in the lymphatics. These embryos migrate to the blood stream and then invade the peripheral blood vessels while the host sleeps.

The embryo or **microfilaria** is approximately 300 microns long and 8 microns wide, and is enclosed in a sheath which is longer than itself. The caudal end is sharply pointed. In stained preparations, great numbers of embryonal nuclei or somatic cells can be seen. Where these somatic cells are absent, there are clear zones. In dried blood, the curvatures are regular, not sinuous.

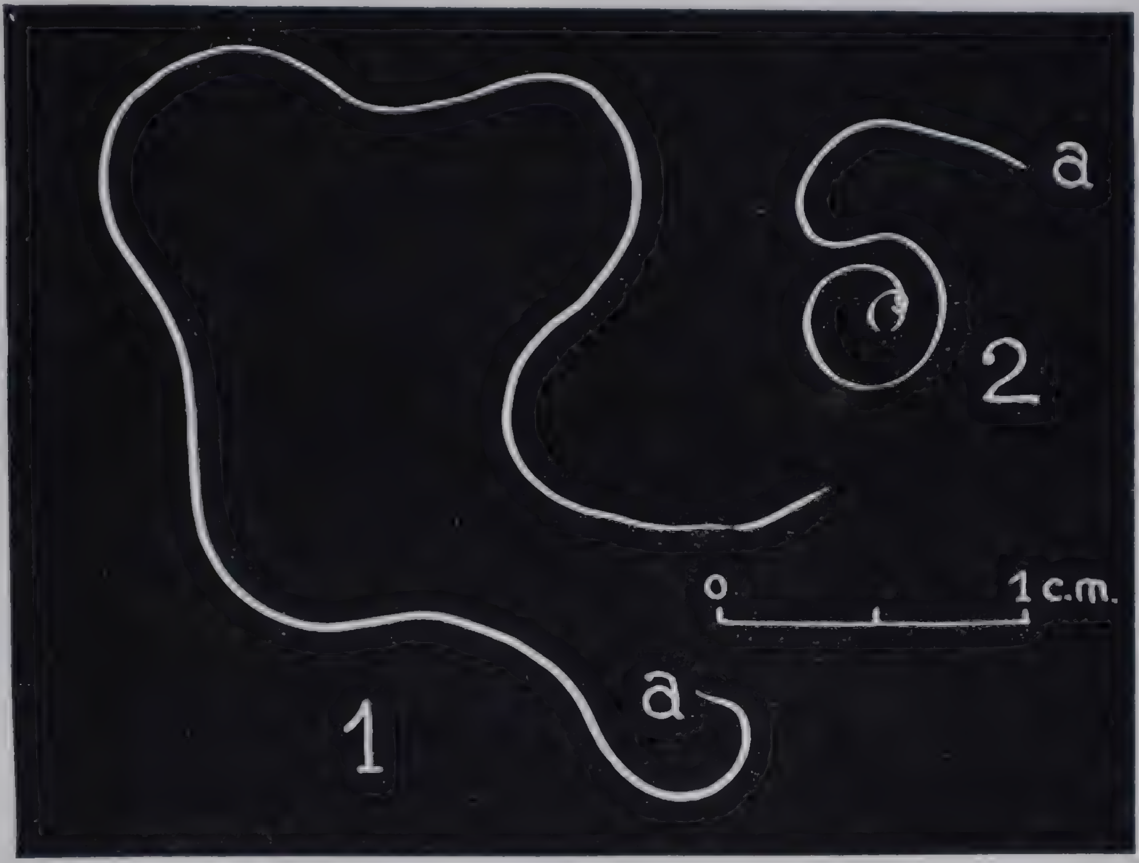

Fig. 512.—*Wuchereria bancrofti.* Two adults: female (*1*), 8.2 cm. long; and male (*2*), 3.7 cm. long. *a,* Anterior extremity. (Finlay Museum, specimen No. 1041.) The parasites, while alive, were tightly coiled; after several days in the refrigerator, where they died, they became uncoiled and took the form seen here after they were fixed in 10 per cent Formalin.

Life Cycle.—The life cycle is seen in Fig. 513.

The intermediate host is the *Culex fatigans.*

In Fig. 514 will be seen various types of lymphangitis, or elephantiasis, produced by this worm.

Diagnosis.—Parasites may be found in the blood often without any disturbances attributable to the parasite. Microfilariae are found in a drop of hemolyzed blood stained with Giemsa stain. Diagnosis is made by microscopic examination of a drop of blood obtained during the patient's sleep and examination of chylous fluid obtained any time during the day. The microfilariae appear in the peripheral blood at night and disappear almost completely during the day.

A good, rapid diagnostic method is to put defibrinated blood on a slide, allow it to dry, hemolyze it, and stain with Giemsa stain.

When this direct examination gives negative results, concentration methods are used. These methods consist in centrifuging a rather large volume of citrated blood, hemolyzing with distilled water slightly acidified by acetic acid, washing by centrifuging several times until the supernatant fluid is colorless, and then removing some of the sediment and examining it microscopically.

The **serologic test** recommended by Pandit and Iyer consists in mixing equal volumes of the serum of the patient and a suspension of microfilariae in citrated blood, and examining microscopically after 14 hours. In negative cases, agglutination of the microfilariae is observed; in positive cases, the leukocytes become fixed to the microfilariae, thus affecting their vitality. A large percentage of patients with elephantiasis give positive results with this test.

Biological Characteristics of Microfilariae.—

Microfilariae are from 100 to 400 times more numerous in the peripheral blood at night than during the day. During the day they accumulate in viscera, such as the capillaries of the lungs, left ventricle of the heart, cardiac muscle, aorta, and carotid arteries. They are never found in the liver, spleen, or bone marrow (Manson).

Rao has determined that the life span of microfilariae in the body of the host may be as long as 70 days. If inoculated into different unusual hosts, the microfilariae may live for variable periods.

TABLE 185.—KEY FOR IDENTIFYING THE MOST COMMON MICROFILARIAE IN HUMAN PARASITISM

MALAYAN FILARIASIS

Wuchereria Malayi (Brug 1927) Rao and Maplestone 1940

The adult worm is similar to *W. bancrofti.* The female is smaller, being 55 mm. long and 0.16 mm. wide; the male is 23 mm. long and 0.09 mm. wide. It differs from *W. bancrofti* in minor details. The posterior extremity is twisted like a spiral.

The sheathed microfilaria is 177 to 260 microns long by 5 to 6 microns wide. It has a smooth cuticle, a double stylet at the anterior end, and two nuclei in the caudal extremity. The tail presents nuclei. Its nocturnal periodicity is less absolute than that of *W. bancrofti.*

Life Cycle.—Man is the only definitive host. The intermediate hosts are mosquitoes belonging to Mansonia, Anopheles, and Armigeres genera. The microfilaria undergoes two moltings in the mosquito and is transformed into the infective larva in 6 to 12 days at 29° to 32° C.

Diagnosis is made by finding the microfilaria in the peripheral blood.

LOAIASIS

Loaiasis is parasitism produced by *Loa loa.* This is a parasite of tropical Africa, particularly throughout a large part of the West African coastal region.

Loa Loa (Guyot 1778) Stiles 1905

The adult parasite is a white, opalescent, transparent organism attenuated at the two extremities, which are obtuse. It is a parasite of man exclusively. The male is 3 cm. long and 350 microns wide. The female is 5.5 cm. by 245 microns. They are ovoviviparous. Uterine eggs are 50 microns by 25 microns.

The larval form develops in various gadflies that act as intermediate vector hosts, especially the Chrysops.

The adult parasites localize in the subcutaneous cellular tissues of man, and the embryo in the blood. The **embryo or microfilaria** is 250 to 300 microns long and 6 to 8 microns wide, and is surrounded by a sheath. The sheath is much shorter than that of the embryo of *W. bancrofti,* and is difficult to stain. In stained preparations, the embryo shows a series of undulations. The somatic nuclei are larger than those seen in microfilariae of *W. bancrofti.*

Individuals after a night's sleep show microfilariae in their peripheral blood from 9 o'clock on in the morning; these increase in number up to 1 to 2 o'clock in the afternoon, and disappear toward 8 or 10 o'clock at night.

Life Cycle.—Mating doubtless takes place in the cellular subcutaneous tissue. The embryo develops in the uterus of the fertilized female, distending the membrane of the egg to form a sheath which protects the embryo, and in this form leaves the female, remaining free in the lymph. It then enters the blood stream, from which it is extracted by the intermediate hosts, which bite during the day when the embryos are abundant in the peripheral blood. After about 10 or 12 days, the infective larvae which have developed in the Chrysops accumulate in the inferior labium and leave at the moment of the bite, bore through the skin of the host in 60 seconds, and enter the subcutaneous cellular tissue, where they grow to adult stage.

Diagnosis.—The clinical diagnosis is confirmed by microscopic examination of blood, although at times the microfilariae cannot be found. There is frequently marked eosinophilia. The microfilariae have been found in the urine and saliva of patients.

ONCHOCERCIASIS

Onchocerca Volvulus (Leuckart 1893) Railliet and Henry 1910

Onchocerciasis is parasitism produced by *Onchocerca volvulus*. This disease is widely dispersed throughout Africa, but is more isolated in America. In America, it is found along the slopes of the cliffs overlooking the Pacific Ocean in Guatemala, and in Mexico in the States of Oaxaca, Chiapas, and Guerrero.

The American species localizes chiefly in the scalp, while the African species is commonly found in the skin of the trunk, especially in the region of the hips.

The male is 3 cm. long by 130 microns wide. The female can attain a length of 50 cm. and a width of 360 microns. The caudal extremity is curved backward and bears three papillae on each side of the anus.

The disease is characterized by the appearance of fibrous subcutaneous nodules located in the aponeurosis, in the muscular tissues, and in the periosteum of the cranium. These vary in size from pinhead to a hen egg. Each nodule harbors 4 to 5 males and 1 to 3 females interlaced with one another. These tumors, in the scalp, vary in number from 1 to 17. Patients show cutaneous, visual, and auditory disturbances.

DRACUNCULIASIS

Dracunculus Medinensis (Linnaeus 1758)

Dracunculiasis is parasitism produced by *Dracunculus medinensis*. It is found in Africa, in the valley of the Nile, in Equatorial Africa, and along the west and northwest coast. In Asia, it is found in Arabia, Persia, Afghanistan, Turkestan, and India. In 10 human cases found in the United States, the patients were foreigners, or the diagnoses were erroneous. It has been introduced into the Antilles, Guianas, and the District of Bahía in Brazil.

The gravid female is 50 to 1,200 mm. long by 0.9 to 1.7 mm. wide. The male, which is rarely found, is 12 to 29 mm. long by 0.4 mm. wide. It shows a cephalic prominence and a small oral aperture surrounded by an internal ring of 4 to 6 well-developed papillae.

Life Cycle.—Fertilization probably occurs in the beginning stages in the deep tissues of the host. The larvae, freed in the water, are ingested by appropriate species of Cyclops, and grow into the infective forms in about 3 weeks. The definitive hosts are infected by drinking water containing infected Cyclops. Other definitive hosts, in addition to man, are dogs, cats, wolves, and foxes. When the definitive hosts drink water infested with Cyclops, the larvae bore through the wall of the digestive tract and migrate toward the loose connective tissues.

Diagnosis.—Diagnosis is made by examining the local lesion for worms or larvae. Dead or calcified parasites may be located by x-ray.

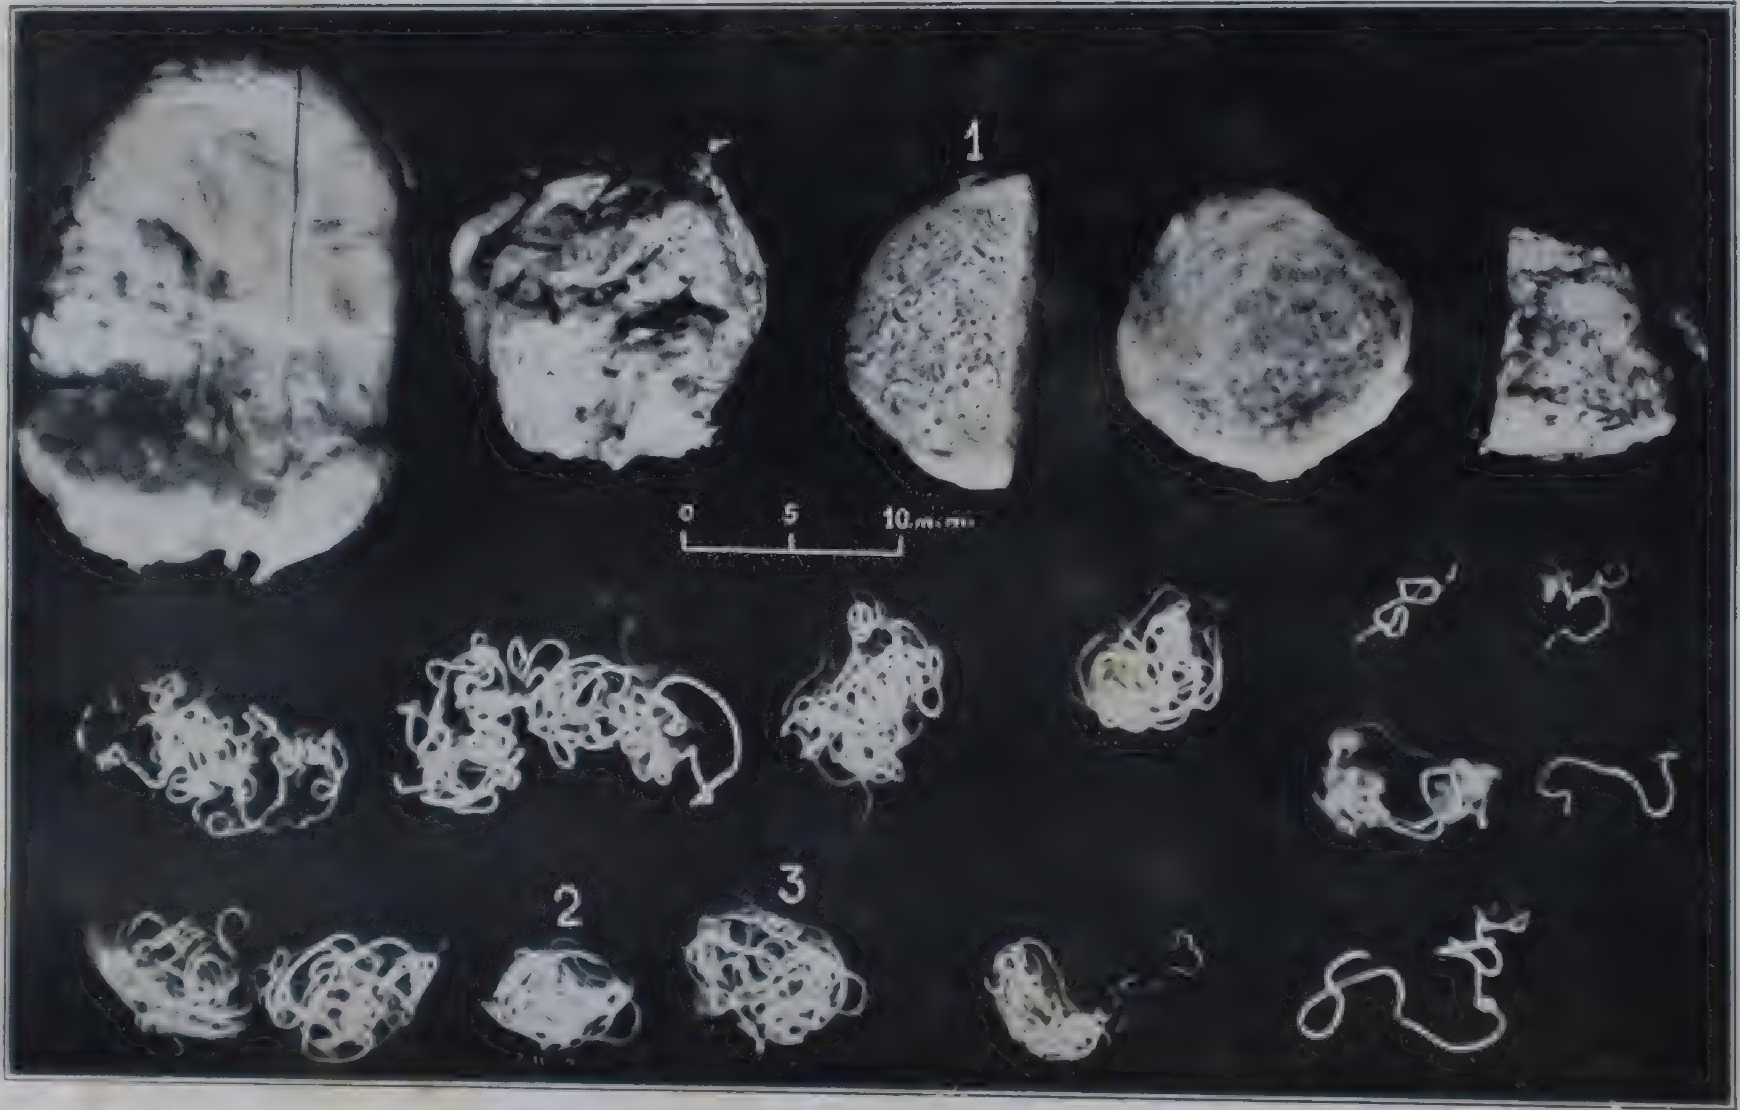

Fig. 516.—*Onchocerca caecutiens.* *Upper row*: several tumors produced by the parasite. *1*, represents a cross section of a fragment of tumor produced by *Onchocerca caecutiens.* It is enlarged in Fig. 518. *Lower rows*: bundles of parasites, obtained by artificial digestion of the tumors. *2* and *3* are enlarged in Fig. 517. (Original photograph of Kourí of material from Mexico sent by Dr. Eduardo Caballero.)

MICROSCOPIC PSEUDOPARASITES IN NEMATODOLOGY

Under this heading are included all those microscopic elements which are found in secretions or excretions of man and which, through lack of knowledge or by erroneous interpretation on the part of technical workers, are confused with parasitic elements. Two large groups of microscopic pseudoparasites will be considered: (1) elements in transit; and (2) elements derived from outside contamination.

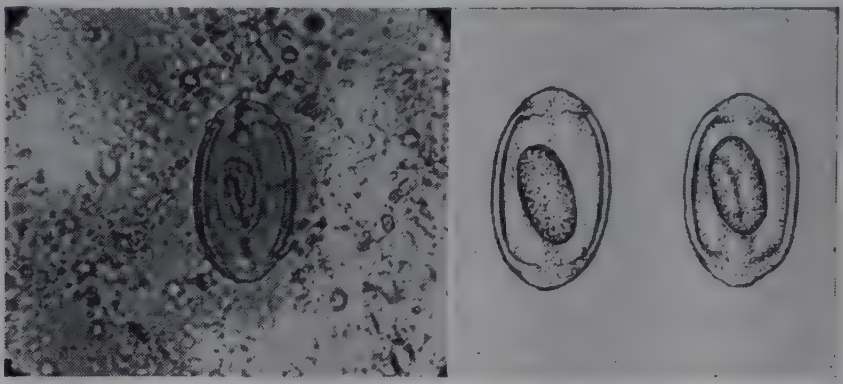

Fig. 520.—Microscopic pseudoparasites, original figure. Eggs in transit, found in human feces concentrated by Telemann method.

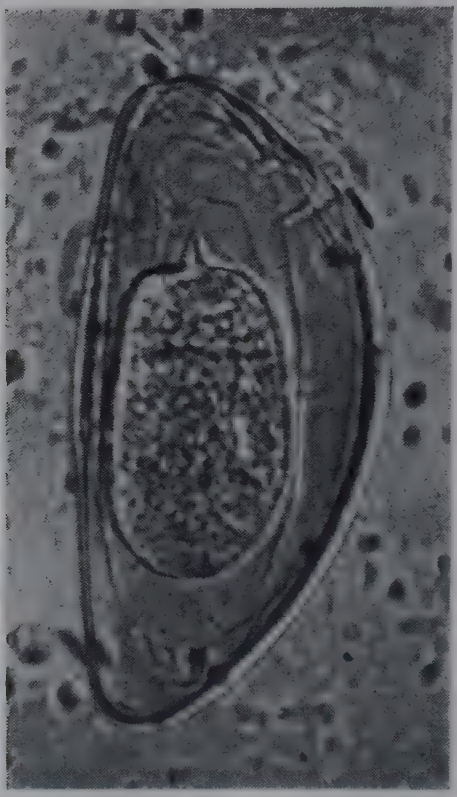

Fig. 521.—Microscopic pseudoparasites, original figure. Eggs found in the human feces concentrated by the flotation method using sugar cane and glycerine.

(1) **Elements in Transit.**—Included in this group are all those microscopic pseudoparasites found in the feces, which are simply elements in transit through the alimentary tract. These elements have been ingested in food and either undergo mild modifications or no modifications at all, and are eliminated in the excreta. In this group there are two categories: (a) eggs, larvae, etc., of Nemathelminthes of animals or vegetables which have been swallowed by man in animal or vegetable food and which are merely passing through the alimentary

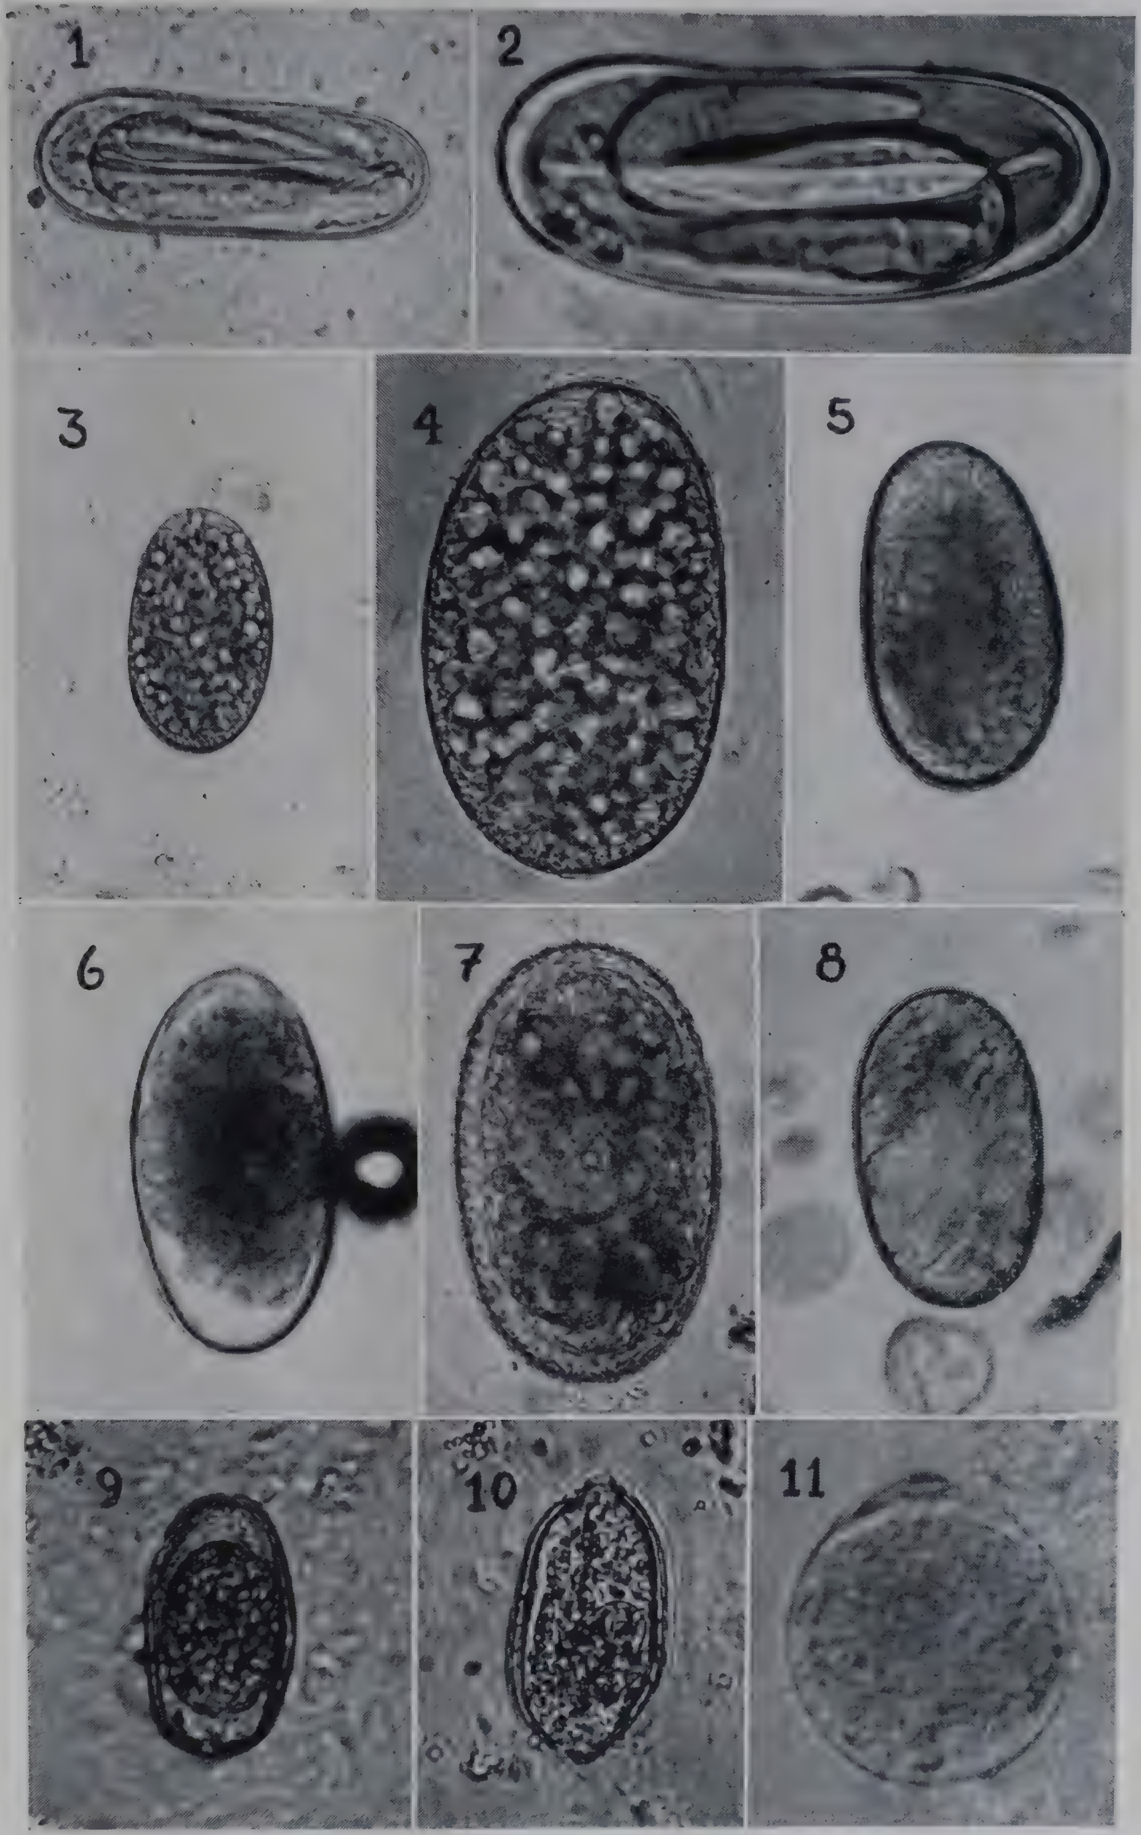

Fig. 522.—Microscopic pseudoparasites. Eggs in transit and nonparasitic elements, found frequently upon microscopic examination of human feces—microscopic pseudoparasites. Original figure. *1* and *2*, Egg of *Heterodera radicicola;* *3* to *8*, eggs of *Tyroglyphus* sp. in different stages of development; *9* and *10*, vegetable elements sometimes confused with eggs of helminths or with Coccidia; *11*, pine pollen grains, which frequently contaminate the stools.

tract without causing parasitism; and (b) elements not of parasitic nature, such as vegetable cells, pollen grains, etc., which are swallowed with food and may be mistaken for the eggs.

(2) **Elements Derived From Outside Contamination.**—This group also contains the two classes (a) and (b) described under (1) above. However, these are microscopic elements which have contaminated the stools after they were passed, either because the stools were collected in dirty containers or because the elements dropped into the specimen in the container.

PHYLUM PLATYHELMINTHES

(Flatworms)

Platyhelminthes, or flatworms, are metazoa with soft integument; parasitic adult forms without body covering; bilaterally symmetrical; lacking coelomic cavity; usually flat, more rarely cylindrical (Schistosoma). The majority are hermaphroditic, although some have separate sexes (Schistosoma). They are almost always tape-like and segmented (Cestoda), or leaf-shaped and not segmented (Trematoda); without digestive tract (Cestoda) or provided with an incomplete digestive tract, without anus (Trematoda); excretory system bilaterally symmetrical, ending in flame cells or "solenocytes." The Platyhelminthes generally have organs of attachment, such as suckers and hooklets. The majority are endoparasites.

The Cestoidea are exclusively parasitic; adults are hermaphroditic, covered with a nonciliated integument. When present, the ciliated epithelia are confined to the embryo which emerges from the egg (coracidium). Scolex is provided with suckers and frequently with hooklets which enable the worms to attach themselves to the tissues of the host. No digestive tract. In most of the species, the bodies are divided, transversely, into sexually complete, separable entities, called proglottids.

Order **CYCLOPHYLLIDEA** Braun 1900

Family **TENIIDAE** Ludwig 1886

TAENIASIS

Taenia Saginata Goeze (1782)

Taeniasis saginata is parasitism produced by *Taenia saginata,* the beef tapeworm. It is found in almost all of the countries of the world except the Slavic countries Czechoslovakia and Yugoslavia. It is acquired by eating inadequately cooked infected beef. It is found more frequently than the pork tapeworm, *T. solium,* which is common wherever raw or inadequately cooked or processed pork is consumed by man.

T. saginata is 4 to 10 meters long. Three portions are important: the head or **scolex,** the **neck,** and the body trunk or **strobila,** which is composed of segments or **proglottids.** The shape of the scolex, when viewed with a hand lens or under the low power of a microscope, is fusiform, with a terminal quadrangular base. It has two pairs of elliptical suckers, 0.7 to 0.8 mm. in diameter, which usually contain a black pigment. It lacks a rostellum and has no hooklets. A neck, which is smooth, connects the scolex with the strobila.

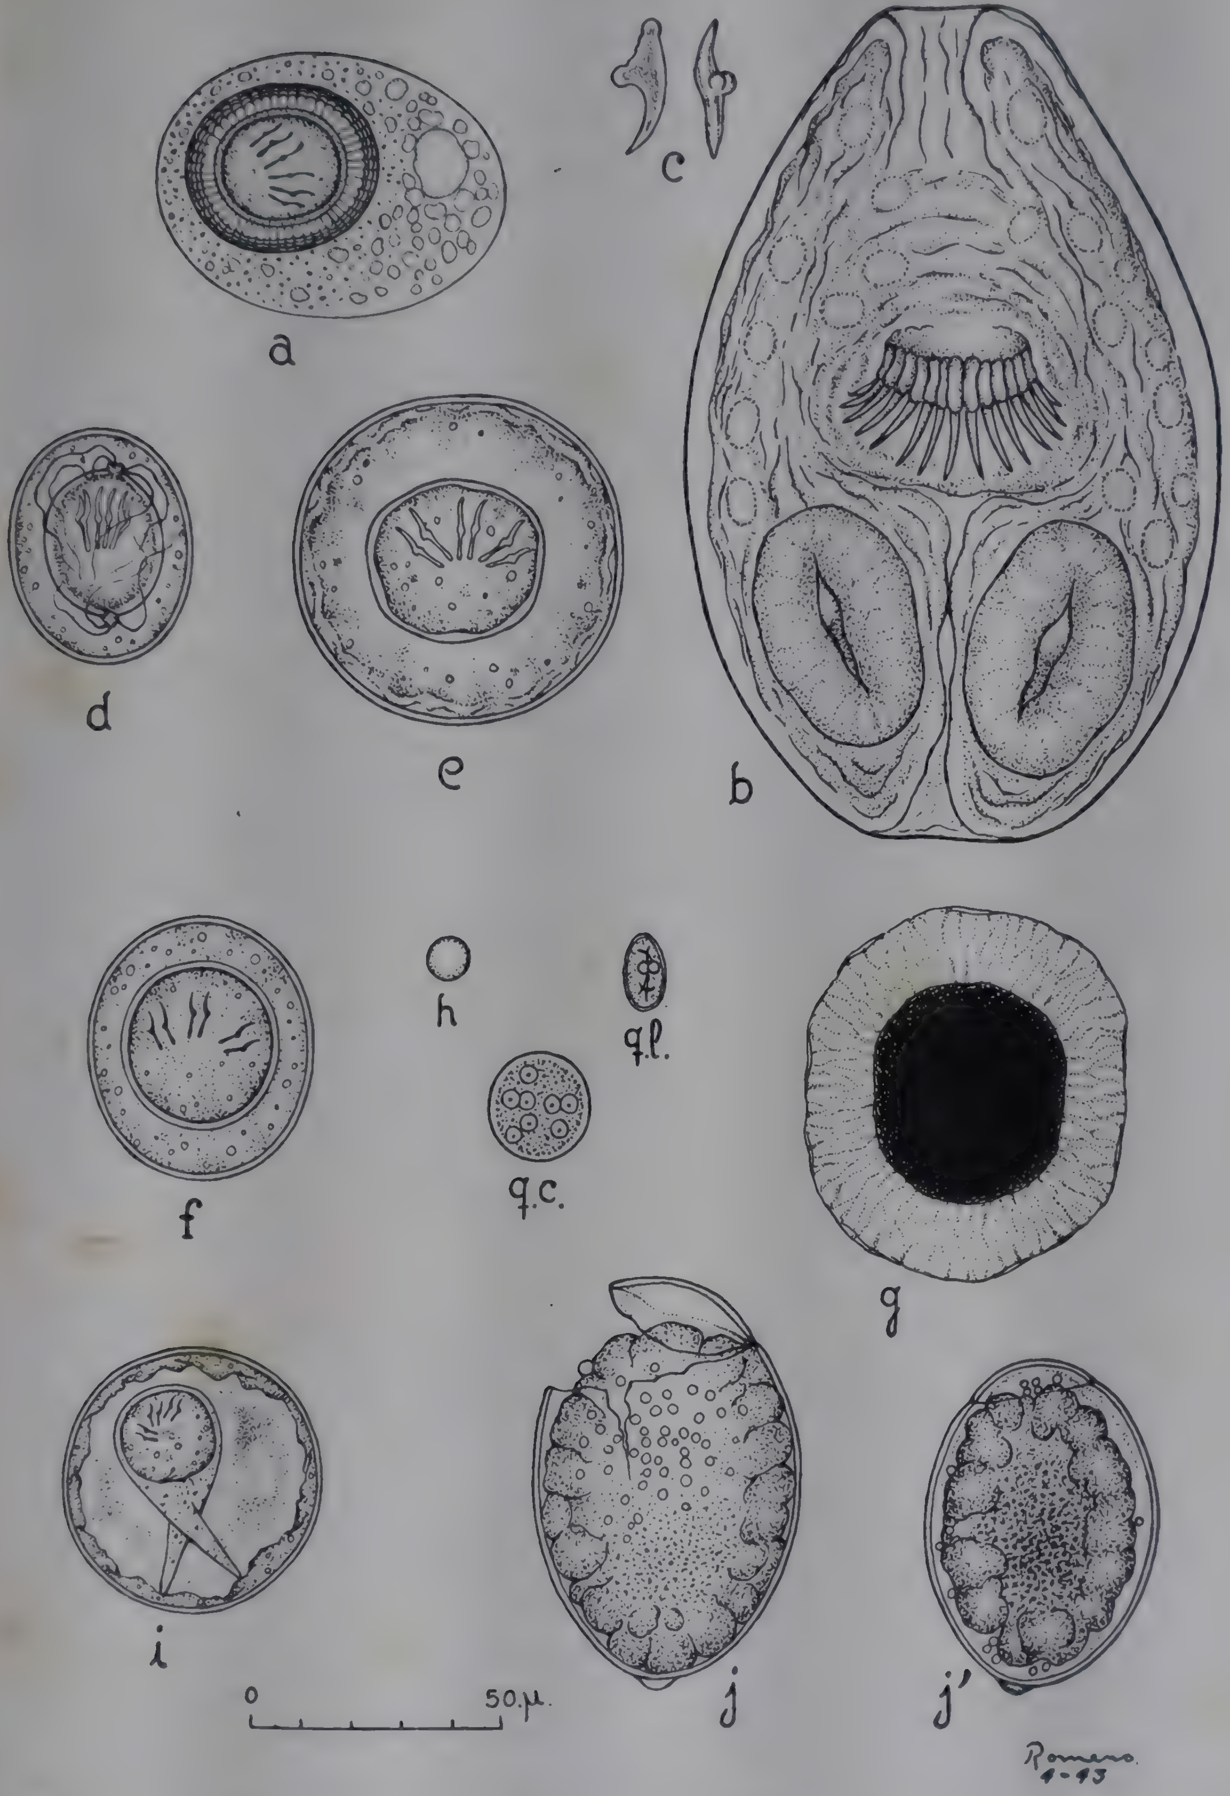

Fig. 523.—Cestodes. Eggs, oviferous capsules, scolex, and hooklets. Original drawing, at the same scale, with camera lucida. *a*, Eggs of *Taenia saginata;* *b*, scolex of the larva of *Echinococcus granulosus* (hydatid sand) fixed in 10 per cent Formalin; *c*, hooklets; *d*, eggs of *Hymenolepis nana;* *e*, eggs of *Hymenolepis diminuta.* *f*, Egg of *Dipylidium caninum.* *g*, Oviferous capsule of *Inermicapsifer cubensis.* *i*, Egg of Anoplocephalinae of the hutia conga. *j,j'*, Eggs of *Diphyllobothrium latum.* (*j*) crushed to show the opened operculum. Human erythrocyte (*h*), cyst of *Giardia lamblia* (*q.l.*), and cyst of *Endamoeba coli* (*q.c.*) for comparative purposes. (After Kourí in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

The gravid proglottid, outside the body of the host, contracts and expels a white powdery-appearing substance, which is composed of thousands of eggs (Bacigalupo phenomenon).

Eggs.—The eggs consist of an ovoid embryophore 20 to 30 microns wide and 30 to 40 microns long, with a thick, dark brown, radially striated wall. Within this embryophore is a hexacanth or 6-hooked embryo or onchosphere, 20 microns in diameter. The gravid proglottid tears open its terminal uterine branches when it separates from the strobila, permitting the eggs to escape.

Life Cycle.—The life cycle is given in Fig. 526.

When the patient eats raw or slightly cooked beef containing the larvae, these larvae, *Cysticercus bovis,* reach the intestine. Intestinal secretions digest the wall of the cyst, liberating the scolex. The scolex anchors itself to the mucosa, the neck proliferates to form the proglottids, and the adult worm develops. It takes two to three months to form the adult taenia. At the end of this period, the expulsion of gravid segments begins, and thus dissemination of the eggs onto the soil. If these eggs are then ingested by cattle, a new cycle begins.

Cysticercus Bovis.—*Cysticercus bovis,* the larval form of *T. saginata,* is an ovoid vesicle 5 to 10 mm. long and 3 to 4 mm. wide. In muscle tissue, it is surrounded by a fibrous capsule. It offers an elastic resistance when pressed between the fingers. The larva has two pairs of suckers and is unarmed as is the adult taenia. The larva dies at a temperature of 46° C., but remains alive for about 40 days in meat kept at 1° to 4° C. It is destroyed at −8° to −10° C. in 3 hours. Parasitism by the larval form is known as bovine cysticercus.

Taenia Solium Linnaeus 1758

Infestation by *T. solium* is known as taeniasis solium, the pork tapeworm disease. The adult tapeworm is 2 to 3 meters long, but may be as long as 8 meters or more. The globular scolex has a diameter of 600 microns to 1 mm. and is pigmented. The rostellum is apical, is capable of invaginating, and bears 2 crowns of hooklets arranged in alternate rows, numbering 22 to 32. They vary in size from 160 to 180 microns; some are smaller. The neck is short. Behind this structure are the immature, mature, and gravid proglottids. The fully developed proglottid is almost square. Gravid proglottids are not as long as those of *T. saginata.*

Eggs.—The eggs are expelled with fragments of the strobila after expulsion from the patient. They contain a hexacanth embryo or onchosphere about 20 microns in diameter and armed with 6 stylets. Eggs are indistinguishable from those of *T. saginata.*

Life Cycle.—Outside the human body the eggs are viable for weeks in soil. When ingested by hogs (or man), they hatch immediately. The liberated onchosphere penetrates the intestinal wall, reaches the lymphatic or circulatory system, and the embryos are distributed throughout the body. They usually localize in the musculature or subcutaneous tissue. Within 60 to 70 days they metamorphose into infective bladder worms or *Cysticercus cellulosae,* measuring 5 by 8 to 10 mm. Cysticerci reach man when he eats raw or inadequately prepared pork. The larvae are digested out of the cysts, become attached to the intestinal wall, and grow to maturity in 4 to 12 weeks.

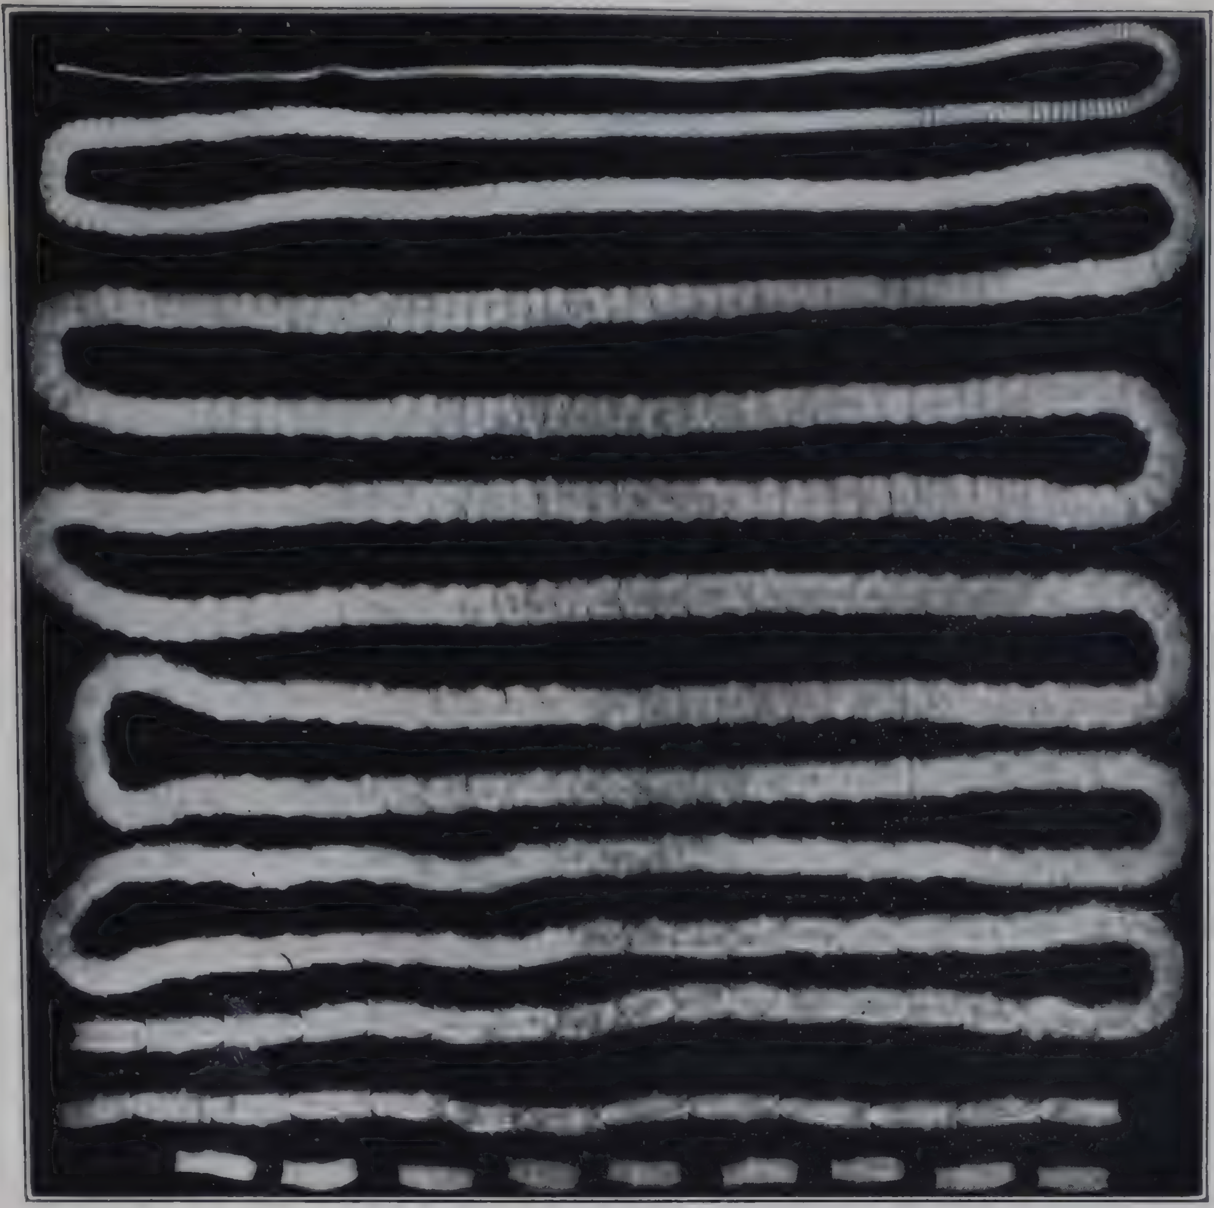

Fig. 524.—*Taenia saginata.* Complete specimen expelled after treatment with ether extract of male fern and carbon tetrachloride in oily solution. Note the scolex and fine portions of the strobila, above; and the gravid proglottids, separated from the strobila, below. (Original photograph of Kourí.)

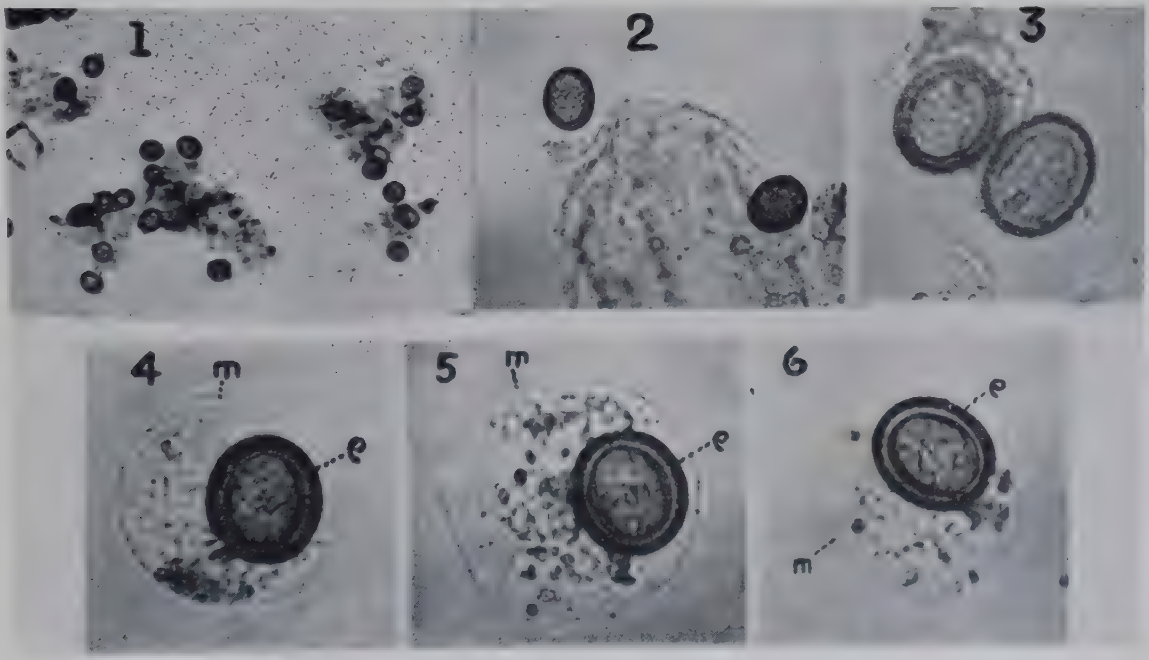

Fig. 525.—*Taenia saginata.* *1* to *6*, Photomicrographs of eggs, with progressively increasing magnification; *4*, *5*, and *6*: *m*, external membrane of the egg; *e*, embryophore containing onchosphere or six-hooked embryo. (Originals of Kourí.)

Man is the definitive host, the hog the intermediate host. Human infection results from ingestion of viable eggs.

Differential Characteristics of Taenia Saginata and Taenia Solium

The scolex of *T. saginata* is quadrangular and unarmed, that is, it bears no rostellum or hooklets, while the scolex of *T. solium* is spherical and smaller, and bears a rostellum with two crowns of hooklets. *T. saginata* is usually longer and contains a greater number of segments. *T. solium* is shorter, has a smaller number of segments, its genital pores are less regularly staggered, and the vagina is not provided with a sphincter. The larvae of *T. saginata (Cysticercus bovis)* localize in adipose tissue and striated muscles. The larvae of *T. solium (Cysticercus cellulosae)* localize in the muscle tissue of the pig, and accidentally in that of man.

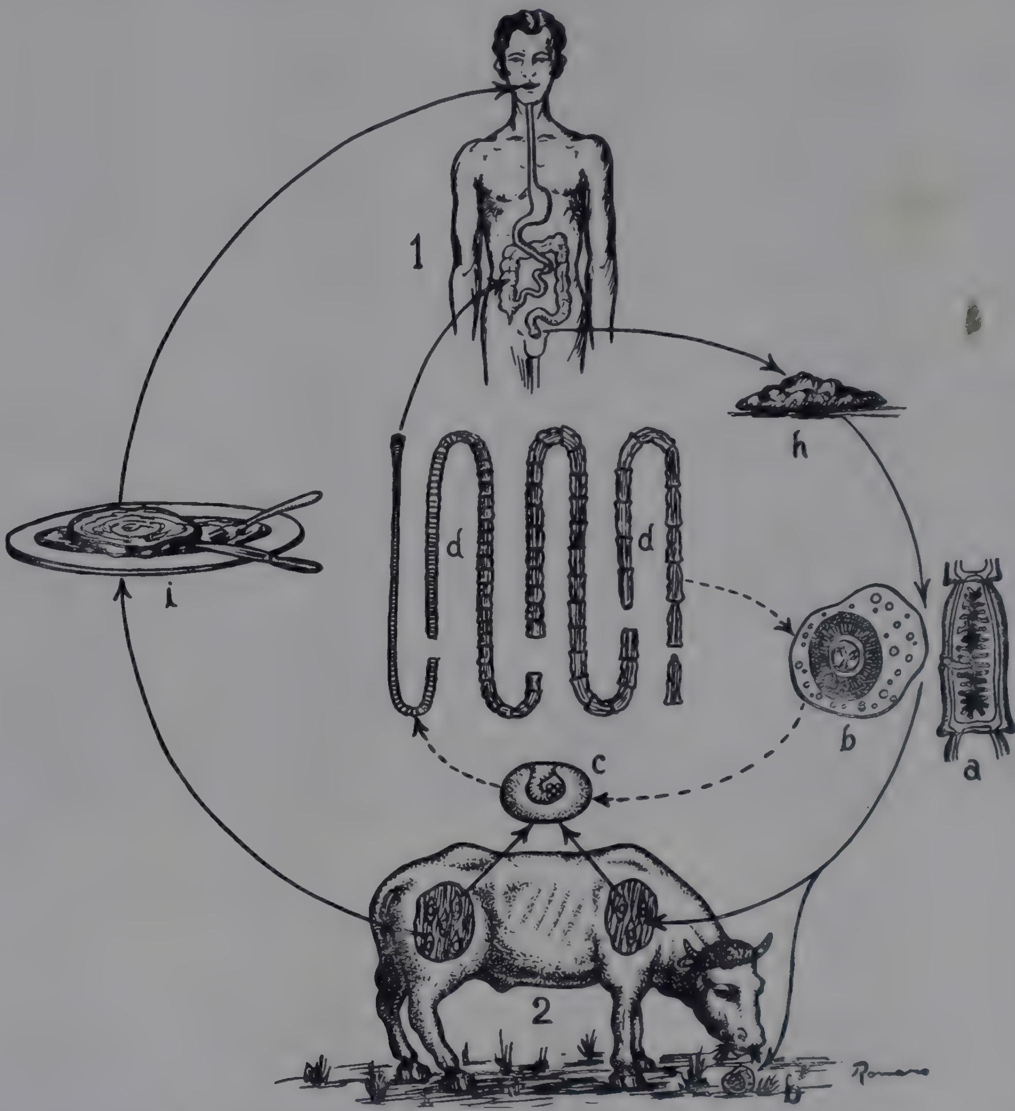

Fig. 526.—*Taenia saginata.* Life cycle. Man is the definitive host (*1*), harboring the adult parasite (*d, d*) in the small intestine. In the feces (*h*), gravid proglottids (*a*) and eggs (*b*) are passed and (*b'*) are ingested by cattle (*2*), the intermediate host. *Cysticercus bovis* (*c*), which is the larval stage, develops in the muscular system of cattle. This Cysticercus develops into the adult Taenia (*d, d*) in the small intestine of man (*1*) when ingested with raw or poorly cooked beef (*i*), beginning a new cycle. (Original drawing of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

Laboratory Diagnosis

The laboratory worker may have to deal with one of three contingencies: (1) The patient may bring him the segments of the parasite. (2) The patient may bring him a sample of the feces. (3) The patient may merely consult him without these objective findings.

(1) The segments are usually discovered by the patient himself in the feces, on his own body, or on his clothes. Segments are occasionally found in surgically removed appendices. Quite rarely they are vomited or found in abscesses or fistulae, umbilical or perineal. If the segments are brought into the laboratory wrapped in paper without water, or in gauze, they dry out, but when placed in water they resume their former typical appearance of gravid segments. By rubbing the dried proglottid lightly with a wet platinum loop, and placing the material thus obtained in a drop of water on a clean slide, a preparation is obtained which, when observed microscopically, will most likely show numerous eggs of the parasite. There is no difficulty when the fresh proglottids are brought for examination, dead or alive, in a small flask or test tube, in water, alcohol, or 10 per cent Formalin. In 10 per cent Formalin, they retain their original size and white color.

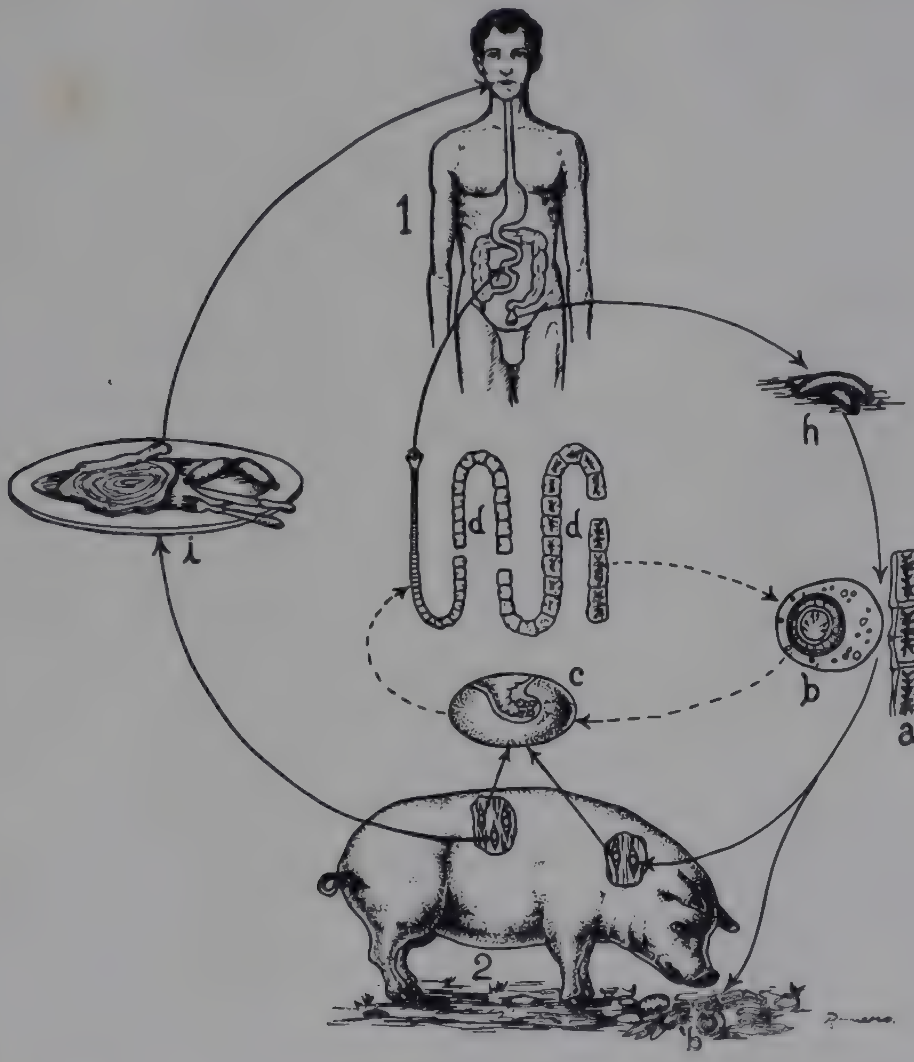

Fig. 527.—*Taenia solium.* Life cycle. This parasite follows the same cycle as *Taenia saginata* except that the intermediate hosts for *T. solium* are swine, which harbar the larval form, *Cysticercus cellulosae.* (Original drawing of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

(2) If the patient brings a sample of feces to the laboratory, the procedure is (a) immediate macroscopic examination; (b) microscopic examination; and (c) macroscopic examination by screening the feces.

Step (a) is very important, for, in the majority of cases, enough proof is obtained by macroscopic examination to establish an accurate diagnosis. The segments can be seen in the feces specimen in a wide-mouthed bottle.

Step (b), a complete microscopic examination of the stool, includes (1) a direct thick preparation; (2) a direct thin preparation; (3) a thin preparation stained with Lugol solution; (4) a preparation of feces concentrated by one of the low density solutions, such as Telemann's or others; (5) a preparation of feces concentrated by one of the high density solutions; (6) a preparation of a dilution of the stained and centrifuged feces.

All these slide preparations should be covered by cover glasses 22 mm. by 22 mm., and the entire specimen should be examined carefully.

Indirect Methods.—Eosinophilia is frequent though not constant or specific in parasitism by *T. saginata.* Complement fixation and intradermal reactions, applicable in cases of echinococcosis and other parasitoses, have not given satisfactory results in cases of parasitism by *T. saginata* and *T. solium.*

HYDATID DISEASE

Hydatid disease is produced by the larval form of *Echinococcus granulosus.*

Echinococcus Granulosus (Batsch 1786) Rudolphi 1805

E. granulosus, and its larval form, the hydatid cyst, are found on all the continents. The parasites live in any climate. Factors favoring infestation are occupation, personal habits, and food habits. In those countries where cattle raising is one of the principal industries, where meat and milk and all their derivatives, sausage, cheese, and butter, are important products, or wherever man and dog inhabit the same territory, conditions are ideal for the spread of this disease.

E. granulosus, in its adult form, is a habitual parasite of the intestines of dogs, jackals, and wolves. In its larval form, it parasitizes the tissues of man, pigs, sheep, cattle, etc., and forms what is known as ''hydatid cyst.''

This tape worm is the smallest of the important cestodes of man. It is 3 to 6 mm. long, 300 microns in diameter. It is provided with four ovoid suckers, has a projecting rostellum with a double crown of 30 to 36 hooklets. The neck is short, becoming narrow toward the back. The strobila is composed of 3 to 4 proglottids.

Eggs.—There are from 500 to 800 eggs in the gravid proglottid. They resemble those of *T. saginata* and *T. solium,* and are from 32 to 36 microns long and 21 to 30 microns wide. They contain a hexacanth embryo 25 microns long.

Larva or Hydatid Cyst.—The hydatid cyst is a tumor of variable size, which may reach the size of the head of an adult human being. It is frequently localized in the liver, lung, abdominal cavity, pelvis, or any other part of the host. It has an elastic consistency and is composed of two parts, a fibrous capsule, and the larva, which is found inside this fibrous capsule.

Brood Capsules and Scolex.—Brood capsules are formed by proliferation of the internal germinal layer. They are spherical; their walls have the same structure as that of the mother layer. This wall is very thin; it gives rise,

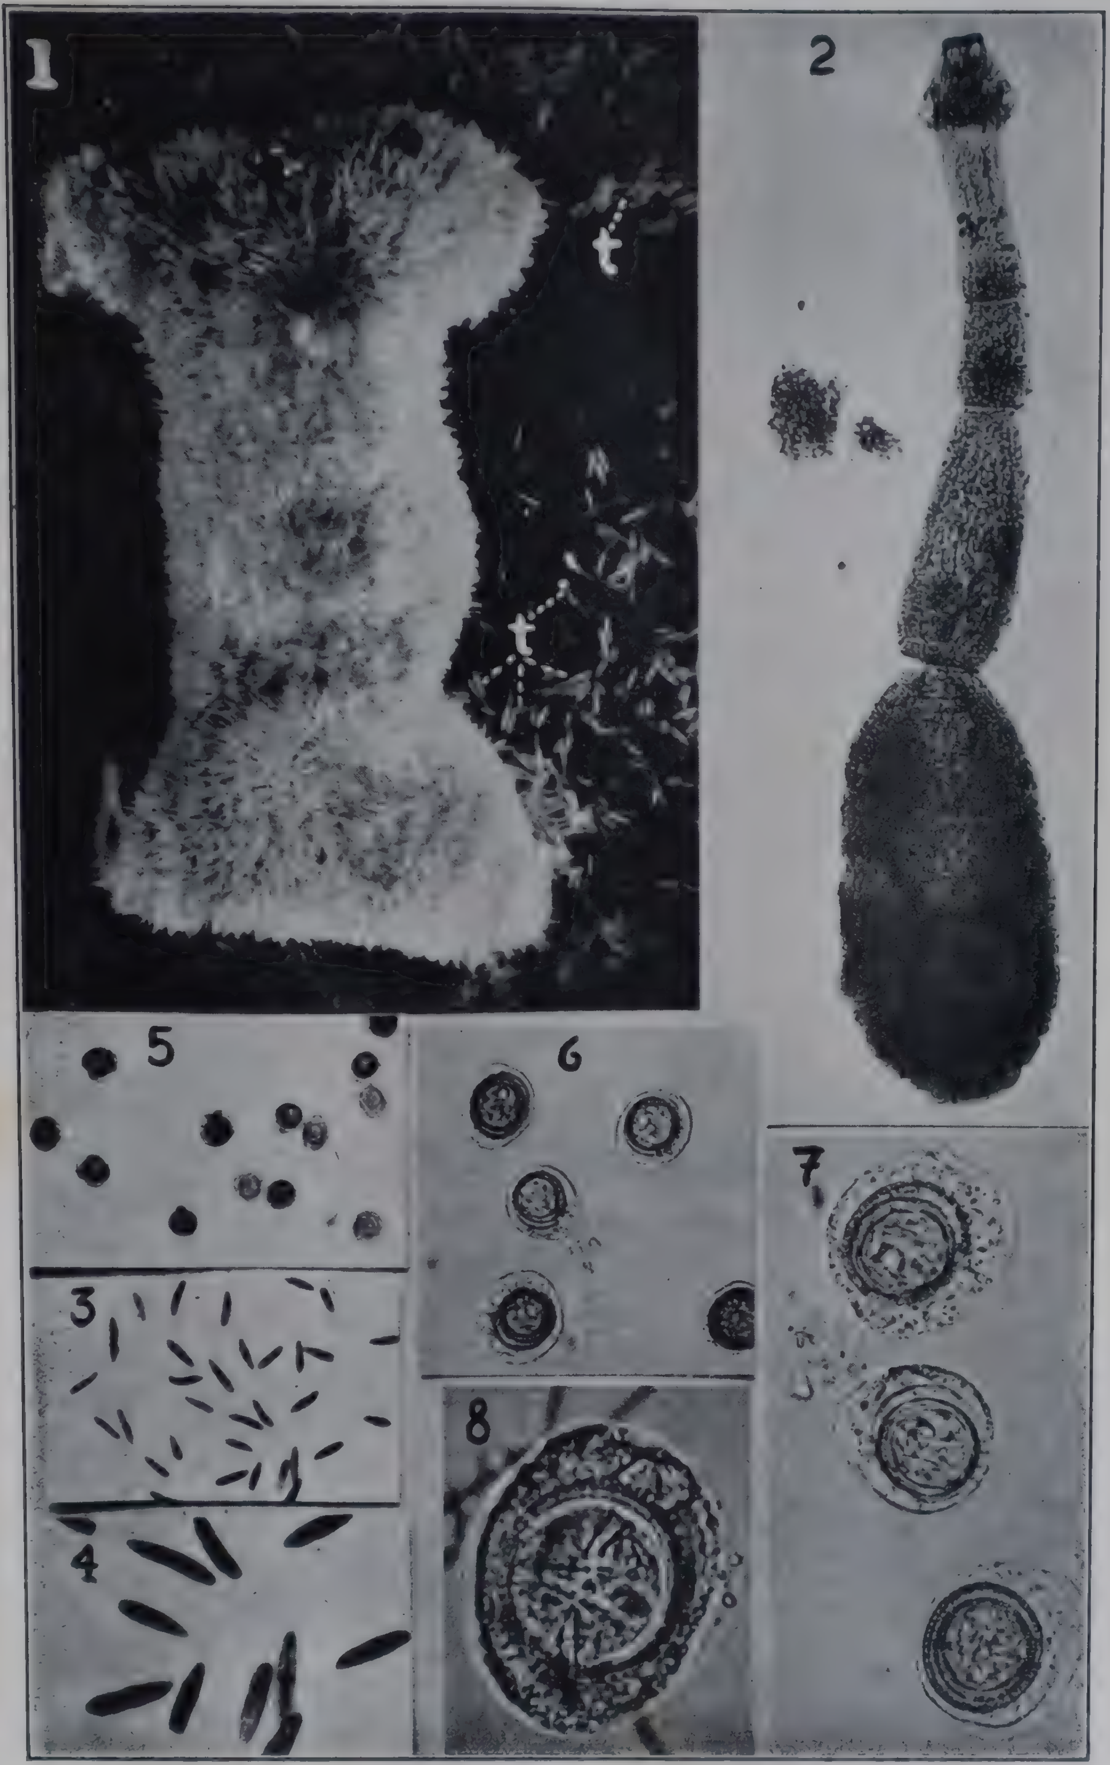

Fig. 528.—*Echinococcus granulosus*. *1*, Intestine of a dog experimentally infested with *E. granulosus* through ingestion of a hydatid cyst (Aguirre Pequeño). The intestine is filled with taenias, many unattached. *2*, Photomicrograph of adult taenia. *3*, Gravid segments, natural size. *4*, Same segments magnified. *5* to *8*, Eggs obtained from gravid segments, photomicrographs of different magnifications. (*3* to *8*, Original photographs by Kourí of material sent by Dr. Aguirre Pequeño from Mexico.)

through internal proliferation, to a variable number of scolices. These brood capsules, at first attached by a broad base, develop a pedicle, and finally are set free in the fluid of the cystic cavity. The scolices remain attached by a thin pedicle. When the brood capsule bursts open, the scolices become arranged in radial formation around the membrane which is now in the center.

Daughter Cysts or Vesicles.—The daughter cysts may be endogenous or exogenous, depending on whether they are found inside or outside the true wall of the mother cyst. The wall is the same as that of the mother cyst. There is a fluid in the cavity of these daughter cysts, with the same characteristics as the fluid in the mother cyst.

Hydatid Cyst of the Liver and Other Organs.—A cyst in the liver may never be noticed. When symptoms do appear, it is usually several years after the beginning of the disease. At first hepatic and epigastric pains are present. Lack of appetite, most frequently for fats, usually accompanies these symptoms. There is often a history of urticarial crisis, and a high percentage of eosinophiles in the blood. The tumor attains a voluminous size and pushes out the abdominal wall, causing a noticeable distention of the abdomen.

Diagram of Hydatid Cyst

Fig. 529.—Schematic drawing of *E. granulosus.* Adult parasite, left, and larva in a hydatid cyst, right. (According to Leuckart in Blanchard and Kourí.)

There may be hydatid cyst of the lung, of the peritoneum or the pelvis, of the kidneys, the brain, bones, or circulatory system.

Cysts may become calcified and degenerated, and retract. Bacterial infection between the cuticular and adventitious membranes kills the larva. Bacteria enter the hydatid fluid, which, being a good culture medium, aids their growth; abscess formation follows.

Life Cycle.—The life cycle of this parasite is found in Fig. 531.

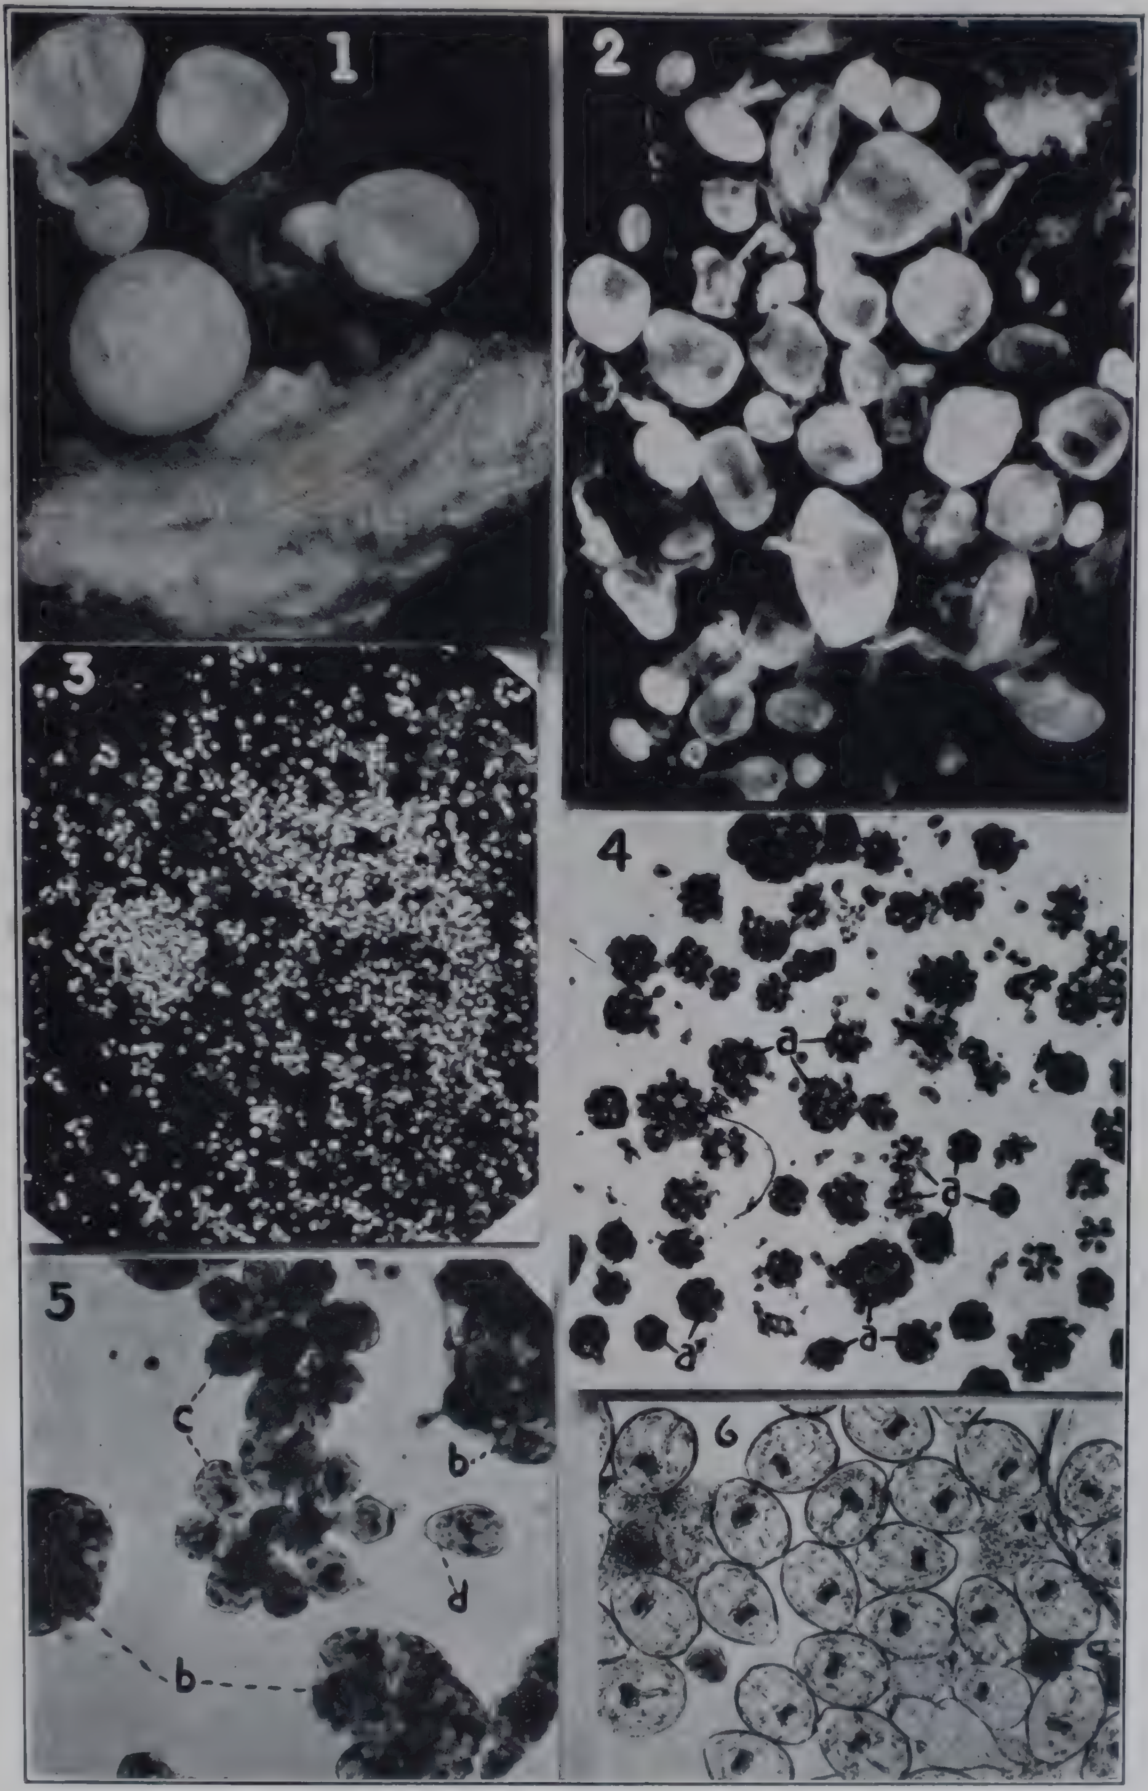

Fig. 530.—*Echinococcus granulosus.* (Original of Kourí.)

1 and *2*, Endogenous daughter cysts, natural size. Hydatid cyst of the liver opening into bile ducts. Cysts expelled in the feces. *2*, Case of Kourí.

3, Photograph, slightly enlarged: "hydatid sand." Material sent by Prof. Bacigalupo from Buenos Aires. Each grain of sand is a brood capsule enclosing a varying number of scolices. Dark background, illuminated from above.

4, Photomicrograph of "hydatid sand," low power. Each brood capsule *a* encloses a variable number of scolices and represents a grain of sand.

5, Brood capsules *b*, slightly magnified. Each consists of a group of scolices enveloped by a germinal membrane. This membrane, when broken, assumes a central position, with the scolices radially attached, *c*. *d*, free scolex.

6, Free scolices, low magnification.

Diagnosis.—Diagnosis may be made by finding hooklets, scolices, vesicles, membranes, or hydatid fluid in feces, bile, urine, sputum, or vomica, or in the material obtained by puncture, by operation, or at autopsy. The hooklet is important in diagnosis, because of its resistance to disintegration, even in degenerating or suppurating cysts.

In most cases, indirect serologic methods must be used to establish a clinical diagnosis. Precipitin, complement fixation, and intradermal reaction tests may be used.

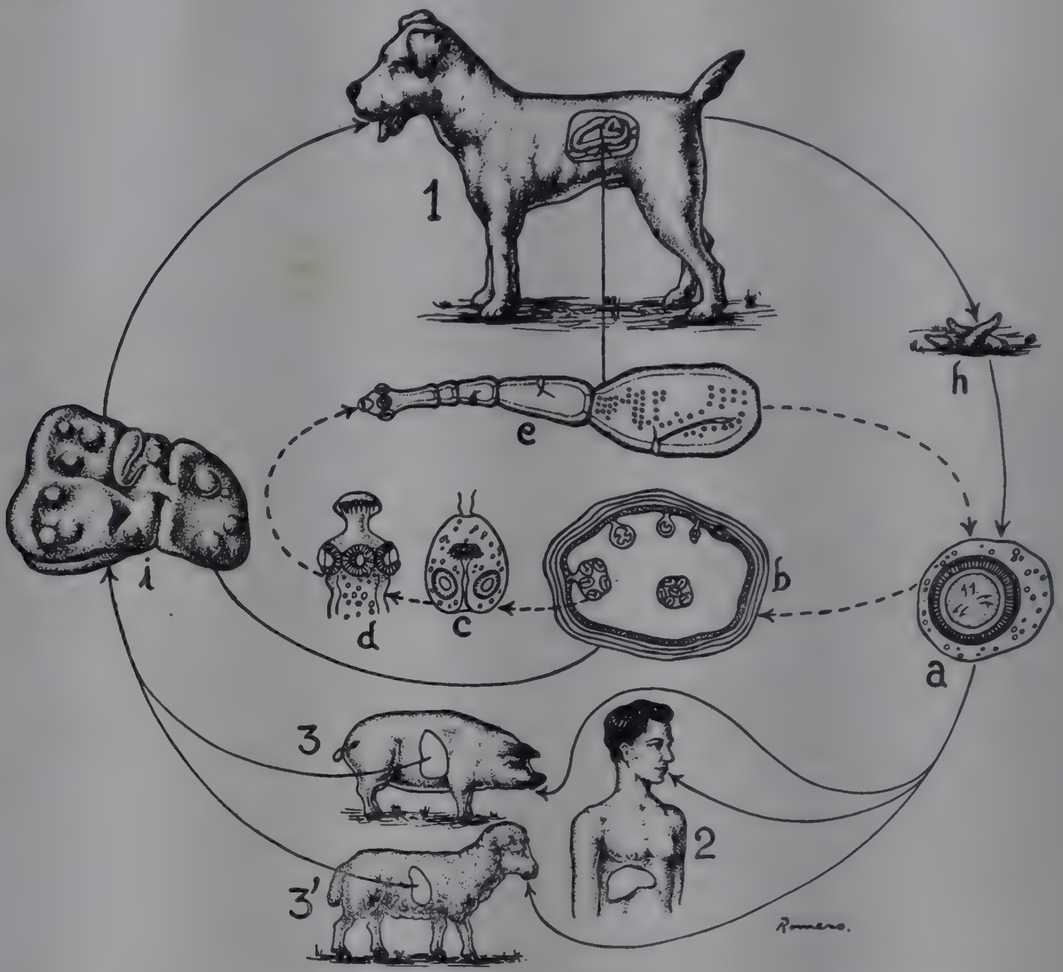

Fig. 531.—*Echinococcus granulosus.* Life cycle. The dog (*1*) the definitive host harbors the adult parasite (*e*) in its intestines. The eggs (*a*) are passed in the feces (*h*); if ingested by an intermediate host: man (*2*); swine (*3*); sheep (*3′*); or others, hydatid cysts (*b*) develop in the liver (*i*) and other viscera. When the infected viscera are fed to dogs, the scolex (*c, d*) within these hydatid cysts (*b*) develops into the adult parasite (*e*) in the intestines of this habitual definitive host, the dog (*1*), in the feces of which (*h*) eggs (*a*) are passed, beginning a new cycle. (Original drawing of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

Precipitin Test.—A mixture of 0.5 c.c. of patient's serum and 0.5 c.c. of hydatid fluid in a small test tube, placed in an incubator at 37° C. for 2 hours, gives a precipitate in positive cases. Positive reactions occur only in one-third of the cases of hydatidosis, and at times it is positive in the absence of the disease.

Complement Fixation.—This is a group reaction. Several antigens may be used: extract of *T. saginata*, of *Fasciola hepatica*, and fluid from *Cysticercus tenuicollis*. Some flatworm infestations give positive reactions with this test. The serum becomes negative within two months after removal of the hydatid cyst. About 50 per cent of cases of hydatidosis give positive results.

Intradermal Test.—Inject into the skin of the arm 0.5 c.c. of pure hydatid fluid less than six months old. Inject 0.5 c.c. of physiologic saline or weak peptone water into the other arm as a control. An accelerated positive reaction shows a wheal about 2 cm. in diameter at the point of inoculation, surrounded by a swollen area, reaching maximum intensity 15 minutes after injection and disappearing shortly afterward. A delayed positive reaction appears 12 hours after injection, and shows an erythematous area with edema and local sensation of heat.

Family **HYMENOLEPIDIDAE** Railliet and Henry 1909

Hymenolepididae are Cyclophyllideae with scolex usually provided with a rostellum bearing a single crown of hooklets, rarely unarmed. In some worms, the scolex is detached during an early stage of development and is replaced by a pseudoscolex. Suckers are usually without hooklets. Proglottids are broader than long.

Hymenolepis Nana (von Siebold 1852)

Hymenolepiasis nana is parasitism caused by *Hymenolepis nana*. *H. nana* is relatively common in certain countries, and totally absent from others of the same climate at the same latitude. It is found in Europe, Africa, Asia, and the Americas.

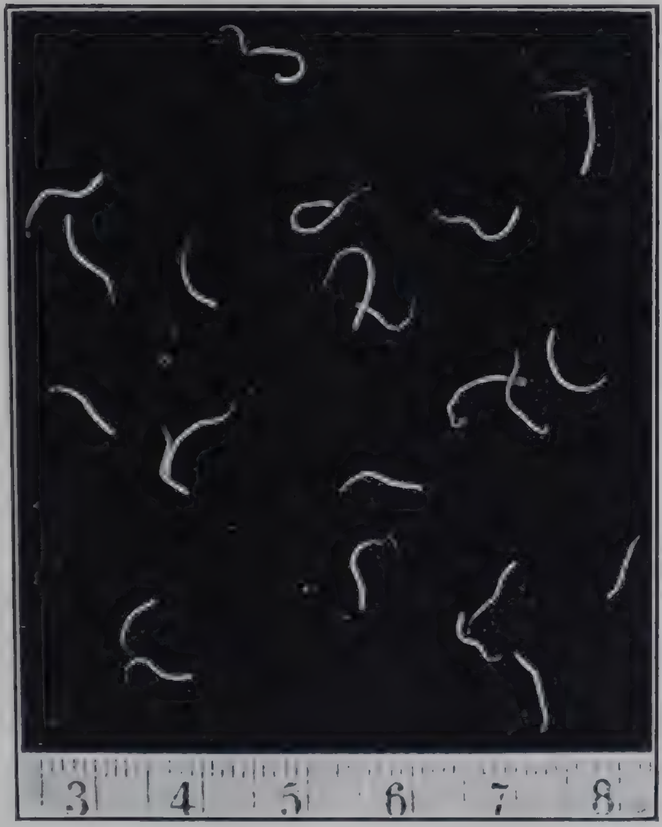

Fig. 532.

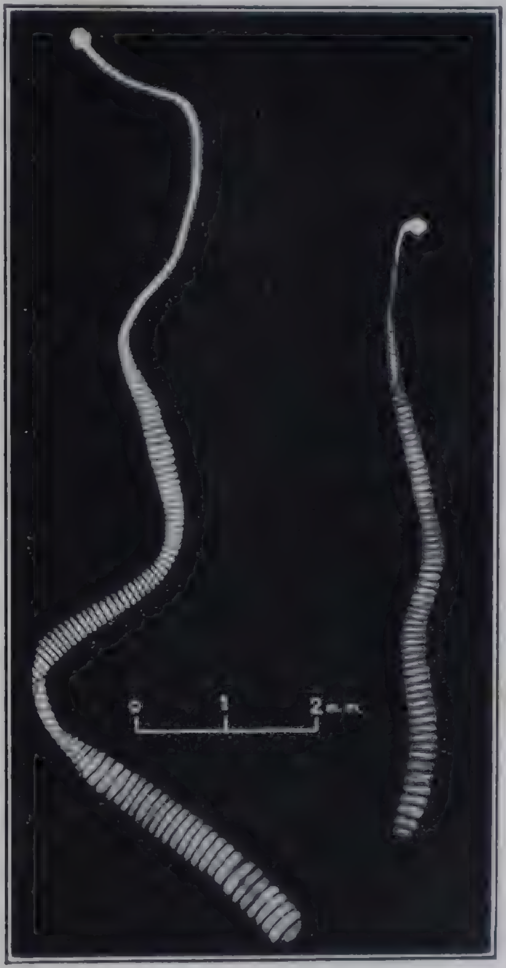

Fig. 533.

Fig. 532.—*Hymenolepis nana*. (Original photograph of Kourí, one and one-half times its natural size.) Millimeter scale. Dark background. Illumination from above. Specimens of human origin fixed in 10 per cent Formalin.

Fig. 533.—*Hymenolepis nana*. (Original figure of Kourí.) Two specimens of *Hymenolepis nana*. Dark background. Greatly enlarged. Parasites fixed in 10 per cent Formalin.

H. nana is a small worm, 25 to 40 mm. long and 0.5 to 0.7 mm. wide. The scolex has a retractable rostellum with a single crown of 20 to 30 hooklets. The neck is long.

Eggs.—The eggs are colorless and refractile, spherical or subspherical, and have two covers, in addition to the wall of the hexacanth embryo, which can be considered a vitelline embryonic membrane. The external cover is 47 microns long by 36 microns wide; the internal cover, usually oblong, is 28 microns by 23 microns, with a mamelon in each pole. From this rises a crest with 4 to 8 sinuous, refractile filaments, which occupies the space between the two covers. Within the internal cover is the onchosphere or hexacanth embryo, 26 by 20 microns. The three pairs of hooklets are lancet-shaped, 11 microns long.

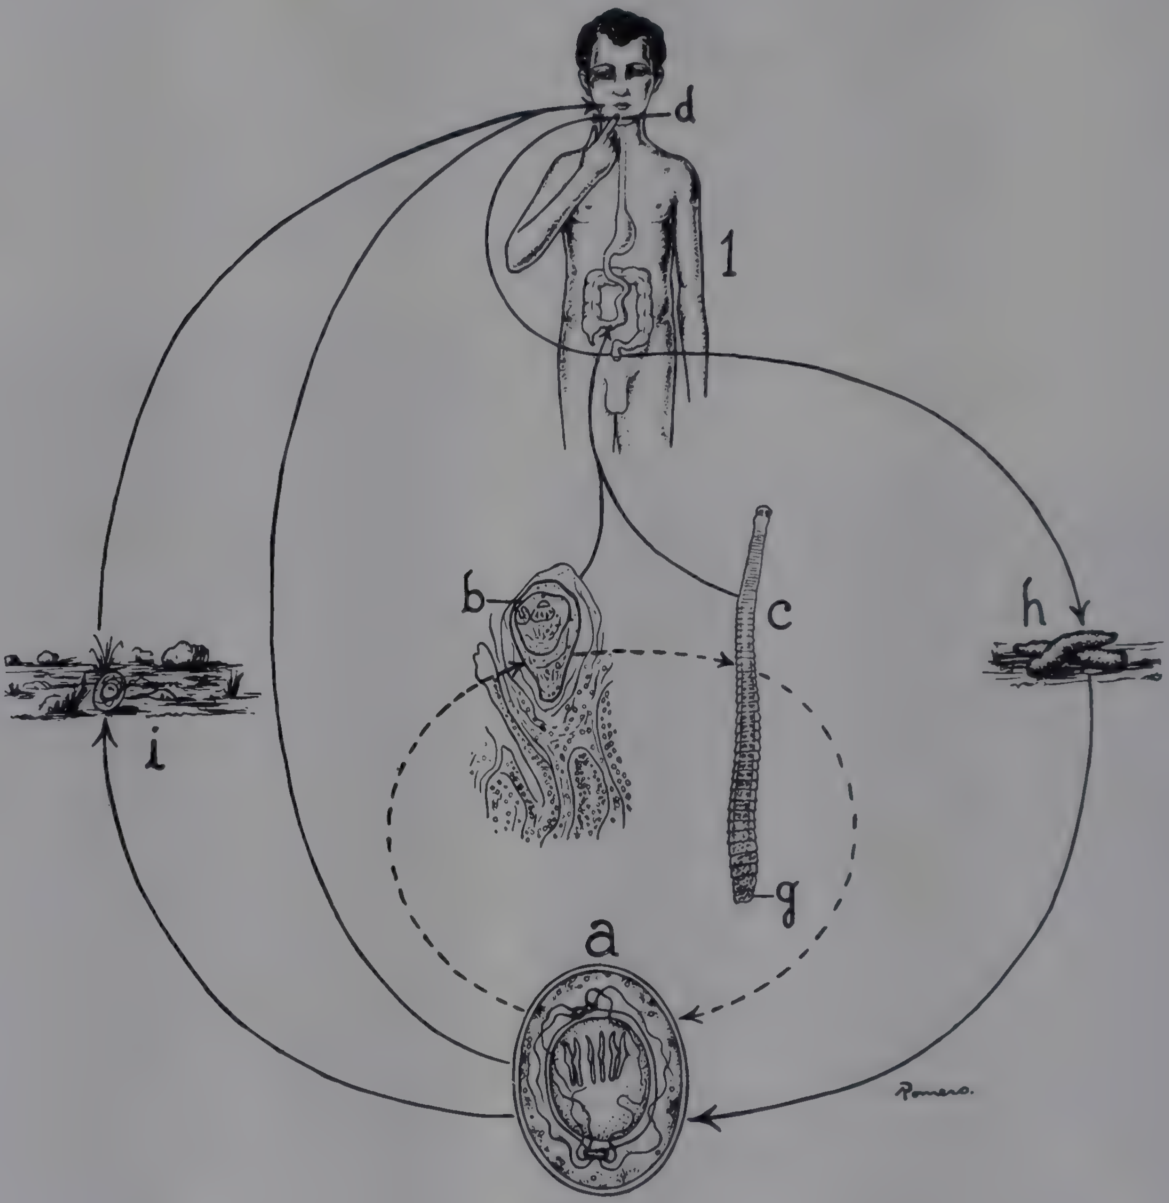

Fig. 534.—*Hymenolepis nana.* Direct life cycle: without intermediate host. Autoinfestation is present in this parasitism because the eggs are directly and immediately infective for the host. The child becomes reinfected by ingestion of eggs which have contaminated his fingers directly from the the anal or perianal regions.

The eggs (*a*) are passed in the feces (*h*); if ingested by direct contamination of the fingers (*d*) or through contamination of food (*i*), they develop into a Cysticercoid (*b*) in the intestinal villi of the same definitive host, who also acts as intermediate host by sheltering the larval form, the Cysticercoid (*b*). This Cysticercoid breaks through the villi and becomes attached to the mucosa; it grows to adult stage (*c*); the terminal proglottids of the strobila become gravid (*g*), set free eggs (*a*), which are passed in the feces (*h*) to begin a new cycle. (*b*, After Brumpt; others, original of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

The parasite is usually found in the distal portions of the ileum of man. Usually massive infestation is seen, especially in children. Two thousand parasites have been found in a single case.

Life Cycle.—*H. nana* has two life cycles. In the direct life cycle, man is both the intermediate and the definitive host. In the indirect cycle, the larvae develop in fleas (Tenebrionidae). See Figs. 534 and 535.

Diagnosis.—Diagnosis is established by microscopic examination of the feces for the presence of eggs, which are usually found in large numbers.

Hymenolepis Diminuta (Rudolphi 1819)

H. diminuta is a common tapeworm of the mouse and rat, and is also found in man. The adult is 20 to 60 cm., at times 75 cm., long, and about 3.5 mm. wide, and has a small scolex. It bears a rudimentary unarmed rostellum, with no hooklets. The proglottids are short, wide, and trapezoid.

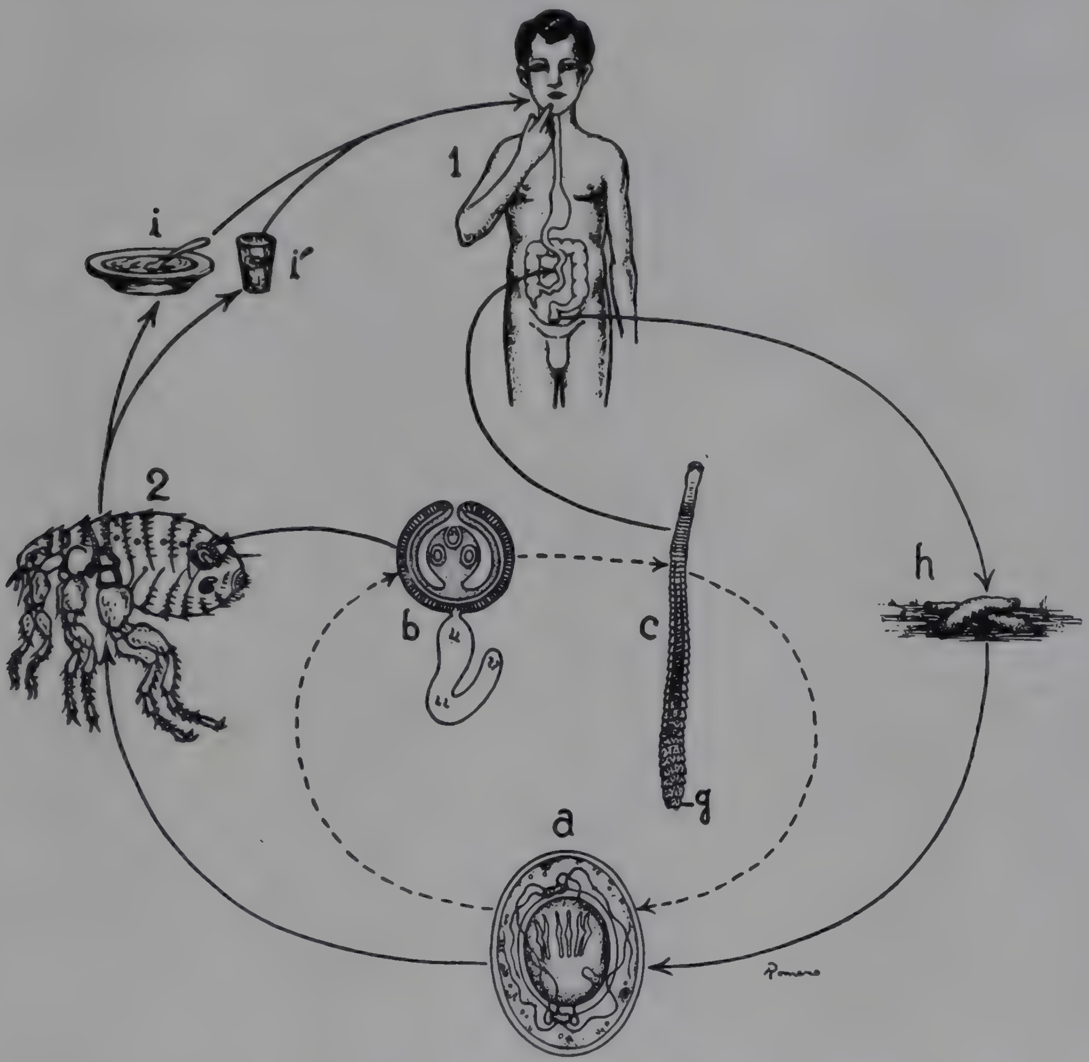

Fig. 535.—*Hymenolepis nana.* Indirect life cycle; with intermediate host. Bacigalupo has been able to infect, experimentally, rat fleas and Tenebrionidae with *Hymenolepis nana* eggs obtaining development of the Cysticercoid (*b*) in the body cavity of these insects. This leads to the thought that children may become infected through a different mechanism from that described in the direct cycle (Fig. 534); i.e., ingestion of Cysticercoid-infected fleas (*2*) which have fallen in a glass of milk (*i'*) of a plate of soup (*i*), as in the case of *Dipylidium caninum.* (Original drawing of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

Eggs.—The eggs are spherical, have two walls, and contain a hexacanth embryo. The outer wall is yellowish and radially striated. The inner wall is smooth, refractive, and colorless. The diameter is 60 to 80 microns.

Intermediate hosts are Lepidoptera (caterpillar and butterfly); Coleoptera; Orthoptera (earwig); Aphaniptera; and *Xenopsylla cheopis.*

Life Cycle.—The life cycle is indirect, requiring an intermediate host. It is shown in Fig. 536.

Diagnosis.—Diagnosis is made by microscopic examination of the feces for the presence of eggs. Direct and concentration methods should be used.

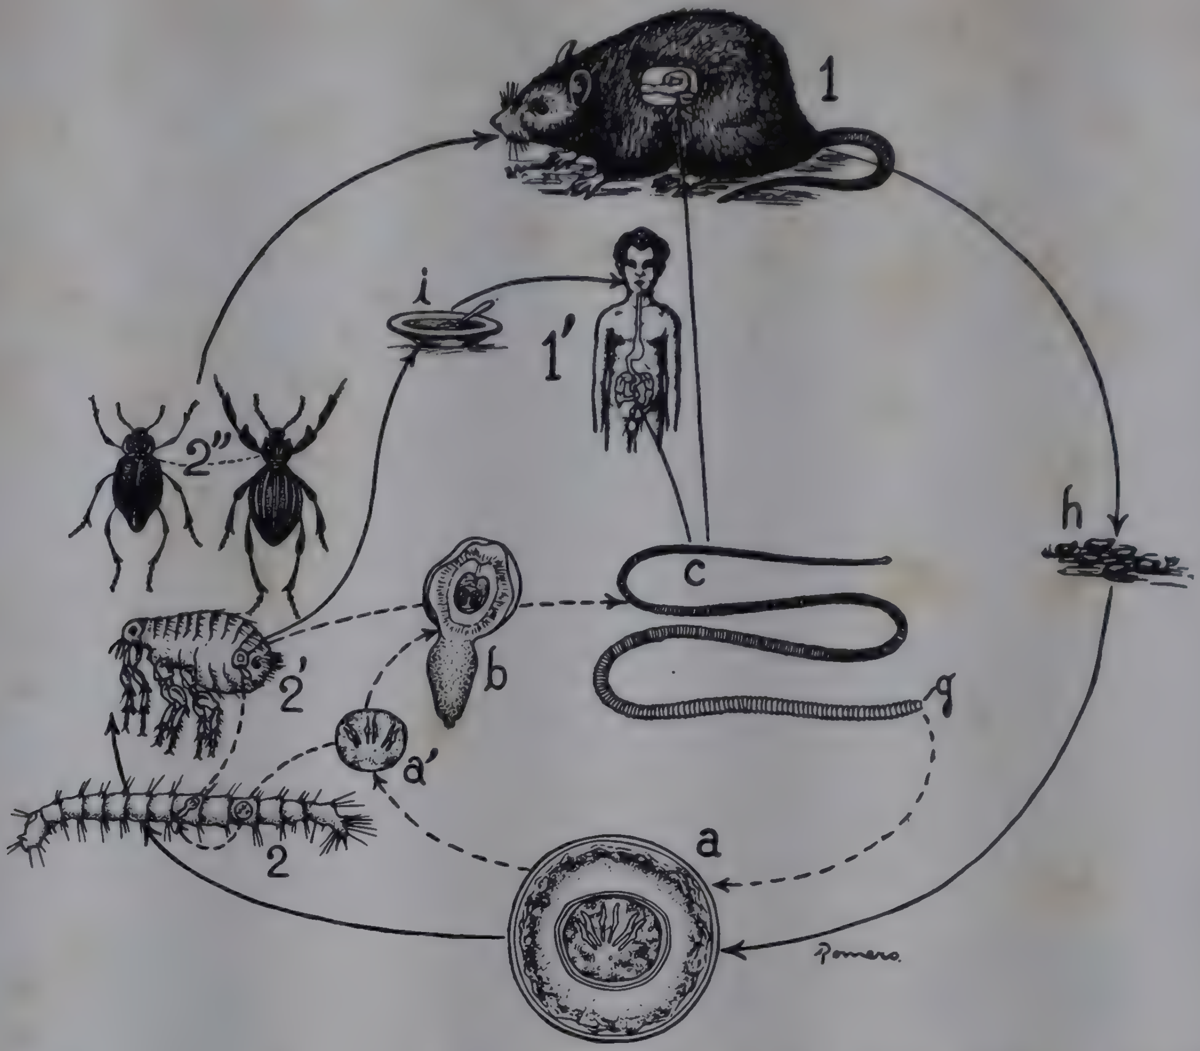

Fig. 536.—*Hymenolepis* (*H.*) *diminuta.* Life cycle. This parasite follows an indirect development. The definitive habitual (final normal) host is the rat (*1*). The child is an incidental (abnormal) host. The habitat of the adult parasite (*c*) is the small intestine of the definitive host. The eggs (*a*) are passed in the feces (*h*) of the definitive host, are freed by disintegration of gravid proglottids (*g*), then ingested by insects, as *Asopia forinalis, Akis spinosa* and *Scaurus striatus* (*2"*); rat fleas: *Xenopsylla cheopis* (*2, 2'*) and *Ceratophyllus fasciatus,* etc., in the body cavity of which they (*a*) develop into Cysticercoid (*b*). If the definitive host, rat (*1*), child (*1'*) ingests this Cysticercoid (*b*), it develops into an adult parasite (*c*) in the small intestine of the definitive host (*1, 1'*). The eggs (*a*) are passed in the feces (*h*) of the definitive host (*1, 1'*), to begin a new cycle.

The flea (*2'*) becomes infected during its larval stage (*2*). Within this larva the hexacanth embryo (*a'*) develops into Cysticercoid before the larva (*2*) becomes an adult flea (*2'*). (*2"* and *b,* After Brumpt. Others original of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.

Family **ANOPLOCEPHALIDAE** Cholodkowsky 1902

INERMICAPSIFERIASIS

Inermicapsifer Cubensis (Kourí 1938) Kourí 1940

Inermicapsifer cubensis is a cestode measuring 27 to 42 cm. in length, with 310 to 368 proglottids in the strobila. The scolex is without rostellum or hooklets, and is approximately 630 microns long and 610 microns broad. The suckers are unarmed. The neck is 3 mm. long. Proglottids of the midportion of the strobila are broader than long, about 2.3 by 1.5 mm. The free-living, gravid proglottids have variable shapes, but, when fixed in 10 per cent Formalin, they tend to become round and rather opaque.

The **life cycle** of this parasite is unknown.

The **life span** in its human host does not seem to be long, usually several months. Man is probably an accidental host. The parasite is easily expelled with the administration of castor oil or any other cathartic.

Diagnosis.—Infestation is usually discovered by the presence in the feces of small, white objects resembling rice grains. Frequently expulsion of frag-

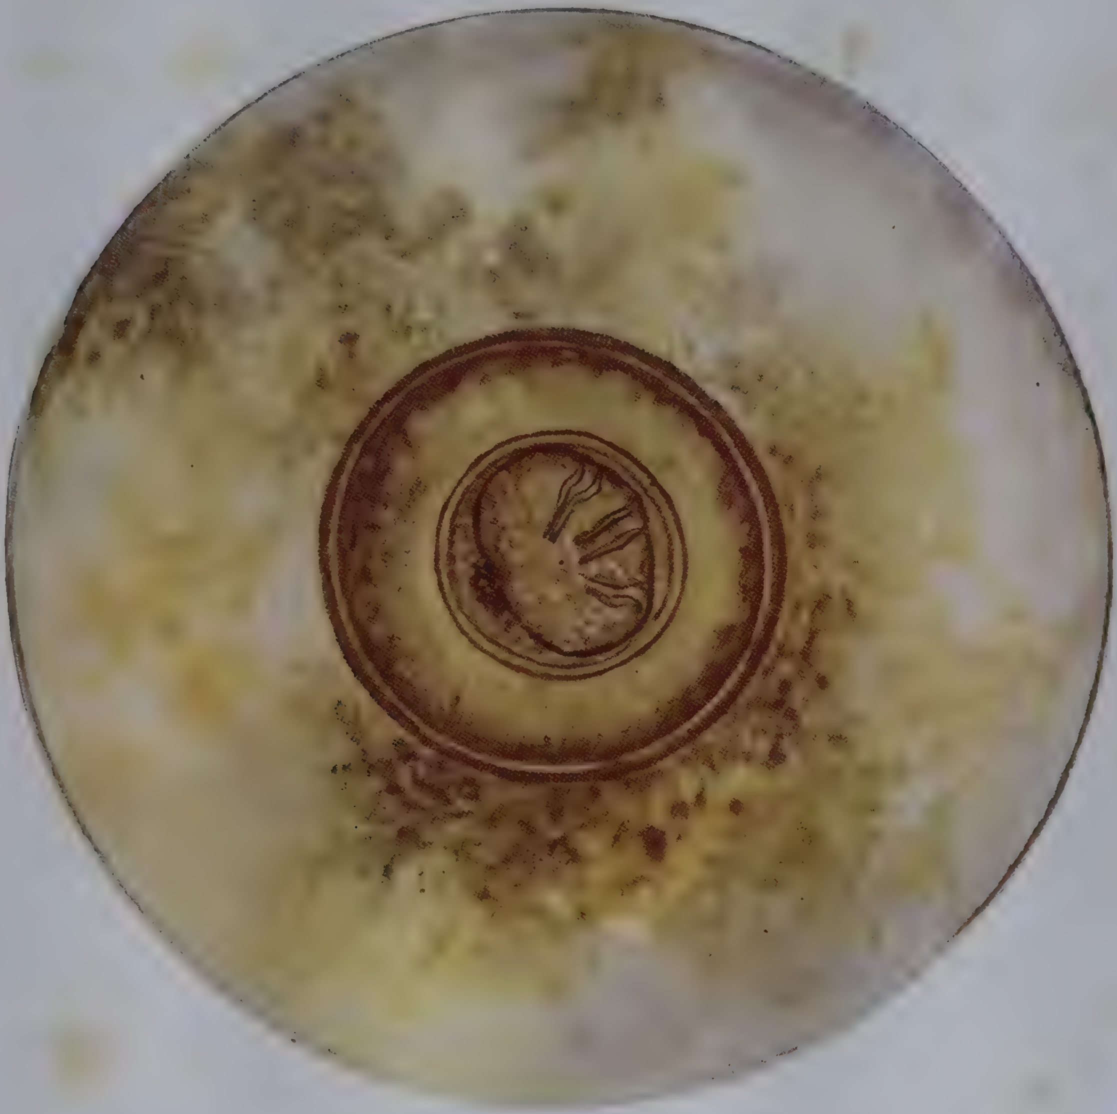

Plate LI.—*Hymenolepis (H.) diminuta* egg. (Original Figure of Kourí.) Drawn From the Microscope.

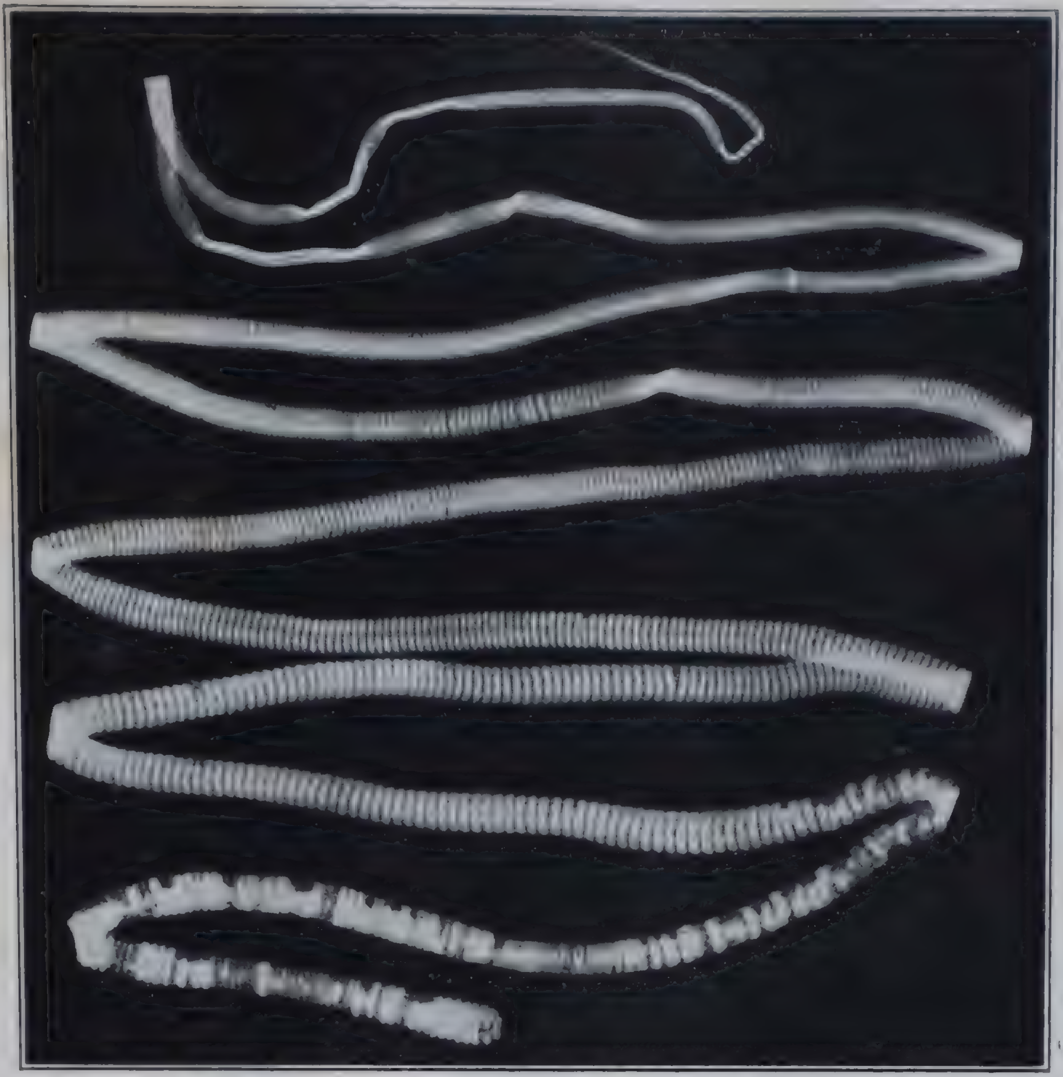

Fig. 537.—*Hymenolepis* (*H.*) *diminuta.* Specimen 75 cm. long, obtained by autopsy of a rat. The scolex is very small. All the proglottids, gravid proglottids included, are wider than long. It is difficult to see the separation between the proglottids with the naked eye. This segmentation is clearly noted if the parasite is observed with a magnifying glass, as in this photograph. (Original photograph of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

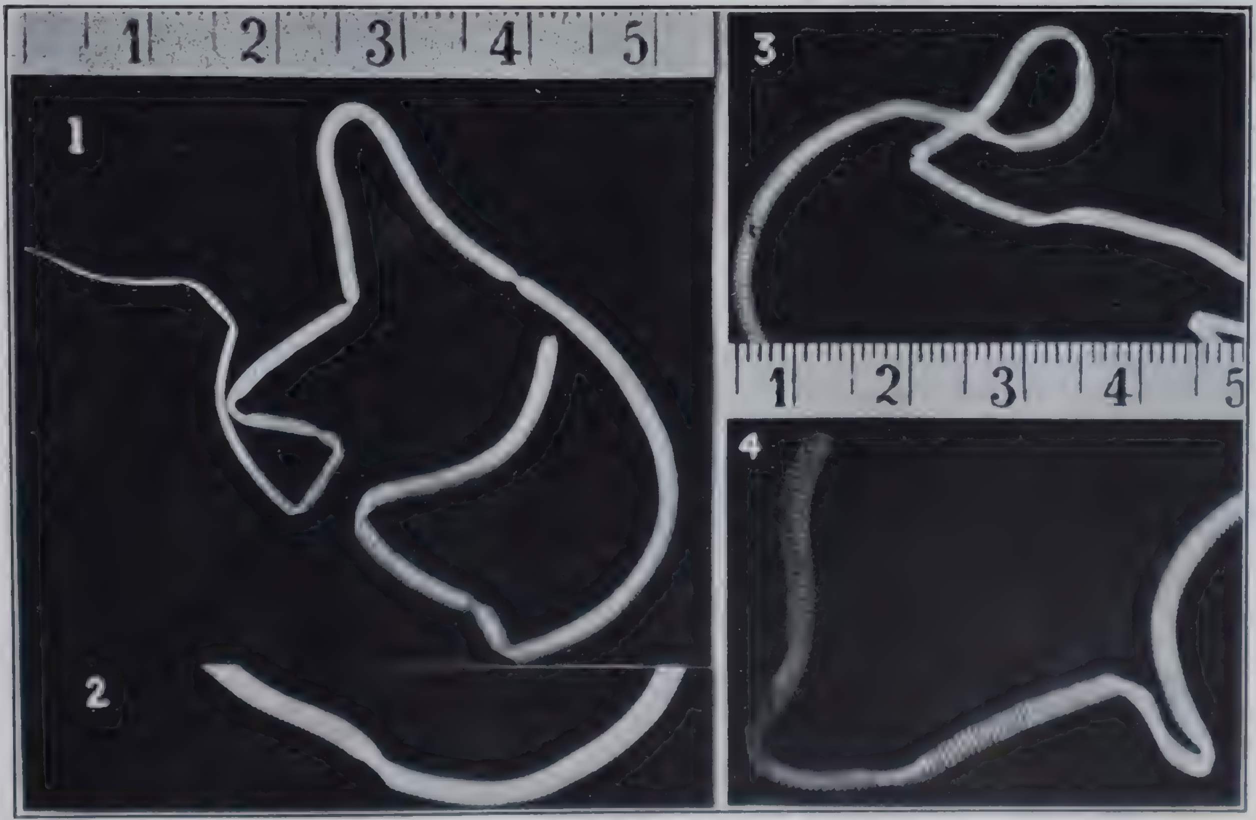

Fig. 538.—*H. diminuta.* Smaller specimen derived from rat. *1*, Complete small specimen. *2*, *3*, and *4*, Fragments of a larger specimen. Fig. 544.—*Inermicapsifer cubensis,* Kourí, 1939. One of the complete specimens expelled, after administration of treatment, by the fifth human case of this parasitism in Cuba (Kourí). This specimen is 34 cm. long with 310 proglottids beginning the count 3.76 mm. from the scolex. (Original photograph of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

ments of strobila in the feces, either spontaneously or after the administration of cathartics, makes the diagnosis possible.

The best procedure for identification of the gravid proglottids is to examine "granules" found in macroscopic examination of the feces, by compressing these granules between slide and cover slip. If they are actually gravid proglottids, they will burst and liberate a great number of characteristic oviferous capsules. (Bacigalupo's phenomenon.) See Fig. 542.

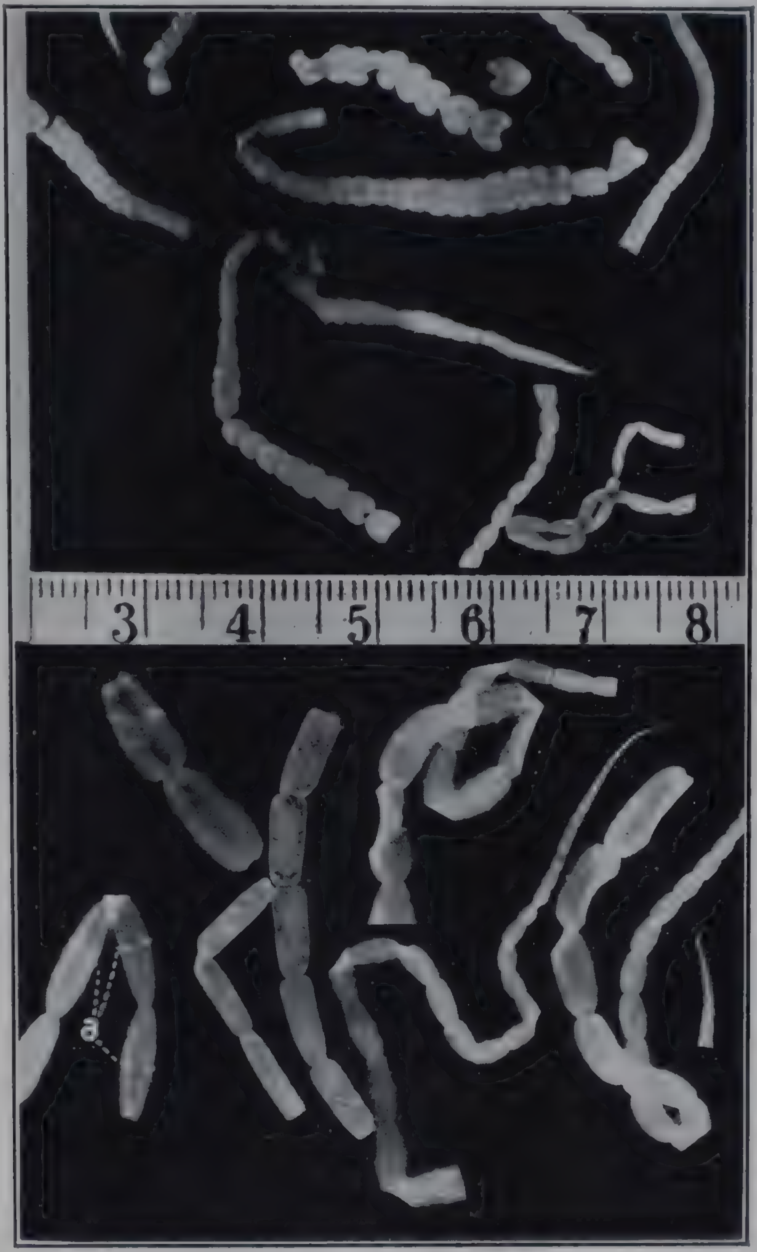

Fig. 545.—*D. caninum.* Fragments of strobila of different specimens. Note variability in shape of segments. Some are biconvex, others heart shaped. Some are long, broad, and thin; others are narrow, short, and thick. Some have almost parallel sides. In segments marked *a*, the double genital system is clearly visible. Fixed in 10 per cent Formalin; dark background, illuminated from above. Millimeter scale. (Original photographs of Kourí.)

Family **DILEPIDIDAE** Fuhrman 1907

DIPYLIDIASIS

Dipylidium Caninum (Linnaeus 1758) Railliet 1892

This tapeworm is a habitual parasite of dogs and cats, but has also been found in man. It is 50 cm. long and 2 to 3 mm. wide. The scolex is relatively small, but larger than that of *H. nana.* It has a retractive rostellum which bears 4 crowns of thornlike hooklets. The hooklets become smaller gradually from the anterior to the posterior crown which bears the smallest hooklets. There are four large, elliptical suckers. The mature and gravid proglottids are longer than wide, have convex borders, and resemble cucumber seeds.

Eggs.—The eggs are almost spherical, 52 microns long by 45 microns wide. There are two thin covers. Eggs contain a hexacanth embryo. The eggs are found grouped in numbers of 8 to 16 within the oviferous capsule, which is inclosed within the gravid proglottid.

Life Cycle.—The gravid proglottids pass outside the body and there expel oviferous capsules containing eggs. They are ingested by lice and fleas of dogs and the human flea, localize in the body cavities of the insects, and develop into larvae or *Cryptocystis*. Fleas become infested while in the larval state and the cysticercoid develops when the insect reaches the adult form. The definitive host is infested by ingesting parasitized fleas and lice.

Diagnosis.—Diagnosis usually remains unsuspected until the gravid proglottids or fragments of the parasite are accidentally discovered in the feces. The eggs and oviferous capsules do not usually appear in the feces and thus microscopic examination of the feces is insufficient to establish a diagnosis.

Order **PSEUDOPHYLLIDEA** Carus 1863

Family **DIPHYLLOBOTHRIIDAE** Lühe 1910

DIPHYLLOBOTHRIASIS

Parasitism by the adult form of *Diphyllobothrium latum* is called diphyllobothriasis or "fish tapeworm disease" or "broad tapeworm disease."

Diphyllobothrium Latum (Linnaeus 1758) Lühe 1910

D. latum is found in regions near the Great Lakes in the United States, in southern Manitoba in Canada; in Europe, the shores of the Baltic Sea and the North Sea up to Holland; the shores of Swiss and Italian lakes; and, less importantly, the delta of the Danube.

D. latum is as long as *T. saginata,* and it may be even longer. It is usually 2 to 10 meters long, but may reach a length of 15 to 20 meters. The gravid proglottids lay eggs until the uterus is empty, then contract and disintegrate. The remnants are eliminated in the feces.

Eggs.—The eggs are 70 microns by 45 microns, and may be found in great numbers by microscopic examination of the feces. They are ellipsoid, of a brownish-yellow color, and are provided with operculated coverings. The operculum is relatively large, and is found in the thicker pole of the egg.

Life Cycle.—*D. latum* inhabits the small intestines of man, dogs, cats, and other animals. The eggs are passed in the feces and eventually become deposited in water. In 11 to 15 days after reaching the water, at 15° to 25° C., ciliated embryos develop and force their way out through the opercula of the eggs, swim around in the water for 12 hours, and are then ingested by certain small crustaceans, or water fleas, called "Cyclops." In the Cyclops, the embryos develop into primary larval forms, or "procercoid" larvae, which have a caudal sphere with six embryonal hooklets called "cercomer." These larvae are ingested by fish, bore through the intestinal wall, and become encysted in various organs. Here they develop into secondary or "plerocercoid" larvae, or "sparganum." The secondary larvae in the fish pass into the intestine of the definitive host, man, dog, or cat, when the fish containing the parasite is eaten raw or poorly cooked. The scolex becomes attached to the wall of the intestines. Through proliferation of the scolex, the proglottids, and finally the complete adult parasite, are formed in 5 to 6 weeks, although after the second week eggs can be found in the stools. The gravid proglottids deposit eggs which are eliminated in the feces to start a new cycle.

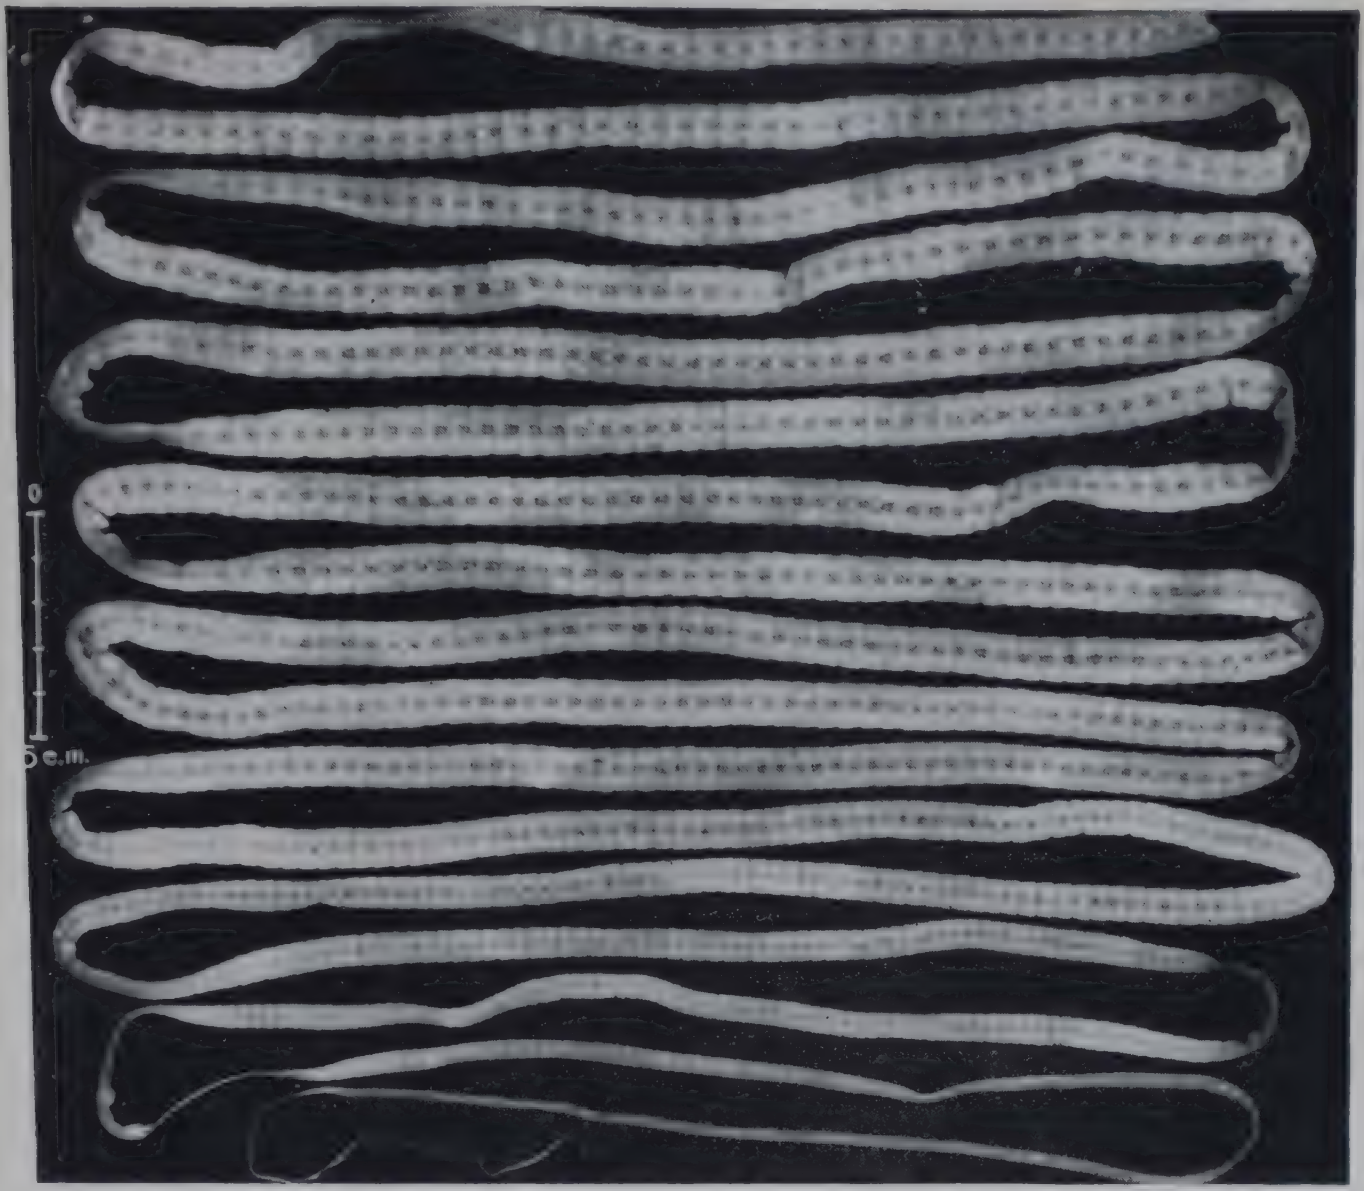

Fig. 546.—*Diphyllobothrium* (*D.*) *latum.* Complete adult specimen expelled during treatment. (Kourí, 1943, in Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

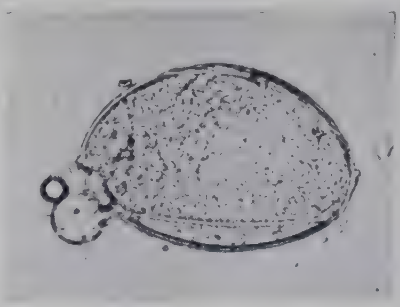

Fig. 547.—Egg of *Diphyllobothrium latum* (×400). (From the collection of R. B. H. Gradwohl.) (Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

Diagnosis.—Diagnosis is established by direct microscopic examination of the feces, where the eggs are found in great numbers. At times the patient expels long fragments of the strobila.

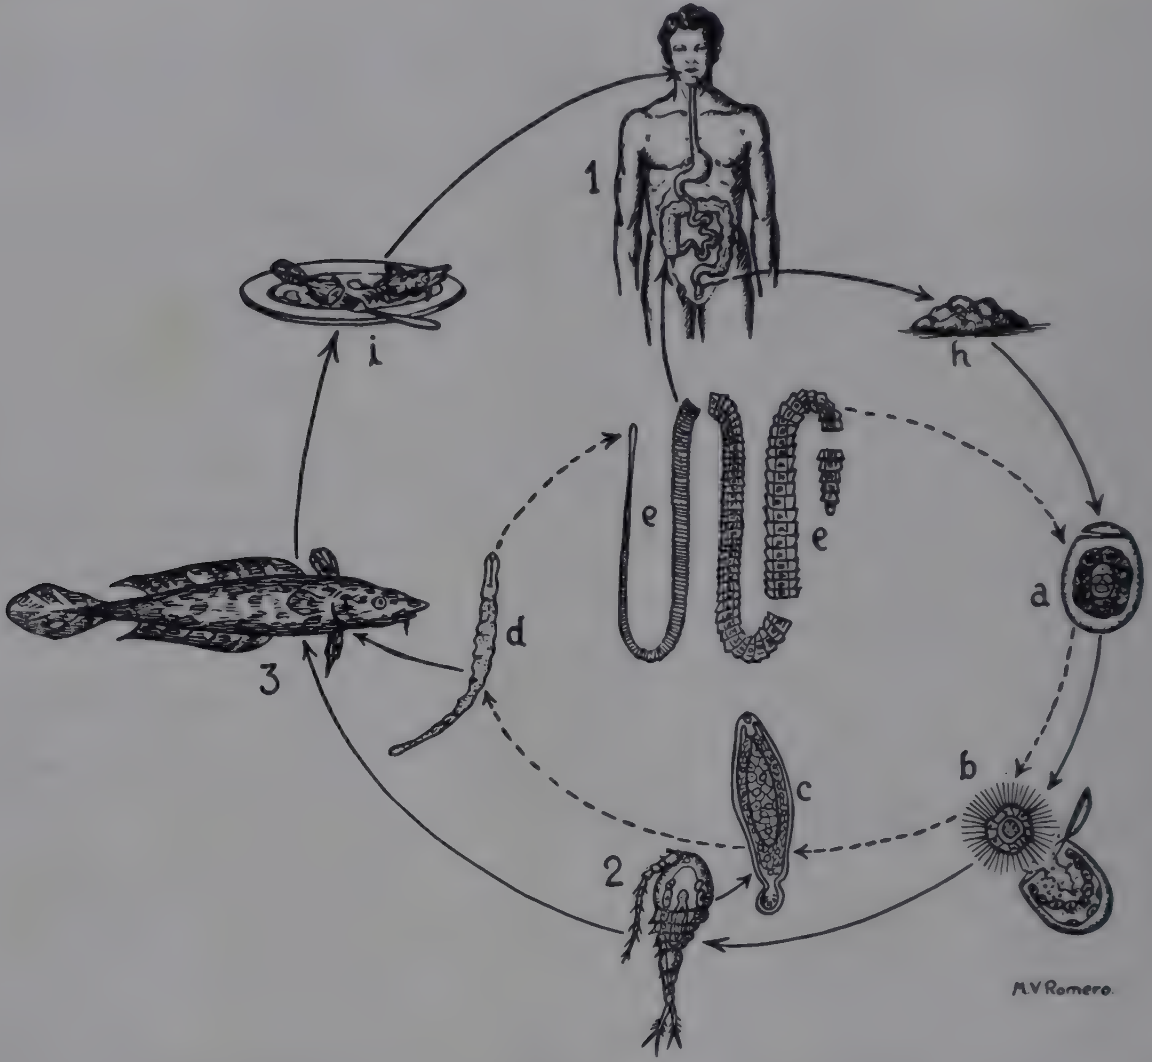

Fig. 548.—*Diphyllobothrium latum.* Life cycle. The adult parasite (*e*) lives in the small intestine of man (*1*), one of the habitual definitive hosts. It lays eggs (*a*) which are passed in the feces (*h*). If these eggs reach the water, a ciliated hexacanth embryo or coracidium (*b*) develops, hatches, and swims freely in the water until ingested by any of the first intermediate hosts, small fresh-water crustacea—copepods—commonly known as water fleas (*2*). The coracidium develops into procercoid larva (*c*) in the body cavity of these crustacea. If the procercoid larva, with the crustacea (*2*), is ingested by different species of fish, acting as second intermediate hosts, the procercoid larva (*c*) becomes a plerocercoid larva (*d*) which localizes in the viscera and muscles of the fish. When the habitual definitive hosts—man (*1*), cat, dog, seal—ingest the infected fish (*i*), raw or poorly cooked, the plerocercoid larva (*d*) becomes adult Diphyllobothrium (*e*) in the intestines of the definitive host (*1*) which passes eggs (*a*) in the feces (*h*), beginning a new cycle. (Original of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.)

THE TREMATODES OR FLUKES

Trematodes are flatworms with smooth integument, unsegmented body, incomplete digestive tract, and no anus. Usually they are leaf-shaped. All except the Schistosomae are hermaphroditic.

Class **TREMATODA** Rudolphi 1808

Family **SCHISTOSOMIDAE**

SCHISTOSOMIASIS

Schistosomiasis is a disease caused by the blood flukes. The species *Schistosoma haematobium, S. mansoni, S. japonicum,* and *S. intercalata* are the most important in human medicine.

Schistosoma Mansoni Sambon 1907

Schistosomiasis mansoni (bilharziasis) is produced by *S. mansoni*, or Manson's blood fluke. It is commonly found among the farmers of the Nile delta. It is found in many places in Africa. In the Western Hemisphere, it is found in northern Brazil, Venezuela, and Dutch Guiana, also in the West Indies. It was introduced into America through the African slave trade, and, having found an appropriate gastropod host, it became endemic.

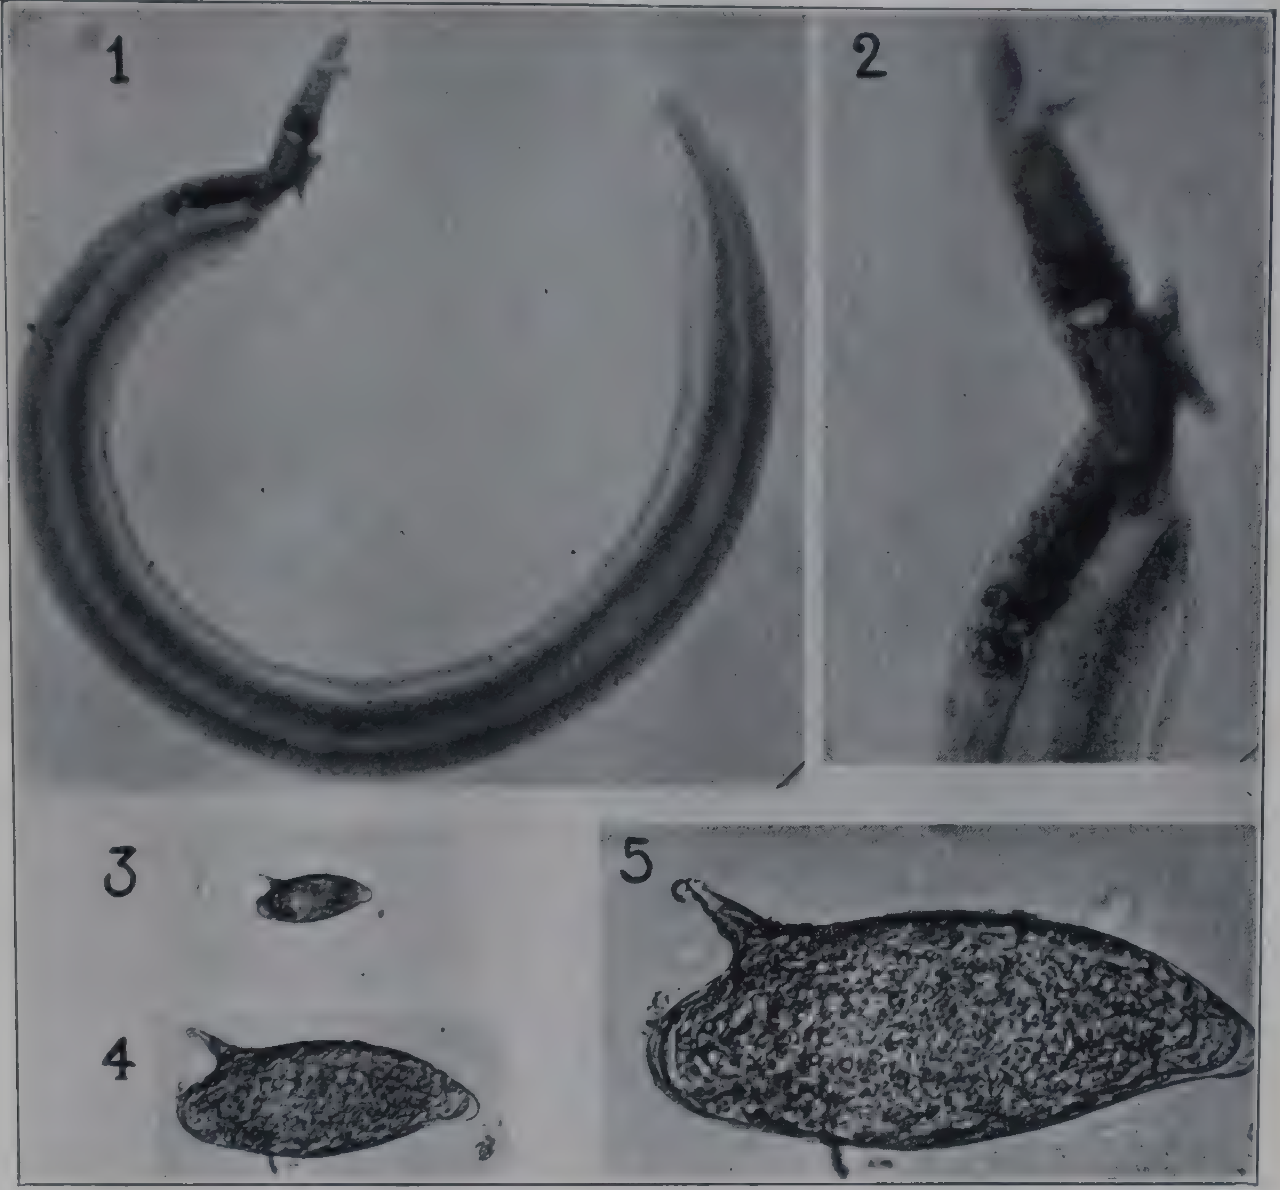

Fig. 549.—*Schistosoma mansoni.* *1*, Male parasite. *2*, Anterior part (enlarged); note the two suckers, the eight testes, and the gynecophoric canal. *3*, *4*, *5*, Photomicrographs of eggs with different magnifications. Note the characteristic lateral hook. (Original figure of Kourf and Basnuevo in Lecciones de Parasitología y Medicina Tropical.) (Photomicrograph of material sent by Dr. W. A. Hoffmann, Institute of Tropical Medicine of San Juan, Puerto Rico.)

S. mansoni causes intestinal and hepatosplenic bilharziasis. The adult parasite localizes in the venules of those branches of the portal vein which drain the colon and rectum. A small proportion of the worms localize in the blood vessels of the urinary bladder and some eggs are passed with the urine.

The female parasite is 12 to 16 mm. long and 170 microns wide. The vitelline glands occupy the posterior two-thirds of the body. The ovary lies in the anterior third. The two intestinal trunks converge, at the level of the ovary, to form a long blind pouch. The uterus is short and contains one single mature ovum at a time. The vulva is posterior to the ventral sucker which lies near the anterior (oral) sucker.

The male is 12 mm. long. It has 6 to 9 small testicular lobules. The short intestinal trunks unite into a singe blind pouch, longer than in *S. haematobium.* The body of the male is flattened and folded ventrally as in the other species of this genus. The female is held in this gynecophoric canal during fertilization.

Life Cycle.—The female migrates toward the small venules which traverse the wall of the large intestine, and deposits eggs, one at a time, into these venules. The eggs follow the capillaries, penetrate into the tissues, eventually reaching the lumen of the intestine, from which they are excreted in the feces. The eggs are carried to the water in the feces, where, at a temperature of 30° C., the embryo can usually escape from the egg within a few minutes. The larvae or miracidium has positive phototropism. It needs certain species of lung-bearing mollusks of the genus Planorbis to complete its life cycle. The miracidium penetrates, in 15 minutes, through the tentacles of the snail, and metamorphoses into a sporocyst. The sporocyst gives rise to a daughter sporocyst at the end of the fifth or sixth day. In about 10 days, the daughter

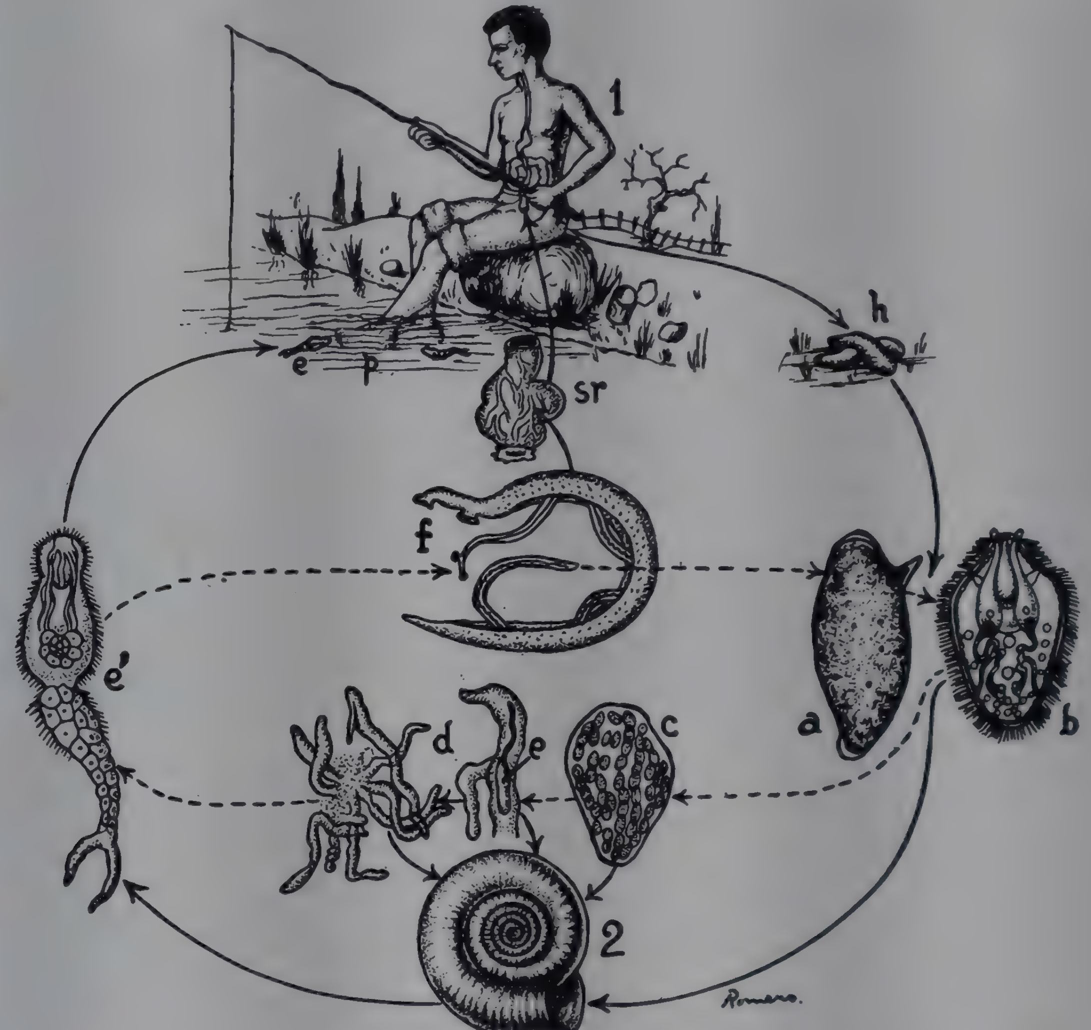

Fig. 550.—*Schistosoma mansoni.* Life cycle. The parasite lives in the veins, especially the venules of the mesenteric veins. Before laying eggs, the female migrates to the veins of the wall of the large intestine. These eggs bore through the tissues and fall in the intestinal lumen; they are passed in the feces (*h*). When the eggs (*a*) reach the water, the miracidium (*b*) hatches in a few minutes. This miracidium penetrates into different species of Planorbis (*2*) which act as intermediate hosts. The primary (*c*) and secondary (*d*) sporocysts develop within the Planorbis and the cercaria (*e*) grows within the secondary sporocyst. The cercariae (*e'*) leave the snail and swim freely in the water until they find the definitive host man (*1*), then bore actively through the skin (*p*) to reach the veins, where they develop into adult male and female (*f*). The female lays eggs (*a*) that are passed in the feces (*h*) to begin a new cycle. (*b*, After Cort, adapted by Faust; *c*, *d*, *e*, after Lutz and Leiper, in Brumpt; *e'*, after Brumpt and Neveu-Lemaire. Others, original of Kourí and Basnuevo, in Lecciones de Parasitología y Medicina Tropical.)

sporocysts give rise to cercariae. The cercariae are about 0.5 mm. long. When they come in contact with the skin of man, they shed their tails and then bore through the skin. The female lays eggs which are passed in the feces, and a new cycle begins.

The eggs are deposited by the female in the coats of the large intestine, causing "intestinal bilharziasis," or a type of splenomegaly resembling Banti's disease.

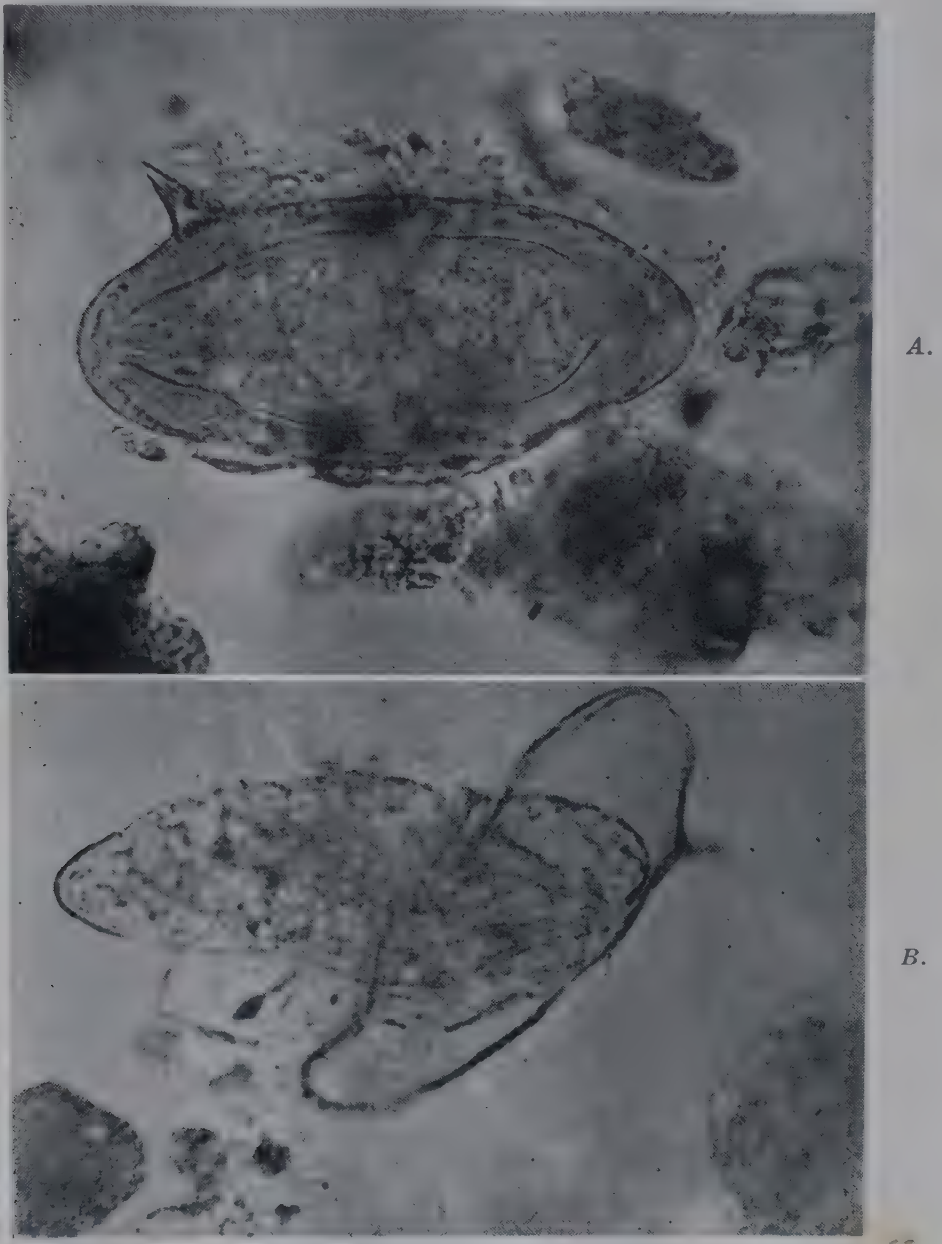

Fig. 551.—Eggs of *Schistosoma mansoni*. *A*, Egg; *B*, miracidium of *S. mansoni* emerging from the egg shell. Water centrifugal sedimentation concentration method of Baroody and Most. (Original photomicrographs of Dr. B. J. Baroody.)

Eggs.—The eggs have a prominent lateral spine. They average 142 microns in length. They usually contain living larvae.

Diagnosis.—Diagnosis is made by microscopic examination of the feces for the eggs with their characteristic lateral spine; biopsy of the lesions caused by the parasite in the rectum, rectal polyps; complement fixation reaction, using an antigen prepared from extracts of the adult parasite or of the larvae; intradermal reactions using antigen prepared from parasitized mollusks.

Rectal biopsy is useful in making a diagnosis. The technic consists in removing, with the biopsy forceps, a piece of mucosa about the size of a large grain of rice, from the right dorsoventral rectal fold, located approximately 8 to 10 cm. from the anus. The sample is then placed in 5 c.c. of a 4% solution of potassium hydroxide and incubated for 3 to 4 hours at 60° to 80° C. The tissue is dissolved in this manner and the eggs can be looked for in the sediment left after centrifugation.

Hernandez-Morales and Maldonado Technic[1]

Hernandez-Morales and Maldonado reported their results with this technic, with certain modifications, over a period of six months. Patients were asked to come to the outpatient department in the afternoon. No purgatives or enemas were recommended unless the patient was hospitalized. The rectoscope was introduced according to the usual technic. The first rectal valve was visualized, and feces, if present, were removed with a cotton swab. From the edge of the fold, a small piece of the rectal wall was pried loose with biopsy forceps, and the site inspected for any bleeding. This was controlled, if present, by pressure with a piece of cotton. The piece of tissue was pressed between two microscope slides with the help of Hoffman clamps, and examined by low power. The eggs can be easily seen and counted, and the live ones can be readily distinguished from the dead ones.

The method is based upon the fact that the *S. mansoni* lays its eggs principally in the thinner branches of the veins of the sigmoid and rectum of man. This fact was corroborated by finding, in one of the untreated cases, an adult female worm in the part of the submucosa that is usually included in the biopsy. This is one of the rare instances in which the parasite has been proved to migrate to such sites to lay its eggs. This method has proved the infection present in 100% of untreated cases of schistosomiasis against 40 and 62%, respectively, obtained through repeated examinations by the DeRivas method and the intradermal test. This test requires only a few minutes.

On several occasions, when stools had been repeatedly negative, the eggs were found by this method. It was also found by this method that the eggs could be divided into three major types: (1) The most common type is the egg which appears heavy and black under the microscope. (2) When the empty shell is found, since the yellow, chitinized remnant of the shell is all that remains of the egg, the eggs are collapsed or very transparent, and may be easily overlooked by the untrained eye. (3) The least common are the live eggs which appear just as in the sedimented stools. The miracidium is clearly outlined, with the flame cells active.

Another type of egg which cannot be placed under any of the above types is one that appears to have been recently laid, with both poles filled with granules that do not show any Brownian movement, and a clear central area. It is believed that these eggs are laid while still immature and therefore have failed to develop further.

Some eggs appear encircled in a pseudotubercle, either singly or in masses.

Schistosoma Haematobium (Bilharz 1852) Weinland 1858

The adult parasites usually live in the bladder and pelvic venous plexuses, although they may be found in the branches of the portal vein and exceptionally in other venules. The male is smaller and wider than the female. It is 10 to 15 mm. long and 0.8 to 1 mm. wide. It is covered by small tubercles and has two suckers. The body is folded from the ventral sucker to the posterior extremity to form a gynecophoric canal, within which the female lodges

---

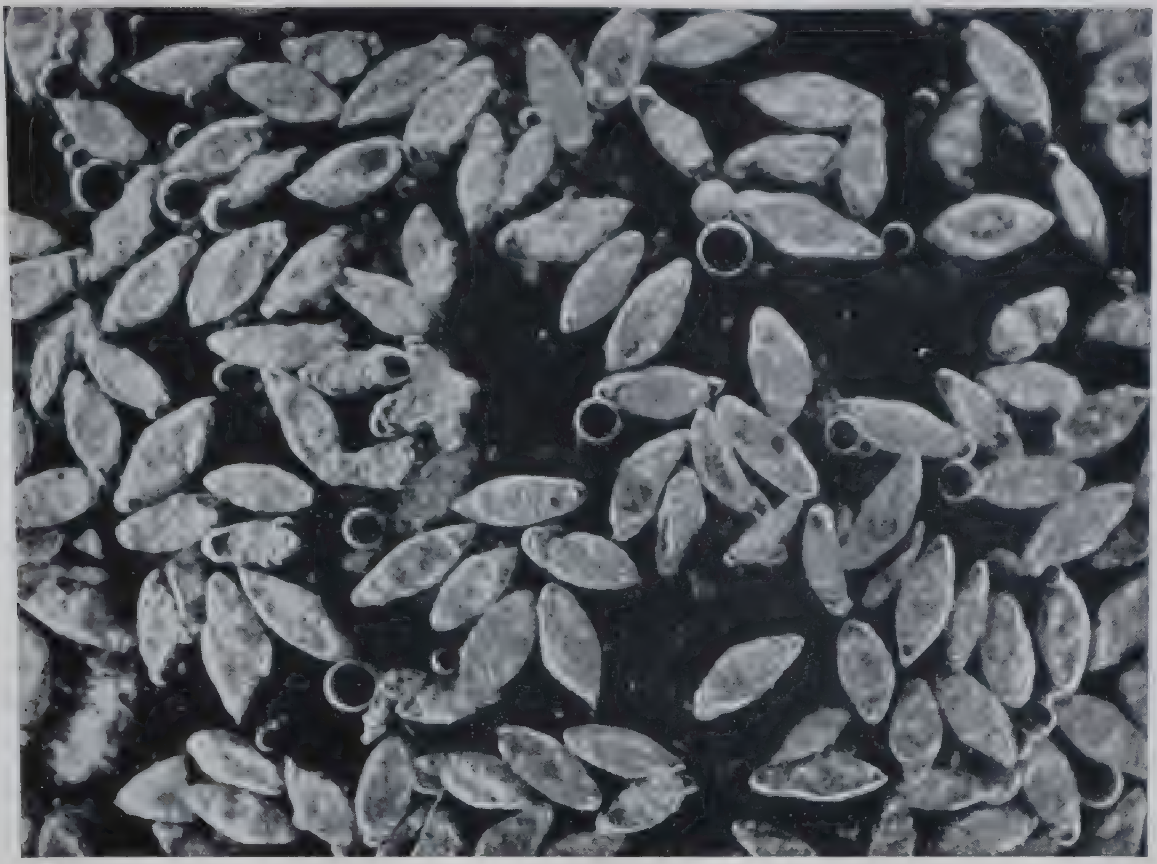

Fig. 552.—Eggs of *Schistosoma haematobium* in urinary deposit, photographed by dark-ground illumination. (Photomicrograph by D. M. Blair; published by permission of F. Goodliffe, Southern Rhodesian Public Relations Department.) (C. C. Chesterman, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

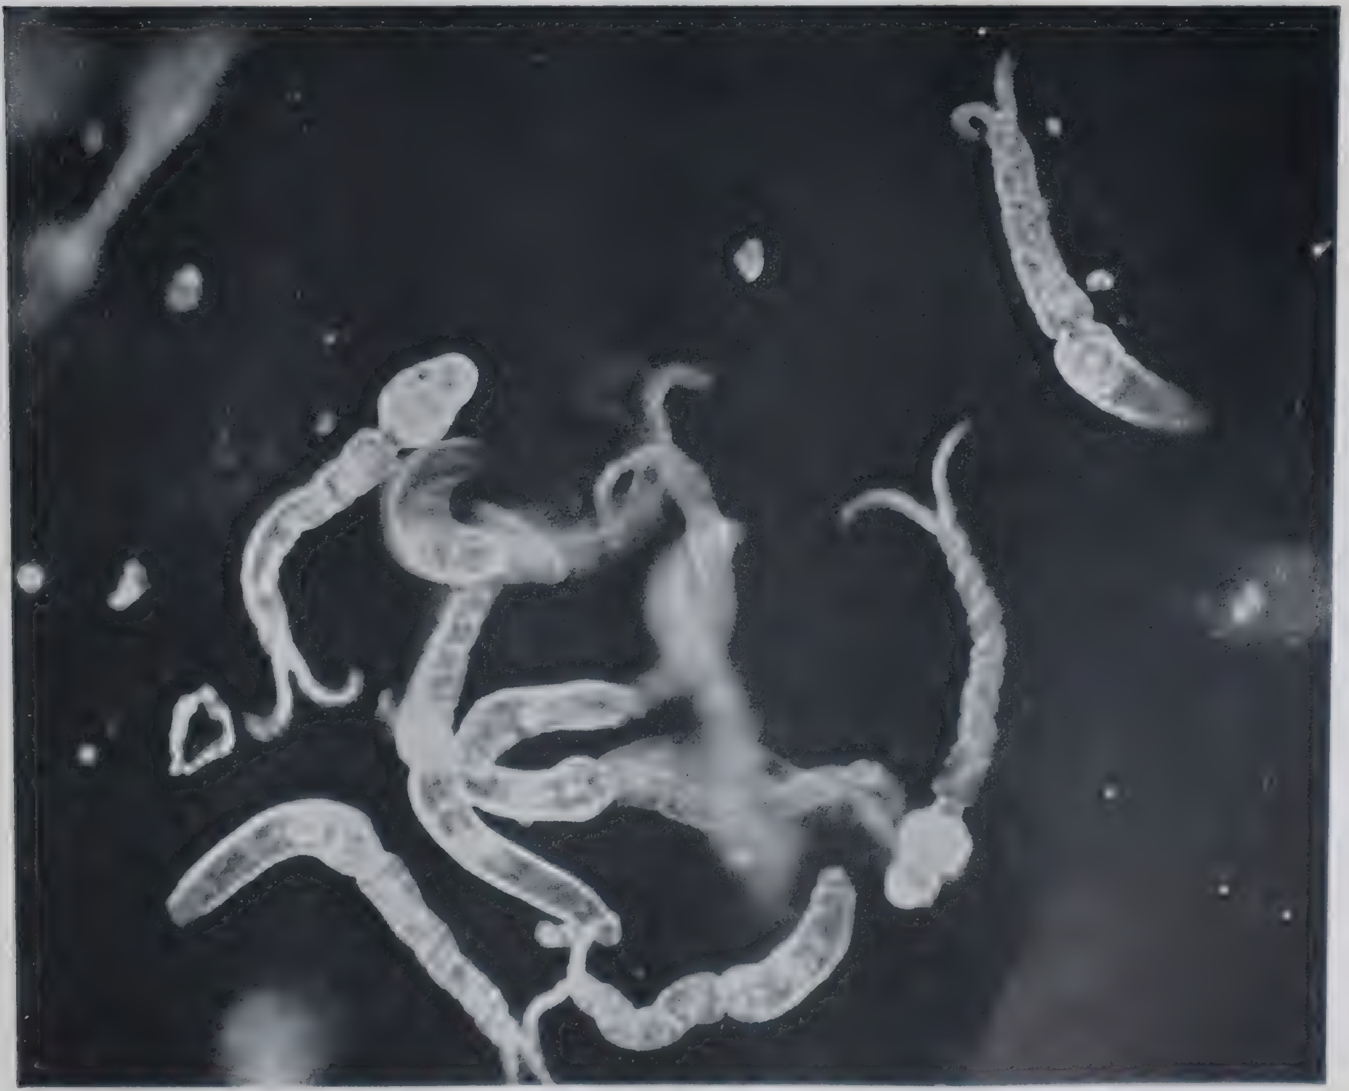

Fig. 553.—Schistosome cercariae photographed by dark-ground illumination. (Photograph by D. M. Blair; published by permission of F. Goodliffe, Southern Rhodesian Public Relations Department.) (C. C. Chesterman, in Gradwohl, Benitez Soto, and Felsenfeld: Clinical Tropical Medicine.)

during copulation and egg laying. The intestinal ceca extend from the pharynx to the center of the body; they unite there to form a single cecum, which terminates near the caudal extremity. The digestive tract is usually dark, the color imparted by the blood which it contains. Four to five testes lie behind the ventral sucker. There is no prostatic gland or cirrus or penis.

The female is long and slender, about 20 by 0.25 mm. The suckers are small, not uniform, and not very muscular. The ovules emerge from the ovary at the posterior extremity and pass through the oviduct to the oötype, where they are fertilized. There they receive the vitelline nourishment and shell-forming substances and pass into the uterus, where they usually number 20 to 30.

Eggs.—Eggs are oval, tapering to a pointed spine at one end, blunt at the other. They average about 150 by 60 microns. They have a yellowish-brown transparent cover.

Life Cycle.—The female usually lays the eggs in the small veins of the bladder or pelvic plexus, and assumes such position that the eggs are deposited with their spines directed backward, one following the other, until the small vein is completely filled. The female then migrates to another small vein to repeat the process. The eggs are almost mature when first laid; they bore through the walls of the vein and bladder mucosa and drop into the lumen of the organ in the extravasated blood. They are passed in the urine usually at the end of micturition. The miracidia leave the eggs when the urine is diluted more than 10 times, and swim about freely. They produce in the snail, their host, two generations of sporocysts, and finally the furcocercariae. These leave the snails in great numbers. When they leave the snail, they swim actively in the water, tail forward, at times descending to the bottom of the water, and at times rising to the surface, where they remain for a short time, clinging by means of their ventral sucker.

When man bathes in these infected waters, the cercariae come in contact with the skin at the surface of the water. As the water evaporates on the skin, the cercariae bore through the skin, seeking protection for themselves. First they shed their tails. Penetration through the skin is made easy by the active movements of the anterior extremity, as well as by the secretions of certain fluids by the glands of penetration.

The metacercariae enter the small veins, are carried to the right ventricle of the heart, thence to the lungs, where they remain for several days. They then bore through the respiratory and circulatory endothelia to enter the left ventricle of the heart. From this point they enter the general circulation. They enter the mesenteric artery, pass through the mesenteric capillaries, and enter the portal circulation. In the intrahepatic portions of the portal system, the larvae begin to feed and grow. At the adolescent stage, they begin to migrate against the current of the blood, pass through the inferior mesenteric veins, and at times localize in the rectal veins. As a rule, they pass through the hemorrhoidal veins and enter the bladder and pelvic plexuses, which they reach approximately three months after they have bored through the skin.

Diagnosis.—Diagnosis is made by finding the characteristic egg of the parasite in the urine, or exceptionally in the stools.

Schistosoma Japonicum Katsurada 1904

Schistosomiasis japonica is parasitism caused by the *Schistosoma japonicum* or the Oriental blood fluke, and is also called "Katayama disease." This disease occurs in south Japan, in the basin of the Yangtze River, and around Canton, parts of Yunnan Province, and in the Philippines. The real endemic areas in Japan are the Tone River, the Kofu, the Numazu, the Fukuyama, and the Kurume areas.

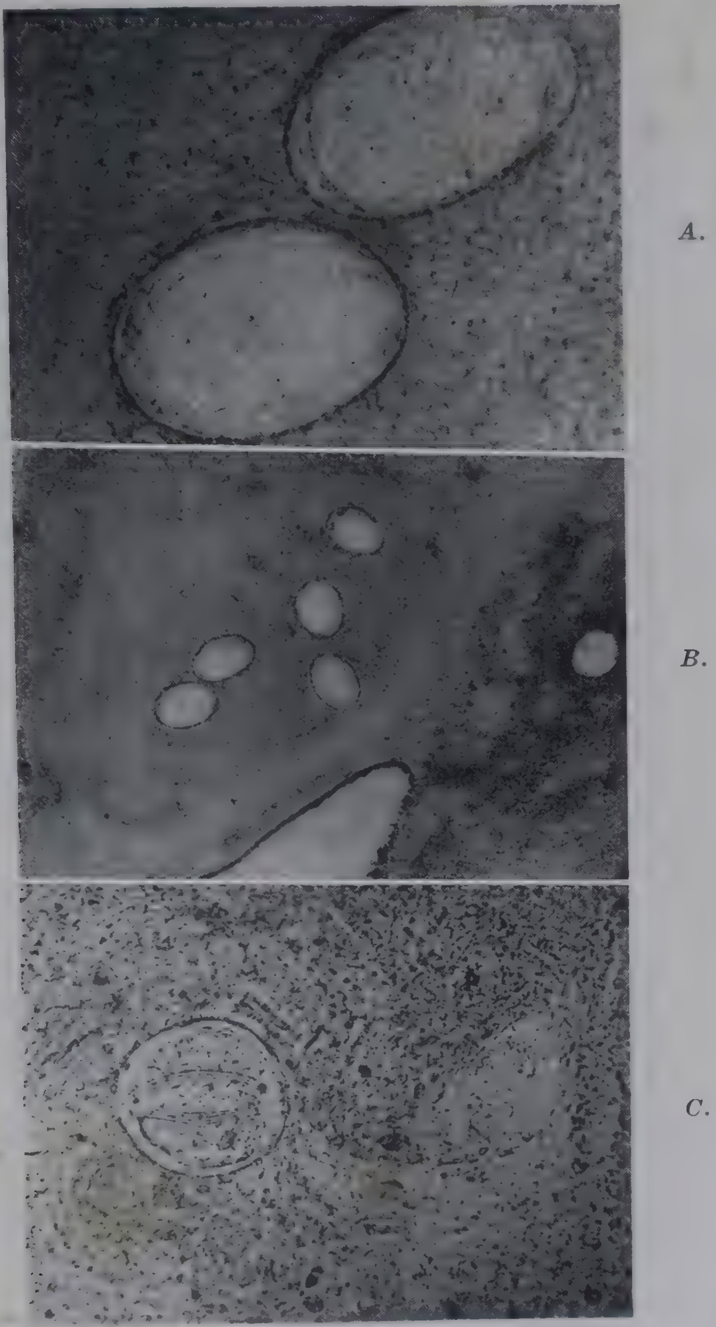

Fig. 554.—*Schistosoma japonicum* eggs. *A*, In bloody mucus of stool specimen; *B*, "nest" of eggs in bloody mucus; *C*, egg shell of *S. japonicum* showing typical break in the shell after emergence of miracidium—miracidium can be seen distinctly to the right of the egg shell. Water centrifugal sedimentation concentration method of Baroody and Most. (Original photomicrographs of B. J. Baroody.)

The adult *S. japonicum* resembles the *S. mansoni* and the *S. haematobium*, but it lacks the tubercular integument. The male is 12 to 20 mm. long and 0.5 to 0.55 mm. wide. It has an integument covered with small spines, more prominent near the suckers and the gynecophoric canal. There are 7 testes.

The female is about 26 mm. long and 0.3 mm. wide. It contains an integument covered with spines. The ovary lies behind the center of the body.

Vitellaria are limited to the lateral fields of the posterior quarter. The oötype lies immediately in front of the center of the body. The uterus is a long, straight tube, which contains up to 50 eggs at one time.

Eggs.—Mature eggs are usually but not always yellowish, discoid oval, and larger than the usual helminth eggs, varying from a minimum of 55 to 60 microns in length in the young eggs to a maximum of 85 to 90 microns in mature eggs. The shell may be covered with varying amounts of detritus, but is never completely obscured. A spine is always demonstrable in newly laid or immature eggs, but it is usually difficult to demonstrate in mature eggs.

The characteristic feature of the egg is the miracidium contained within it. It is well to call an object a schistosome egg only when both the outline of the shell and the embyo can be seen: (1) muscular twisting and jerking of the whole or parts of the miracidium; (2) ciliary action; and (3) the beating of the flame cells.[1]

The viable egg is biconvex, like the shell of a rather flat clam, and measures 58 by 44 microns. It has a noticeable wartlike thickening near one end at the site where the abbreviated spine is sometimes seen. Mature eggs show distinctive visible cilia, which are frequently in motion. Faust calls attention to immature eggs with many types and stages of degeneration, from early fertile but unsegmented stages to dead eggs which have partially or almost completely developed.

Life Cycle.—The *S. japonicum* characteristically lays its eggs in the small veins of the submucosa or even in the small veins of the mucosa of the adjacent organs. They are deposited in radicles of the superior mesenteric vein. These eggs pass from the submucosa to the mucosa, thence to the intestinal lumen, where they are expelled in the feces with some extravasated blood, and a life cycle similar to that of the *S. mansoni* and *S. haematobium* begins.

The amphibian snails which serve as intermediate hosts are *Katayama nosophora* in Japan and along the coast of China; *K. formosana* in Formosa; *Oncomelania hupensis* in the valley of the Yangtze River in China; *O. hydrobiopsis* and the *Blanfordia quadrasi* in Samar and Leyte, the Philippine Islands.

Diagnosis.—Diagnosis is made by finding the characteristic eggs of the parasite in the stools of parasitized individuals. Methods of finding these by concentration are given on pages 1805 to 1812. Blood eosinophilia, as well as the complement fixation test and clinical history of the patient, will serve in the differential diagnosis.

Differential Diagnosis.—

Needle Biopsy of the Liver.—In the chronic stage, the liver is enlarged, and remains tender, with an eventual fibrosis, and a portal cirrhosis develops. Some authors, such as Symmers, believe that the cirrhosis is secondary to the dietary conditions under which these patients live, and that the parasitic infestation is incidental. No adequate description of needle biopsy of the liver in schistosomiasis japonica has previously been found in the literature in reference to hepatic lesions. Stonehill, Cleve, and Webb[2] make an interesting observation on the diagnosis of schistosomiasis japonica by needle biopsy of the liver in the case where there is a chronic liver cirrhosis following this disease. They used a Vim-Silverman biopsy needle, and advocate this as a safe method of obtaining the specimen without exposing the patient to a laparotomy, if the usual diagnostic technics fail to reveal the organism. In their case, multiple rectal biopsies and concentration tests failed to reveal any eggs. This is in line with many reports where stool examinations fail to demonstrate the eggs. Even with rectal biopsies, failures have been reported as high as 11 per cent. With a history of possibility of exposure, needle biopsy of the liver should be considered as a means of establishing the diagnosis. A needle biopsy of the liver in the case cited by Stonehill and associates revealed the presence of an egg of *S. japonicum*.

Fig. 556.—Eggs of *Schistosoma intercalatum* in feces of man. (×135.) (Courtesy Fisher, A. C.: 1934. Tr. Roy. Soc. Trop. Med. & Hyg. 28: 277-306; by permission of the author.)

Schistosoma Intercalatum Fisher 1934 (?)

The adult worms are indistinguishable from *S. haematobium.* The male measures 11 to 14 mm. long by 0.3 to 0.4 mm. wide when not unfolded. There are 3 to 5 testes, usually 4. The mature female is 10 to 14 mm. long, with a maximum diameter of 0.15 to 0.18 mm.

Eggs.—Eggs are intermediate in shape and size between those of *S. haematobium* and *S. bovis.*

Schistosomiasis intercalata is a chronic disease caused by infestation of the inferior mesenteric veins by the adult worm; the eggs produce mild dysenteric and possibly other symptoms, but never invade the genitourinary organs. Sigmoidoscopy reveals characteristic lesions between the anal canal and the pelvirectal junction.

Diagnosis is made by finding characteristic eggs in the intestinal mucus, which can be scraped from the surface of a fecal mass or obtained by means of a rectal swab or curettage through a proctoscope.

DERMATITIS PRODUCED BY NONHUMAN SCHISTOSOMES

Cercariae of the Schistosomes which infect man, when boring through the skin, frequently give rise to a more or less marked itching. Cort in 1928 described a dermatitis produced by cercariae of Schistosoma which in the adult stage are incapable of infecting man. It is common in the north central states, as well as in other parts of the United States, in southern Canada, and in Europe. At least eight species have been reported as capable of producing this dermatitis or "swimmer's itch."

C. physella and *C. stagnicolae* have been reported in Michigan. The most important European form is the cercaria of *Trichobilharzia ocelallata* found in Germany, France, and Wales.

Cercariae penetrate the skin only when the water begins to evaporate on the swimmers.

DISEASES CAUSED BY LUNG FLUKES
PARAGONIMIASIS or ORIENTAL LUNG FLUKE

Paragonimiasis is parasitism caused by the *Paragonimus westermani.* It is also called "Oriental lung fluke." The disease originates in the Far East, where it is found especially in China, Korea, the Philippine Islands, Japan, Indo-China, and Formosa. Occasional cases have been reported in Peru, Venezuela, and the United States.

Family **TROGLOTREMATIDAE** Odhner 1914
Paragonimus Westermani (Kerbert 1878) Braun 1899

Paragonimus westermani is the causative agent of "pulmonary distomiasis," or "parasitic hemoptysis" in man. The worm is 8 to 16 mm. long, 4 to 8 mm. wide, and 3 to 4 mm. thick. It is reddish brown, and when kept in alcohol is the shape and size of a coffee bean. The oral sucker is subterminal; the ventral sucker a short distance in front of the center of the body. The suckers are almost the same size (1 to 1.4 mm.). The two blind intestinal trunks are sinuous and unbranched. The genital pore is near the posterior border of the ventral sucker. The parasite is covered with broad spines, varying in shape; those between the two suckers resemble a cluster of scales. The excretory vesicle is very large and extends to the bifurcation of the intestinal ceca.

Eggs.—The eggs are operculated, ovoid, reddish-brown, 85 to 100 microns long, and 50 to 60 microns wide. They are abundant in the sputum and less frequently found in the feces and other specimens.

The **life cycle** is found in Fig. 557.

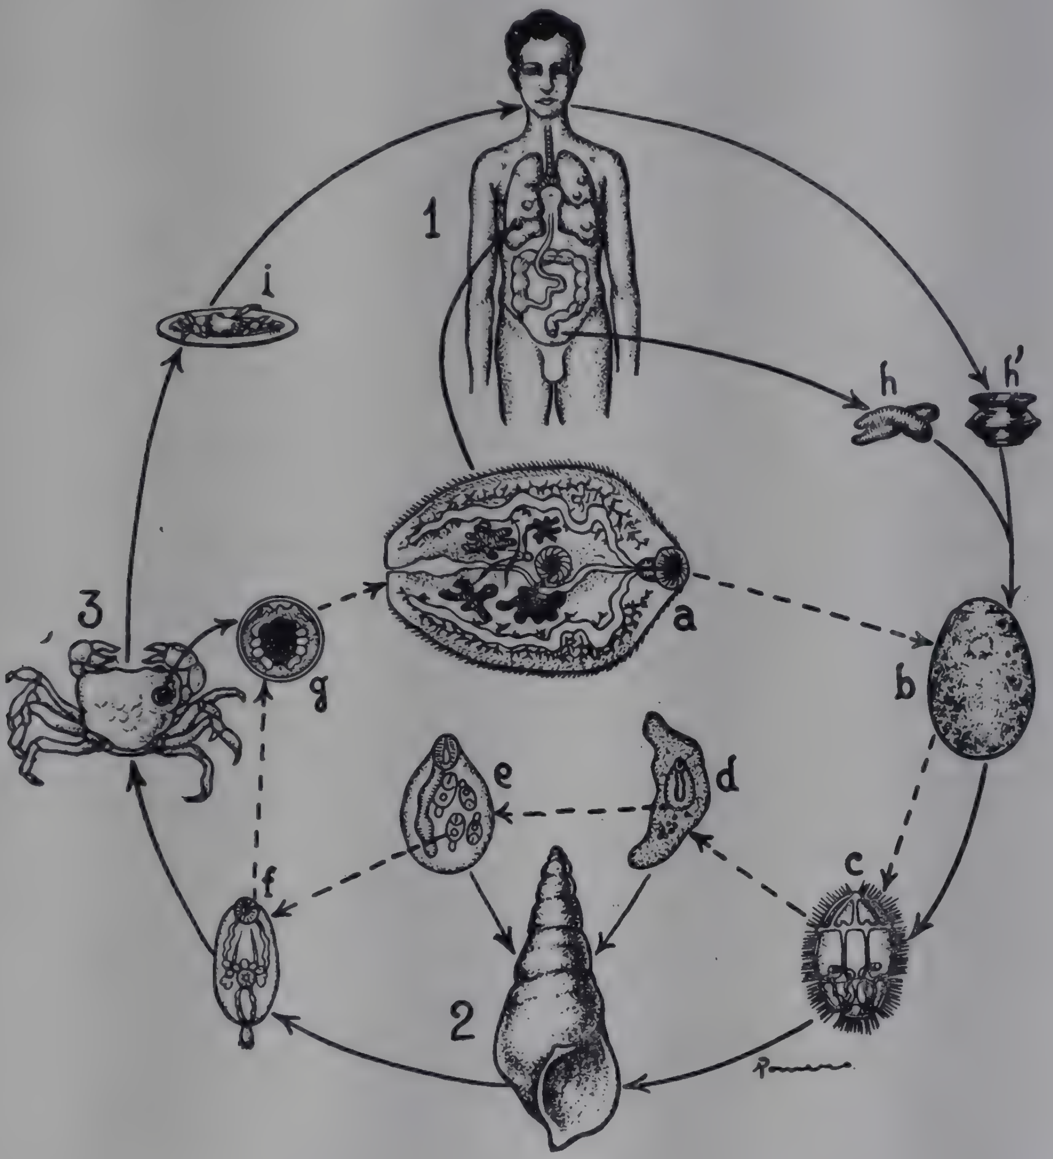

Fig. 557.—*Paragonimus westermani.* Life cycle. The habitat of the adult parasite is the lungs of the definitive hosts, of which man is one; they are found in small cystic cavities, usually in pairs. The egg (*b*) is coughed up in the sputum (*h'*) or passed in the feces (*h*), and a miracidium (*c*) is hatched in from two weeks to two months, depending on the temperature. It (*c*) bores into snails of the genus Melania, especially *Melania libertina* (*2*), one of the first intermediate hosts, develops into sporocyst (*d*) under the epidermis of the mollusk; usually only one redia grows. Daughter rediae (*e*) develop from this redia and become attached to the hepatopancreas of the mollusk, undergo parthenogenesis, and form the cercariae (*f*). These leave the snail and become attached to the thoracic muscles of fresh-water crabs and crayfishes, encyst and form metacercaria (*g*) which is infective 42 to 54 days. A young fluke is set free if the metacercaria is ingested with raw or poorly cooked intermediate hosts (3) (*Potamon dehaani*); it bores through the small intestine and the abdominal and thoracic cavities, remains 30 days, migrates to the pleura and bores through, gaining access to the small bronchi, where the parasites reach the adult stage and lay eggs. These eggs follow the respiratory canal and are expectorated in the sputum (*h'*). If they are swallowed, they are passed in the feces (*h*) to begin a new cycle. (Original arrangement by Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.) (*a,* After Manson; *b* and *2,* after Brumpt and Neveu-Lemaire; *c,* after Ameel in Brumpt; *3 d, e, f, g,* after Makagawa in Brumpt.)

Diagnosis.—A correct diagnosis of pulmonary paragonimiasis is made by examination of sputum, using the direct slide-cover slip preparation, and examining with a 10× ocular and 8× objective. The sputum is frequently stained with blood, and shows rust-brown flakes composed of clusters of eggs of the parasite. Differential diagnosis should be made from bronchopneumonia, tuberculosis, bronchial spirochetosis, and pleural effusion. Cysts in the lungs can be seen plainly in x-ray examination.

The eggs can be found in small numbers in the feces if the sputum is swallowed or in diarrheal stools if the parasite localizes in the intestine.

Family **OPISTHORCHIIDAE** Lühe 1908

CLONORCHIASIS

Clonorchiasis is caused by the parasite *Clonorchis sinensis*, or the Chinese liver fluke.

Clonorchis Sinensis (Cobbold 1872) Looss 1907

C. sinensis, a trematode, is a parasite of mammals which feed on fish. It is found in Japan, China, Formosa, Korea, and French Indo-China. It is prevalent in southeast China, occurs occasionally in central China, and is practically nonexistent in northern China. Emigration has not resulted in establishment of new foci of infection, since no adequate intermediate hosts have been found to exist in other countries. Many cases have been reported among the Cantonese in Cuba.

This fluke is transparent and elongated, with a thinner anterior than posterior extremity. When fixed in Formalin, some specimens are whitish, while others are brownish, more or less dark. Both forms may be present in one human liver. The parasite is very small, 2 cm. by 4 mm. The two ramified testes lie one behind the other, in the posterior portion of the parasite, behind the ovary and overlapping on each side of the intestinal cecum. A fine vas efferens or duct begins at each testis and extends forward in the dorsal plane; these unite to form a thin defferent duct, which shortly becomes thicker and forms the seminal vesicle, long and tortuous; this continues forward, still in the dorsal plane in relation to the uterine convolutions. It narrows at the ventral sucker into a fine, short ejaculatory duct directly toward the ventral surface, which opens into the genital pore in front of the ventral sucker. There is no cirrus or prostatic gland or cirrus pouch in this species.

The female genital apparatus consists of one ovary, sharply lobated, in the median line, at the junction of the third median and the posterior third of the body. It lies in front of a voluminous seminal reservoir, between this and the origin of the uterus or oötype, and is surrounded by the Mehlis gland. The vitellaria occupy the lateral portion, outside the intestinal branches, in the middle third of the parasite. These glands form a granular area which extends forward nearly to the ventral sucker, but does not quite reach it. There are two vitelloducts on each side, the anterior one long, the posterior one short, which unite to form the transverse vitelloducts. These converge toward the center to form the median vitelloduct which unites with the oviduct and the oötype where the Laurer duct and the seminal reservoir also open. The ventral sucker is smaller than the oral sucker. The intestinal branches are not ramified and end in the cecum near the posterior extremity of the body. There is a voluminous seminal receptable between the ovary and the anterior testes. The tortuous uterus extends from the oötype, near the ovary, to the genital pore, in front of the ventral sucker, and occupies the central portion of the body. The excretory canal is easily visible. It occupies a dorsal position in relation to the testes. The excretory pore appears as a protrusion in the center of the posterior extremity.

Eggs.—The egg is very small, characteristically pyriform, the posterior extremity being broader than the anterior. A prominent operculum can be seen at the narrower anterior end. It has a single yellowish-colored covering. It contains a completely developed miracidium when laid. The egg is 26 to 30 microns long by 15 to 17 microns wide.

Life Cycle.—The adult parasite lives in the bile ducts of man, dogs, cats, rats, swine, and certain wild carnivorous animals of the Far East which are the definitive hosts. The first larval forms develop within several species of mollusks or snails. The last larval stage encysts under the scales, on the skin, and in the muscles of the second intermediate hosts, which are several species of fresh-water fish. See Fig. 559.

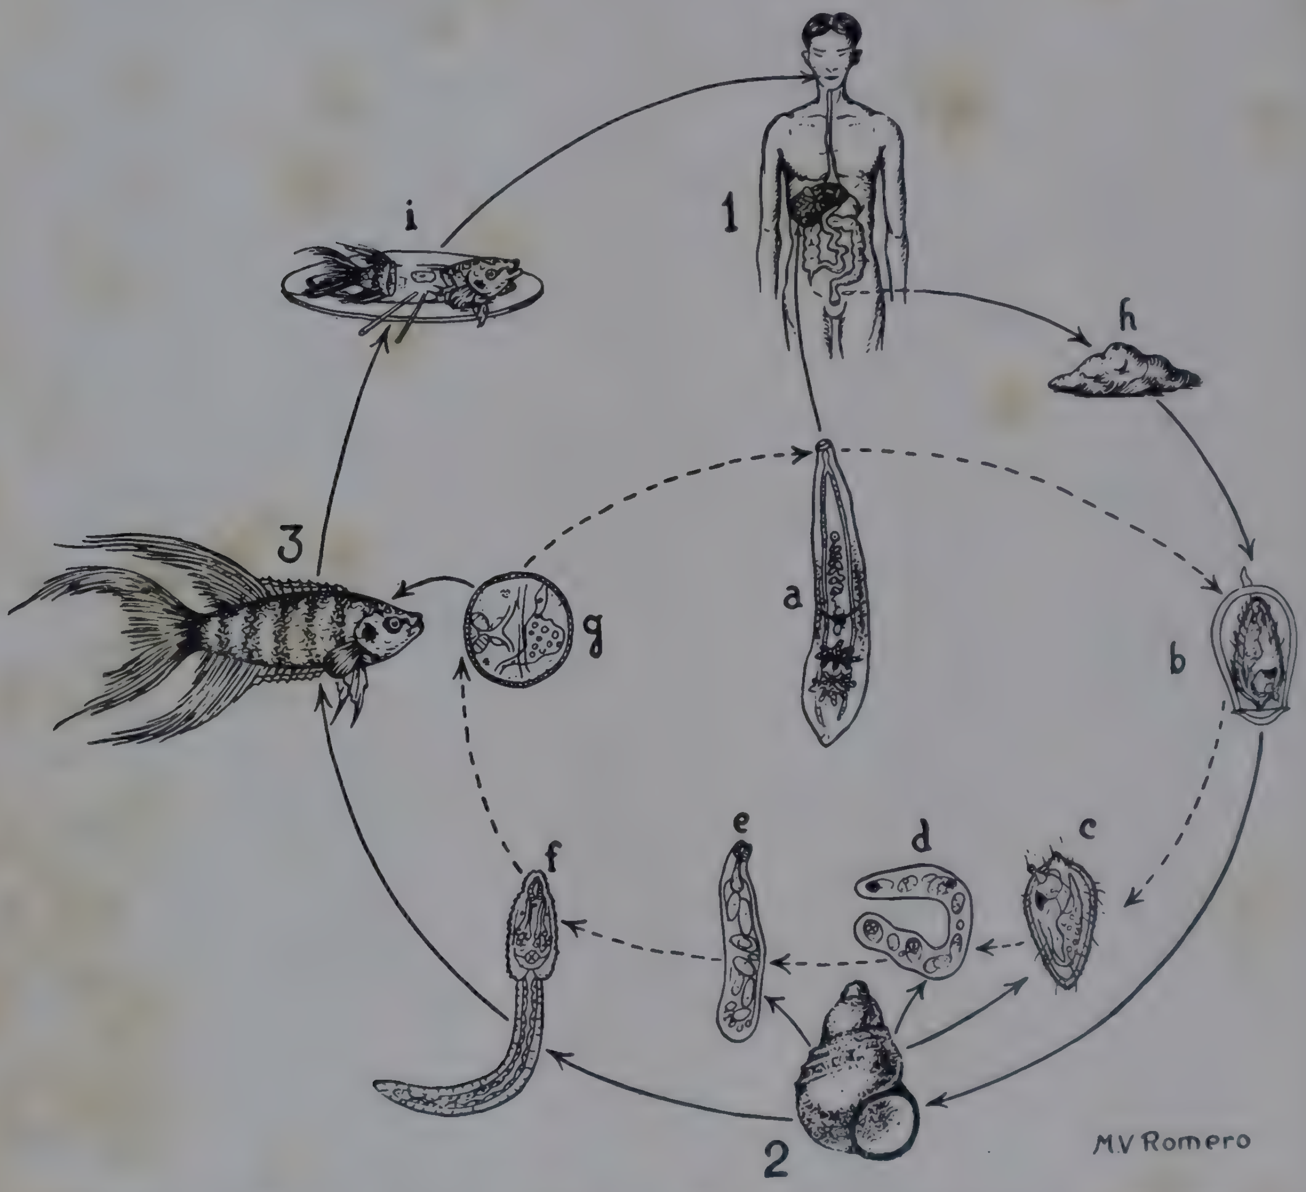

Fig. 559.—*Clonorchis sinensis.* Life cycle. The eggs (*b*), containing a miracidium, are passed in the feces (*h*), of the definitive host (*1*). If this egg (*b*) is ingested by an intermediate host (*2*), the miracidium hatches and bores through the esophagus of the mollusk (according to Faust and Khaw) to give rise to a sporocyst, rediae, and cercariae (*d, e, f*). The cercaria (*f*) leaves the snail and encysts as a metacercaria (*g*) under the scales, on the skin, and in the muscles of one of the second intermediate hosts (*3*), which are fishes. When the metacercaria (*g*) is ingested with the second intermediate hosts, it develops into an adult parasite (*a*) in the bile ducts of the definitive host (*1*). The eggs (*b*) are passed in the feces (*h*) to begin a new cycle. (Original arrangement of Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.) (*b*, In part after Faust and Khaw; *c, d, e, f, g*, after Faust and Khaw; *2*, after Germain and Neveu-Lemaire; *3*, after Neveu-Lemaire and Pellegrin. Others, original of Kourí and Basnuevo.)

This parasite may live many years in the biliary passages in man. Two cases of clonorchiasis have been reported in Panama.

Diagnosis.—In cases of digestive and hepatic disturbances, with or without fever and with eosinophilia, one should always keep in mind the possibility of clonorchiasis if the patient comes from the Far East. This disease has been found frequently in individuals who migrated from the Far East or

China to Cuba. They have shown symptoms or clinical pictures which simulated those of malaria, bilioseptic fevers, cholecystitis, hepatic colic, and jaundice. The diagnosis must necessarily be verified by microscopic examination of the feces and of bile obtained by duodenal intubation. The eggs are so small that they might escape detection in the stool, especially in thick preparations. It is well to examine the specimen under high-power magnification. Telemann concentration method is excellent. Or use Kourí's technic for examination for fascioliasis hepatica.

OPISTHORCHIASIS

Opisthorchis Felineus (Rivolta 1884) R. Blanchard 1895

Opisthorchis felineus causes a disease called the "cat liver fluke" disease. Human infection occurs as a result of eating raw or partially cooked fish infested with the metacercariae.

The parasite is found in dogs and cats in central and eastern Europe and in Siberia. It is the common parasite of dogs and cats in east and central Europe. The adult parasite is lanceolate, the anterior extremity being narrow and the posterior extremity rounded. It is 7 to 12 mm. long by 2 to 3 mm. wide. The living parasites are red or reddish-orange. There are no spines in the adult stage, but spines are visible in the sexually immature specimens. The ventral sucker is located in the anterior fifth of the body; the oral is subterminal and directed toward the ventral surface. It is followed by a bulbous pharynx, then a very short esophagus, which becomes bifurcated to form the intestinal ceca. These ceca extend almost to the posterior end of the parasite. The excretory pore is terminal. Testes are lobate and lie in the posterior fourth of the body, one on the right, one on the left of the excretory vesicle. The efferent vasa originate in the anterior portion of the testes and unite in the median region to form the vas deferens, which is directed forward, and widens to form the seminal vesicle, which ends in the ejaculatory duct, directed toward the genital atrium. There is no cirrus pouch or cirrus or prostatic glands. The ovary is small and ovoid and slightly lobate, lying along the median line slightly in front of the anterior portion of the excretory vesicle.

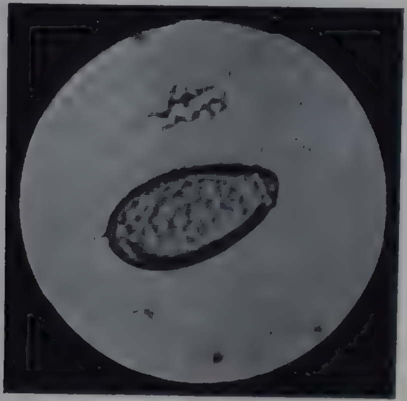

Fig. 561.—Egg of *Opisthorchis felineus* (×1,000).

Behind the ovary, to the right, is the Laurer duct; to the left is the seminal receptacle. In front of the ovary to the right is the oötype, surrounded by the Mehlis glands. The vitellaria occupy the middle third of the body, outside the intestinal cecum. The transverse vitelloducts unite to form one median vitelloduct, which joins with the oviduct before penetrating through the oötype. The uterus originates in the anterior portion of the oötype and is directed forward to form a tightly coiled tube, which ends in the vagina. The vagina opens into the genital atrium at the side of the male duct.

Eggs.—Eggs are ovoid, about 30 microns long, by 11 microns wide. When the egg is laid, the miracidium has already developed.

Life Cycle.—The egg must be ingested by the intermediate host before the miracidium leaves it. The intermediate host is *Bithynia tentaculata,* within which, near the region of the rectum, the sporocysts develop. About two months after the snail has been infected, the cercariae begin to leave. The cercariae adhere to the scales of the second intermediate host, the fish, lose their tails, then penetrate into the muscles of the fish, encysting after 24 hours. The cercariae, encysted in the muscles of the fish, require about six weeks to mature. When the definitive host ingests raw or partially cooked fish, the metacercariae leave the cyst in the stomach of the host, pass to the duodenum, and go rapidly through the ampulla of Vater to the distal bile passages, where they adhere to the biliary epithelium and grow to the adult stage in three to four weeks.

Diagnosis.—Diagnosis is established by finding the eggs in the stool, or the adult parasite.

Suborder **FASCIOLOIDEA** Stiles and Goldberger

Family **FASCIOLIDAE** Railliet 1895

FASCIOLIASIS

Fasciola Hepatica Linnaeus 1758

Fascioliasis hepatica is a cosmopolitan parasitism produced by the *Fasciola hepatica,* the sheep liver fluke. It is found in America, in Puerto Rico, Cuba, Venezuela, Argentina, and Chile; in Europe, throughout Italy, Romania, Hungary, France, Russia, and Scotland; in Asia, in China, Turkestan, Syria, Turkey; in Africa, in Algeria and French Somaliland; in Australia, in Queensland.

F. hepatica is quite commonly found among cattle. It is also found in hogs and sheep.

This fluke is flat and leaf-shaped, varying in size from 2 to 3 cm. long by 1 to 1.5 cm. at the widest portion. See Fig. 562. At the anterior extremity is a conical prolongation, on the tip of which is found the oral sucker. The ventral sucker lies from 3 to 5 mm. behind the oral sucker. It is larger and has a triangular opening, the base of which lies toward the anterior end. The body of the parasite narrows gradually. The posterior end is blunt. With a hand lens can be seen the following structures: The first two-thirds of the body has a whitish zone almost completely filled with the highly branched testes. The rest of the parasite is gray, the color imparted by the vitelline glands which are numerous. At times it is dark brown, the color coming from the digested blood in the blind intestinal branches which are numerous throughout this region. The rosette-shaped uterus is filled with eggs; it is a distinct yellowish mass continuing cephalad the clear zone described above. There is a rounded area corresponding to the ventral sucker lying before the uterine mass or rosette; in front of this are the cirrus sac and the small genital pore. The short esophagus, muscular pharyngeal blub, and the oral sucker are anterior to the aforementioned structures, in the order described. A circular zone, the cochlear or shell gland, is clearly visible directly behind the undulations of the uterus. Transverse vitelline ducts, vitelline ampulla, both located posterior to the cochlear gland, and the branched ovary at the right of the median line in front of the ramification of the anterior testes can also be seen. The short esophagus divides into trunks. The cirrus sac lies behind the fork made by the trunks. From its convex surface each trunk sends ramifications which extend toward the anterior conical prolongation of the parasite and is called the cephalic cone. The two trunks turn back on each side of the median line, then send out external ramifications which extend toward the borders of the body.

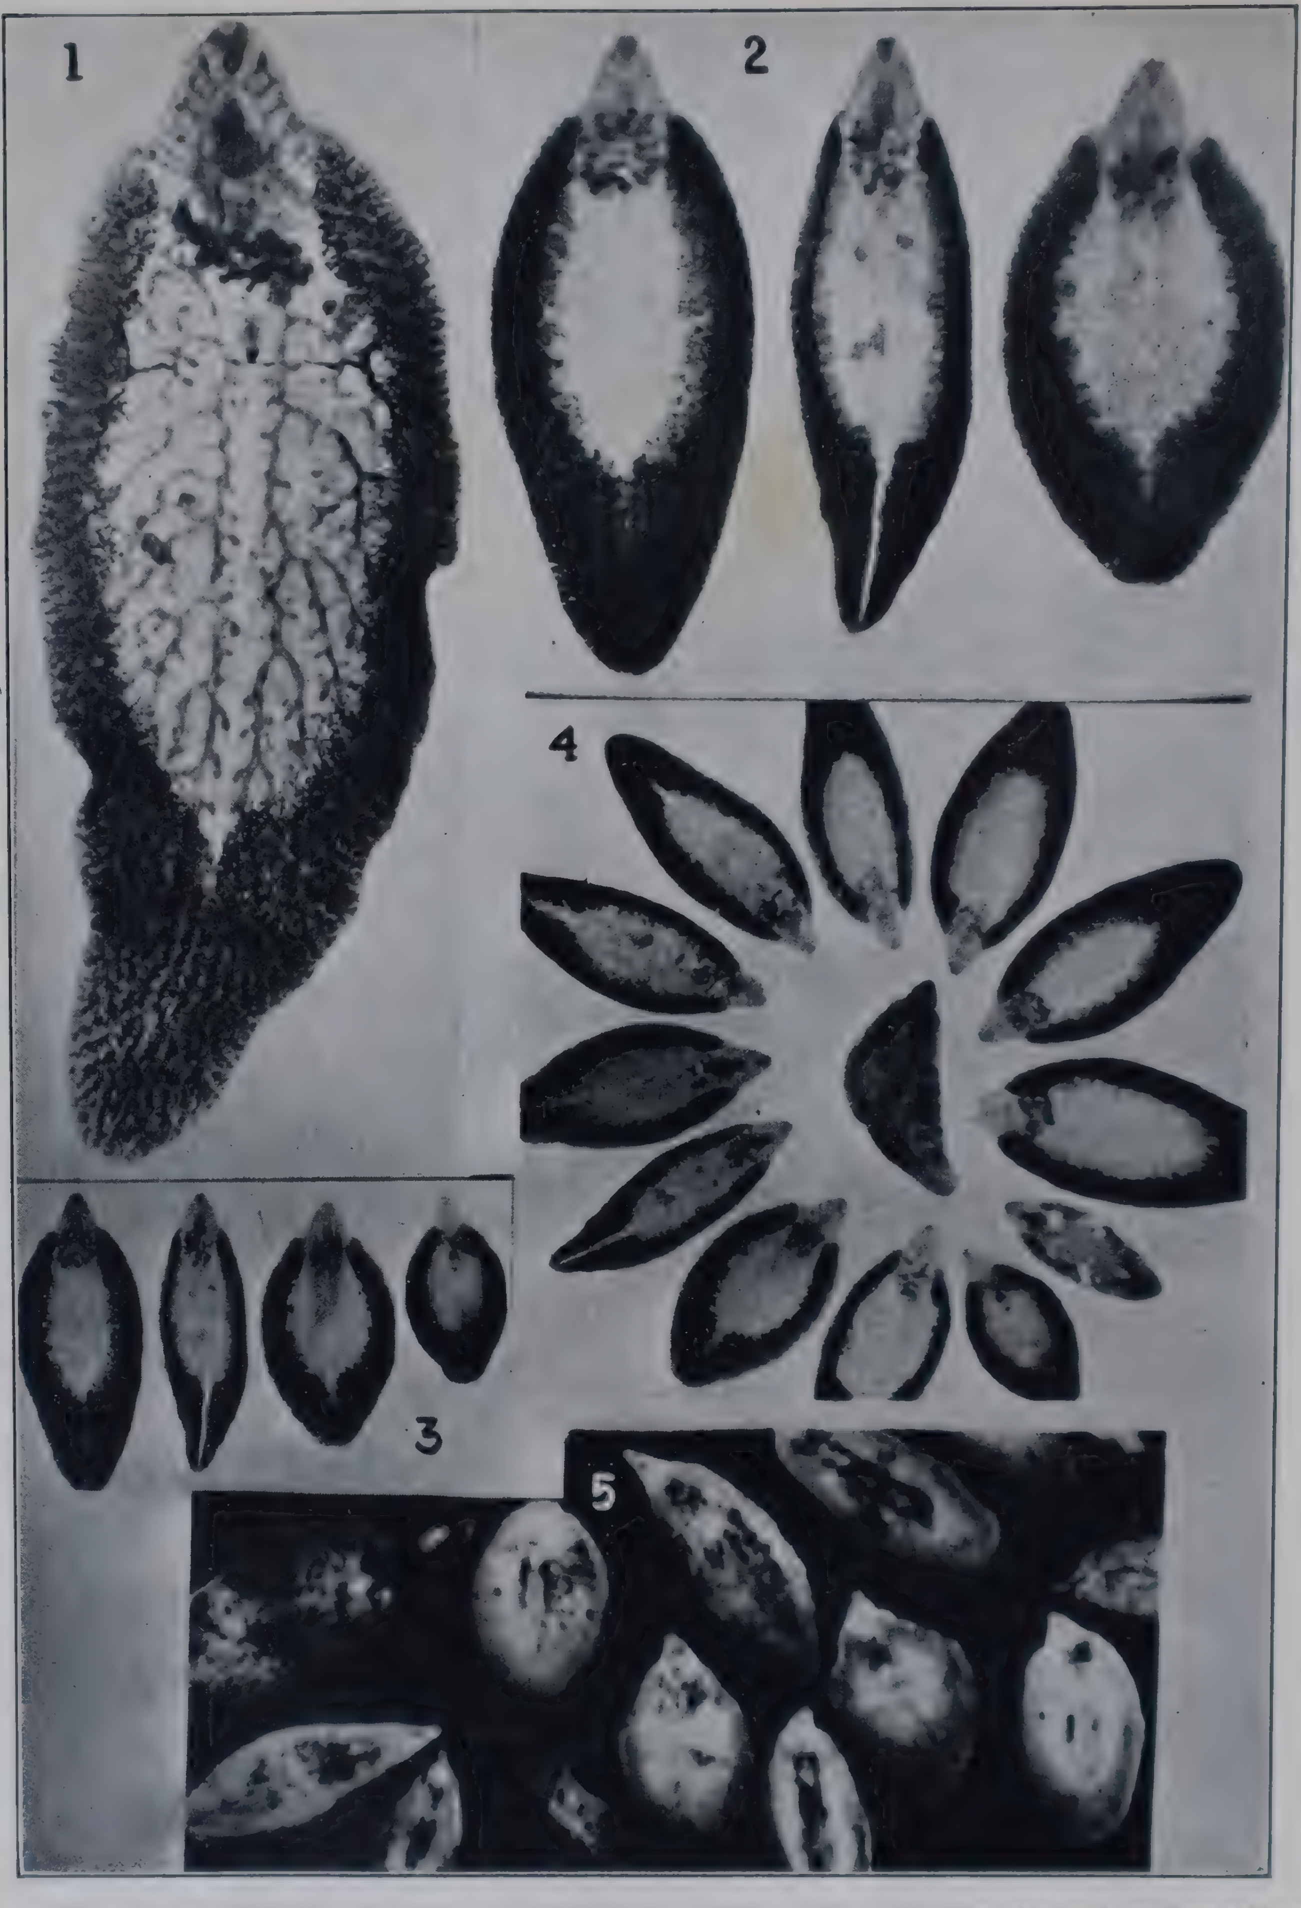

Fig. 562.—*Fasciola hepatica*, characteristic shape with anterior conical prolongations. The white central oval zone is occupied by the testes, *1*, *2*, *3*, *4*. The dark zone contains the vitelline glands. *1*, The white central zone is crossed by the two intestinal branches with lateral external ramifications. The trunks and their branches end in blind pouches. Proceeding from the front toward the back of the anterior conical prolongations, note the anterior (oral) sucker, pharynx, the arch formed by the intestinal trunks, the cirrus sac, ventral sucker, and the uterus.

1, Original of Vigueras and Moreno; *2* to *5*, originals of Kourí, Arenas, and Basnuevo; *1* to *4*, photographs illuminated from below; *5*, dark background, illuminated from above; *3* to *5*, natural size; *1* and *2*, various magnifications.

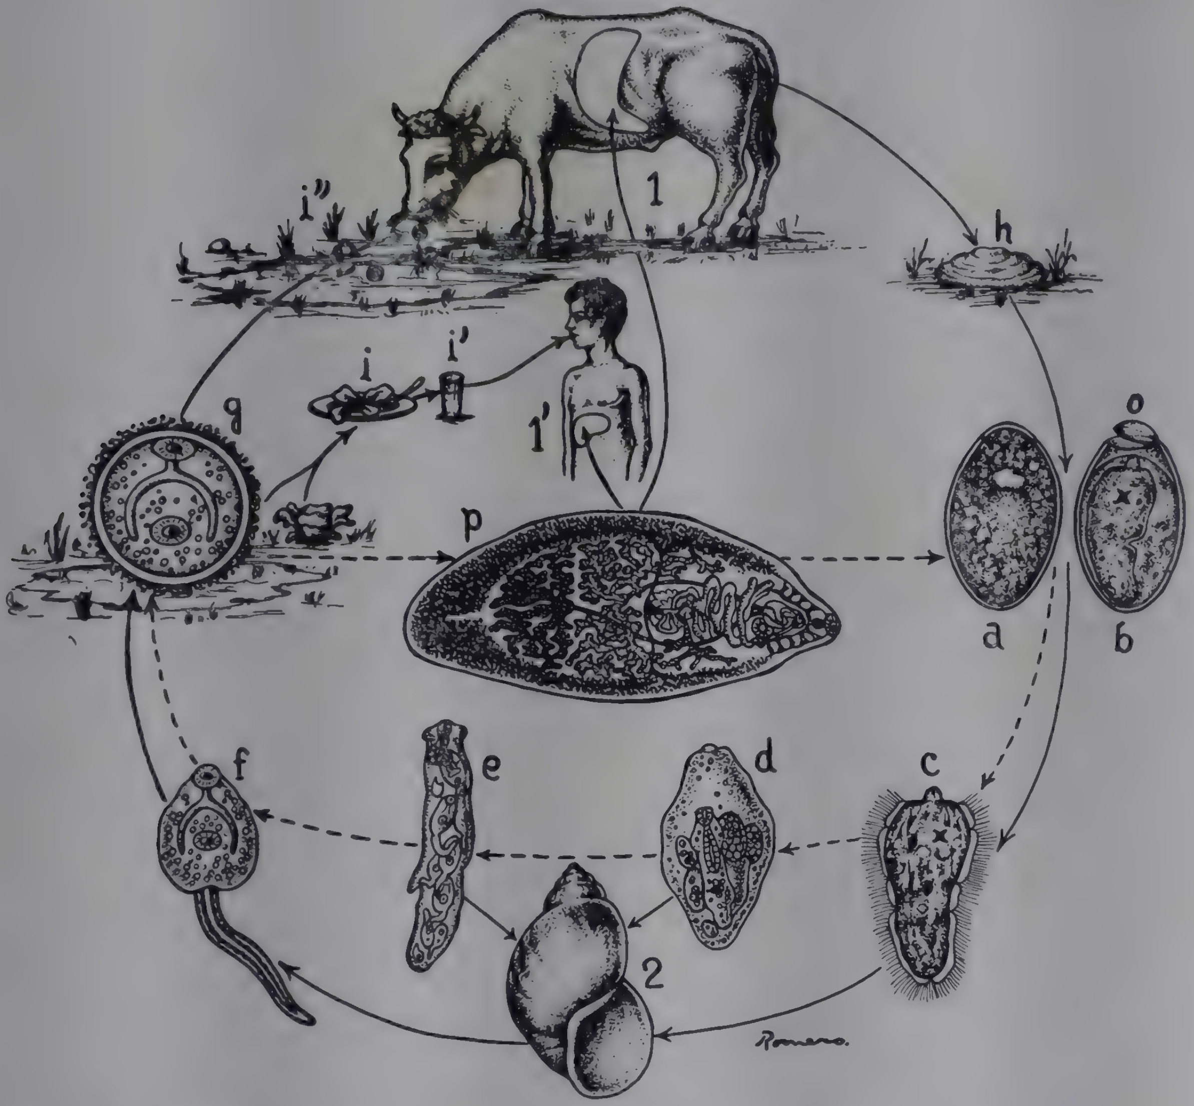

Fig. 563.—*Fasciola hepatica.* Life cycle. The adult parasite (*p*) lives in the bile ducts of the definitive host (cattle, *1;* man, *1'*). The eggs (*a*) are passed in the feces (*h*); after reaching the water they become embryonated (*b*), the miracidium (*c*) hatches through the operculum (*o*), and swim freely in the water until finding the intermediate host (*2*) (*Lymnea cubensis* and *Physa cubensis* in Cuba), where the sporocysts (*d*), rediae (*e*), and cercariae (*f*) develop. The cercaria (*f*) leaves the snail and becomes encysted in the water either freely or attached to water plants, developing into the metacercaria (*g*) which is the infective stage for the definitive host (*1, 1'*). When the definitive host ingests the metacercaria with water or vegetables (*i, i', i"*) it reaches the intestine, the cystic cover dissolves, and frees a young fluke; this bores through the intestinal wall and reaches the liver surface through the peritoneum; when boring through the fibrous capsule and the liver parenchyma, the parasite produces necrosis; in the bile duct it becomes an adult hermaphroditic parasite and lays eggs which are passed in the feces (*h*), beginning a new cycle. (Original arrangement by Kourí and Basnuevo in Lecciones de Parasitología y Medicina Tropical.) (*d, e, f, g,* After Leuckart; others, original of Kourí and Basnuevo.)

Human bile obtained through duodenal intubation. Case under treatment; specimens obtained after the initial doses of emetine.

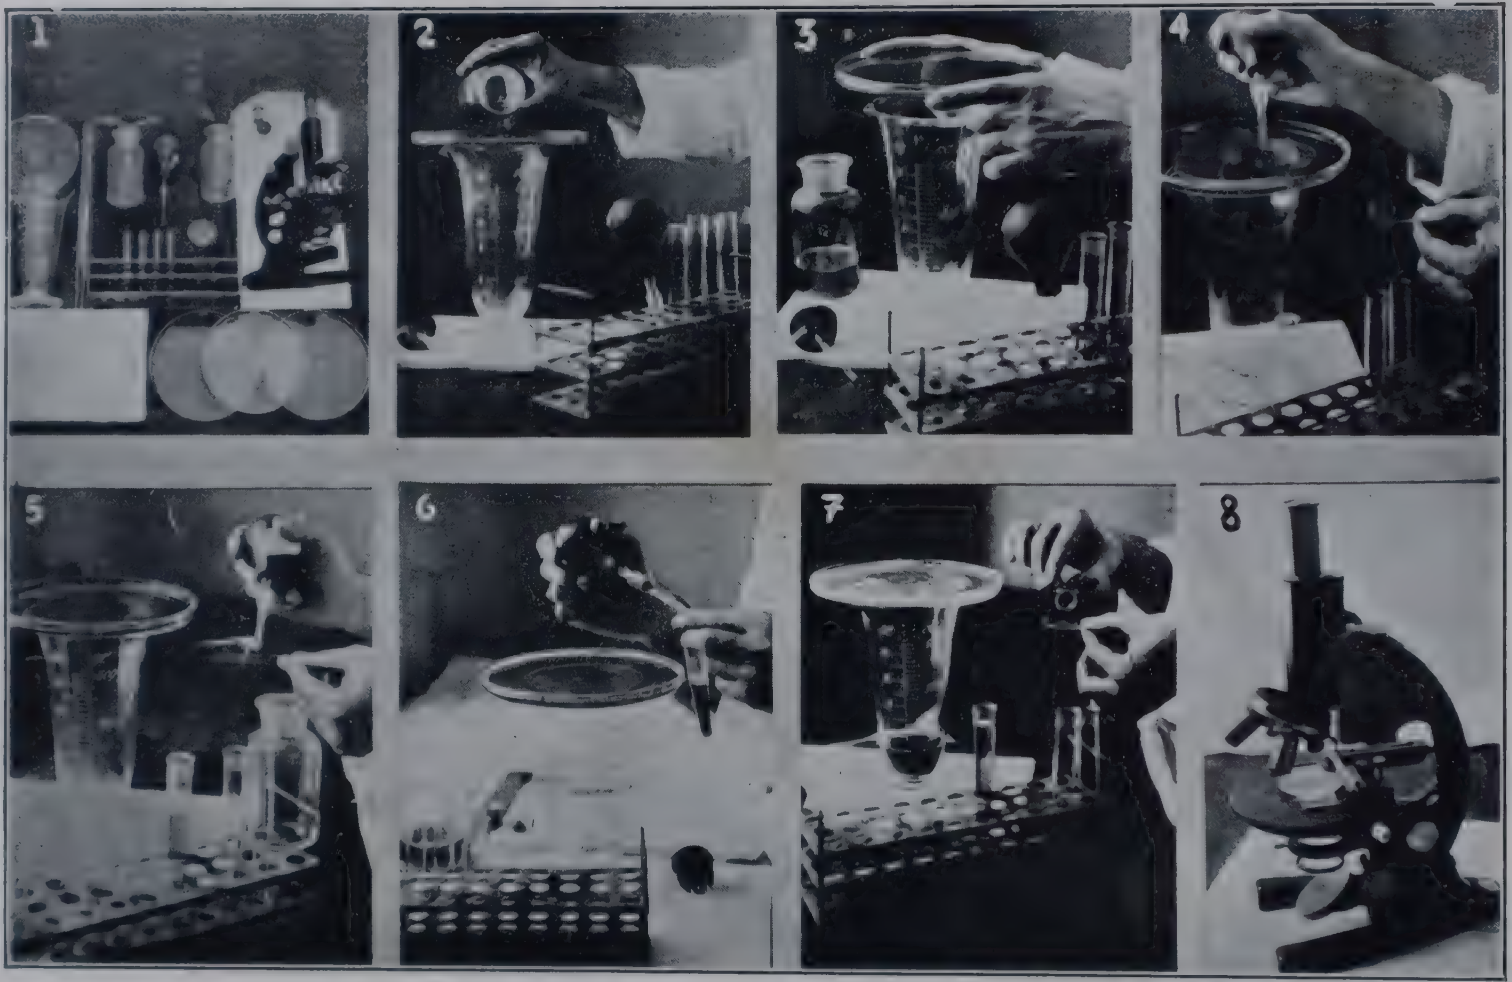

Fig. 566.—*Fasciola hepatica.* Kourí's method of examination of bile obtained through duodenal intubation for the diagnosis of biliary and duodenojejunal parasitism, particularly by *Fasciola hepatica.*

1, Materials needed: graduated beaker (500 to 1,000 c.c.), Petri dishes, 20 cm. in diameter, brick, mold, centrifuge tubes, pipettes, watch glasses, slides and cover glasses, microscope, substage lamp, black paper, white paper. *2*, Step 1: Pour bile into Petri dish on the beaker which is in turn placed upon a piece of white paper. *3*, Step 2: Observe macroscopic characteristics of bile, paying particular attention to the appearance of the suspended mucus. Move the Petri dish alternately over a black and a white background. *4*, Step 3: Brown or yellow mucus contains numerous eggs; white mucus contains none. Use a short pipette with a large bore and with a large bulb; suck up the suspected mucus flakes, transfer to a watch glass or slide. *5*, Examine microscopically. The eggs are found in greater numbers in the center of the watch glass. *6*, Step 4: Transfer all the flakes to the centrifuge tube. *7*, Step 5: Examine microscopically in a watch glass all the centrifuged flakes after washing them and decanting the supernatant fluid. *8*, Step 6: Place the watch glass with the flakes on a slide on the mechanical stage. Use low power (3X ocular, 3 objective, Zeiss). With binocular dissecting microscope examination is made directly in the Petri dish placed on the mechanical stage. This technic affords a rapid and accurate diagnostic method for fascioliasis hepatica. Examination of oviferous flakes (Kourí) usually provides sufficient evidence of infestation. This technic is very useful in clonorchiasis, lambliasis, and strongyloidiasis because of the frequency of negative results in examination of the feces. It is valuable in necatoriasis, ancylostomiasis, and biliary ascaridiasis.

Eggs.—The egg is one of the largest helminthic eggs of importance in human parasitology. It is ovoid, about 150 microns long and 80 microns wide in its widest portions. It has a yellow cover or shell, with a relatively small operculum. The contents consist of a fertilized ovule, often near one of the poles, surrounded by numerous polygonal vitelline cells.

Life Cycle.—The eggs are excreted in the feces. In tropical countries, they embryonate in water in about 2 or 3 weeks at a temperature of about 20° C. (68° F.). Embryonation of the eggs results in ciliated embryos which escape through the opercula, and swim freely in the water. The complete life cycle is given in Fig. 563.

Development of *F. hepatica* in the bile ducts may cause a series of lesions known as hepatic distomiasis, or, more specifically, hepatic fascioliasis. During the period of invasion, there is a febrile eosinophilia, and acute abdominal symptoms with hepatitis. The eggs do not appear for three months. The majority of patients studied have given a long history of gastrointestinal, hepatobiliary, nervous, and general disorders. The real cause of this disease is not known until the parasite is discovered in the patient.

In Fig. 566 is found Kourí's method of examination of bile obtained through duodenal intubation.

Diagnosis.—Examination of the feces may show the characteristic eggs of the parasite. Direct examination of feces and concentration methods for eggs should be used. One or more negative coprologic examinations are not sufficient proof to deny, in an absolute way, the possibility of distomiasis by *F. hepatica.* For further proof, one must resort to parasitologic examination of the bile obtained through duodenal intubation. See Fig. 566.

Eosinophilia is quite frequent. Intradermal reaction, precipitin reaction, and complement fixation reaction are indirect methods which may be of some value. The antigen used consists of extracts of *F. hepatica.*

DISEASES CAUSED BY INTESTINAL FLUKES

None of the diseases caused by intestinal flukes has been reported in the Western Hemisphere.

FASCIOLOPSIASIS

Fasciolopsis Buski (Lankester 1857) Odhner 1902

Fasciolopsis buski, also called the "giant intestinal fluke," is found in central and southern China, Formosa, Siam, Borneo, Sumatra, Assam, and Bengal. It is a common parasite of man and pigs.

The adult worm, which attaches itself to the walls of the duodenum and jejunum, is a large, fleshy parasite, at times oval, but usually elongated and ovoid. It varies in size, from 20 to 75 mm. long, 8 to 20 mm. wide, and 0.5 to 3 mm. thick. The surface of the parasite is covered with spines. The oral sucker is about 0.5 mm. in diameter, while the ventral sucker is approximately 3 mm. in diameter. The intestinal ceca are not ramified. The testes have many branches and lie one behind the other in the posterior half of the parasite. The cirrus pouch is elongated, with a seminal vesicle, sinuous in the posterior portion. Prostatic glands surround the ejaculatory duct. It has a muscular type cirrus canal covered with spines, and a pre-cirrus canal which opens into the general atrium, which is immediately in front of the ventral sucker. The oötype is found in the center of the parasite and is surrounded by the Mehlis gland. The ovary is ramified and lies to the right of the median line. The Laurer canal is small, a seminal receptacle not having been described. The vitelline glands are formed by small, granular follicles, which extend into the

lateral fields, from the ventral sucker to the caudal extremity. The uterus follows a tortuous course between the öotype and the metraderm, which can be found immediately within the genital pore.

Eggs.—The eggs are quite similar to those of *F. hepatica.* They are 130 to 140 microns long by 80 to 85 microns wide, and are provided with an operculum. They do not contain a developed miracidium when first laid.

Fig. 568.—Life cycle of *Fasciolopsis buski.* (Chart planned and drawn by Dr. Alfonso Bonilla Naar, of Bogotá, Colombia, and published through his courtesy by permission of copyright owner, General Biological Supply House, Chicago, Illinois.)

Life Cycle.—The eggs are passed in the feces of the definitive host. It requires 3 to 7 weeks at 26° to 32° C. (79° to 89° F.) for the miracidium to develop. This miracidium forces open the operculum and swims freely until it finds an appropriate host, a snail. It penetrates into the soft tissues of the snail, and in a few weeks gives rise to sporocysts, rediae, and cercariae. The molluscan hosts in China and Formosa are *Planorbis caenosus, Segmentina nitidella, S. calathus,* and others.

The cercariae are quite similar to those of *F. hepatica.* In endemic regions, cercariae encyst in the roots and bulbs of certain aquatic plants. Man is infected by husking the infected plants between the teeth and lips, before eating the contents. The metacercariae leave the cyst in the duodenum, and cling to the walls of the intestine, where they grow to the adult stage in about 3 months. Human infection is associated with eating certain uncooked aquatic plants cultivated in endemic areas where the appropriate host is abundant.

The life cycle is further exemplified in Fig. 568.

Diagnosis.—Diagnosis is based on finding the eggs in the stools of parasitized individuals.

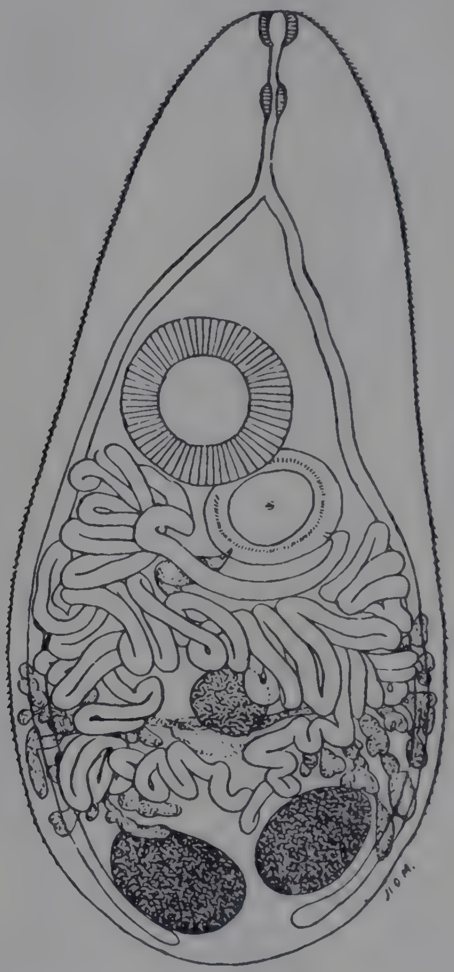

Fig. 569.—*Heterophyes heterophyes,* after Mönnig; adult, ventral face. Note that the posterior extremity is thicker than the anterior. Note the large ventral sucker (acetabulum), and, immediately behind it, the characteristic genital sucker. The two testes are oval, posterior, and horizontal. (×60.) (Kourí and Basnuevo: Lecciones de Parasitología y Medicina Tropical.)

HETEROPHYIASIS

Heterophyes Heterophyes (von Siebold 1852) Cobbold 1886

The worm is very small, 1.5 mm. long and 0.5 mm. wide.

Eggs are small, brownish, and have a thick shell; they are about 26 to 30 microns by 15 to 17 microns.

This fluke is a habitual parasite of dogs, cats, rabbits. It has two intermediate hosts, a salt-water mollusk, and fishes of the family Mugilidae, in the muscles of which the metacercariae infective for man encyst. Man is infected by eating fish contaminated with the parasite.

METAGONIMIASIS

Metagonimiasis is parasitism produced by *Metagonimus yokogawai*. It is found in the Far East, in Northern Siberia, the Balkan States, and Spain.

Metagonimus Yokogawai Katsurada 1913

The adult parasite is very small, 1 to 2.5 mm. long by 0.4 to 0.75 mm. wide. The body is pyriform. The posterior extremity is rounded; the anterior extremity is narrowed and covered with scales. The ventral sucker lies to one side of the median line. The oral sucker is continued by the esophagus which is divided into a pair of intestinal ceca which end in the posterior region of the body. The excretory vesicle is tubular and has two prolongations. The testes lie in the posterior extremity. They are partially or completely lobulated. The ovary is globular, approximately the same size as the testes, and lies along the median line, at the junction of the middle third with the posterior third of

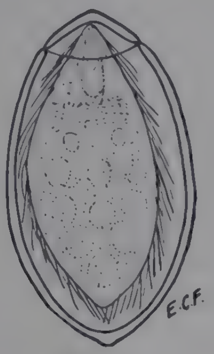

Fig. 570.—Egg of *Heterophyes heterophyes*. Camera lucida drawing. (×1,120.) (Original figure in Human Helminthology by Faust, 1939. Courtesy Lea & Febiger, Philadelphia.)

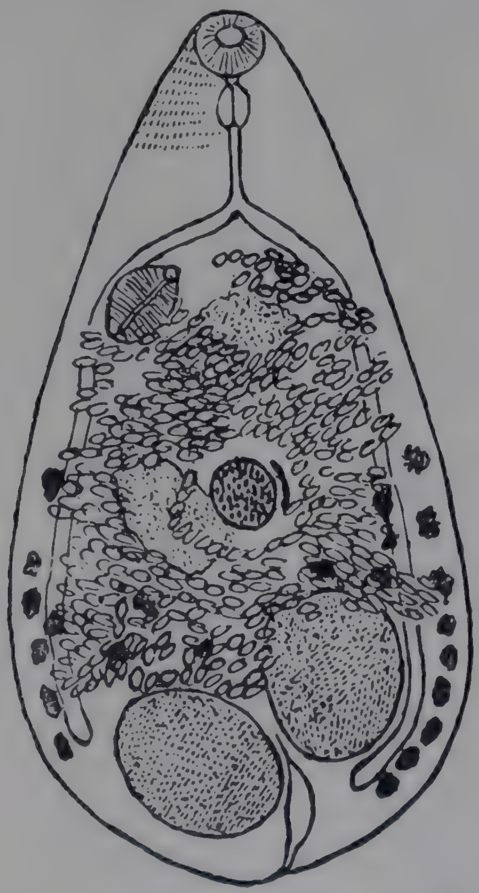

Fig. 571.—*Metagonimus yokogawai*. (×50.) The spines are shown only over a small part of the skin. (After Leiper.) (From Fantham, Stephens and Theobald: The Animal Parasites of Man. Bale, Sons and Danielsson, Ltd., London.)

the body. Toward the back and slightly to the left are the seminal receptacle and the Laurer canal. The oötype and the Mehlis gland are at the left of the ovary. The vitelline glands form a fan-shaped cluster on each side of the parasite. The vitelloducts are directed toward the center of the parasite, forming a median vitelloduct behind the oötype, which it penetrates with the oviduct. The uterus follows a sinuous course until it opens, with the ejaculatory duct, into the genital atrium.

Eggs.—The eggs are brownish-yellow, operculated, ovoid, and 28 microns long by 17 microns wide. When first laid, the eggs contain a completely developed miracidium.

Life Cycle.—The first intermediate hosts are the *Melania libertina* and the *M. ebenina,* within which the sporocysts, rediae, and cercariae are formed. These leave the snail and swim freely in the water until they reach an appropriate host. They attack the host and bore under the scales into the muscles of the fish, the second intermediate hosts. The most common intermediate hosts in Japan are the fresh-water fishes. The larvae encyst in the muscles and grow according to the quantity of nutritive material available and the length of time they have to spend within the fish.

Man is infected by eating raw contaminated fish. In the duodenum, the young distome breaks through the cystogenic membrane which protects it as it passes through the stomach, and adheres to the intestinal mucosa, where it grows into an adult parasite.

Diagnosis.—Diagnosis is based on finding the eggs in the stools, where they must be differentiated from those of *Clonorchis sinensis* and *Opisthorchis felineus.*

DISEASES CAUSED BY ARTHROPODA

Bacteria-Carrying Arthropoda

Arthropoda may carry bacteria and may also serve as intermediate hosts for certain animal parasites. There are a number of mites which may attack man by burrowing into the skin, thus causing inflammation and itching. These are known as mites, red bugs, chiggers, etc. There are many ticks which produce irritating lesions on the skin, but do not produce disease. There are certain ticks, however, that are intermediate hosts for transmission of diseases like relapsing fever and Rocky Mountain spotted fever. Rocky Mountain fever is communicated by the wood tick, *Dermacentor andersoni.*

Certain parasitic insects are found in practice: lice, fleas, and the larvae of certain flies. Fleas have favorite hosts, but may fly to other species. The best-known human flea is called the *Pulex irritans.* A dog flea, *Ctenocephalus canis,* also attacks man at times. The rat fleas, *Xenopsylla cheopis* and *Ceratophyllus fasciatus,* are important because they are concerned with the transmission of plague.

Sarcoptes Scabiei Var. Hominis

A full discussion of the life cycle of *Sarcoptes scabiei* var. *hominis* has been given by Lieutenant Commander Eugene A. Hand (MC) U.S.N.R.*

---

*U. S. Nav. M. Bull. 46: 834, 1946. Permission has been given by the Navy Department, through Captain Louis H. Roddis (MC) U.S.N., Editor U. S. Naval Medical Bulletin, to use the facts and figures presented here.

The first description of *Sarcoptes scabiei* var. *hominis* was given by Bonomo[1] in 1687. This author verified the findings of Friedman[2] that the Acarus could easily be demonstrated by the scrape and smear method and also that the diagnosis could be made from finding the eggs, filled or empty, skeletal parts of the Acarus, the larvae, and the scybala as well as from the adult Acarus. Mary Hopper[3] found this scrape and smear method also by accident and has used it at the Cornell University Medical School. The photomicrographs (Figs. 575 to 583) of the adult female, the hexapod larvae, the Acarus eggs in various stages of hatching, empty Acarus eggs, the Acarus burrow, skeletal parts of the Acarus, and scybala are shown to aid in identifying them.

digital webs, on the hands, wrists, and axillae, use a sharp razor blade to shave off a very thin slice of the vesicle, burrow or cuniculus, or excoriated papulae. For lesions on the abdomen, genitalia, buttocks, and other parts less easily reached, scraping of the lesion with a sterile razor blade or Bard-Parker knife is best. Place the thin slice of epidermis, or the scrapings, on a glass slide, cover with a cover glass, and mount in 10 to 20 per cent potassium hydroxide solution, glycerin, water, or saline solution. Then examine the slide under low power, using the high power when needed.

Potassium hydroxide is used when one wishes to make a quick diagnosis as it rapidly breaks up the skin cells making it easy to see the Acarus or any of its parts or products. If saline solution or water is used it is possible at times to find a scabies organism near the surface of the skin examined and then evidence of vitality can be seen.

Life Cycle (after Brumpt[4]).—The eggs hatch 7 days after being laid, releasing the hexapod larvae, which soon leave the burrow to live on the healthy normal skin where they enlarge and undergo several molts. The first molt occurs about the sixteenth day, giving rise to the octopod nymph which has 12 dorsal spines. These live in crusts on the surface of the skin and molt again about the twenty-first day. Another molt occurs about the twenty-eighth day, setting free pubescent males and females, which copulate. The fertilized females undergo further growth and development before becoming adults. About the sixth week a final molt occurs, and the female develops an oviduct for laying eggs. The female adult is pearly gray or pinkish and is

---

[4] Brumpt, E.: Précis de parasitologie, ed. 5, Paris, 1936, Masson et Cie.

330 to 350 microns long and 250 to 350 microns wide. The female, fertilized, oviparous adult then burrows into the skin making its characteristic burrow, laying eggs as it goes. The eggs nearest the Acarus in the burrow are the ones most recently laid. The eggs measure 150 by 100 microns. The female egg-bearing adult inhabits the end of the burrow. The males at times live in the burrow but usually are found outside the burrow under the epidermis. The male is pinkish and measures 200 to 235 microns long and 145 to 190 microns wide. The male organism has a penis and sucker in place of the last pair of posterior legs. The male Acarus is a very elusive creature and is rarely seen.

Myiasis

(Parasitic Larvae of Flies)

Myiasis is a disease caused by larval flies in man and beast. There are two types: Myiasis interna and externa.

The larval flies are small, whitish-yellow to light brown, wormlike structures, usually consisting of 11 to 12 segments. The forward part is smaller than the posterior part. Each segment carries a crown of fine hooklets or hairs. The mouth shows two deeply stained sharp hooklets. On the posterior end are two dark spots which are the openings of the respiratory organs. The size, dependent upon the developmental stage, is from a few millimeters to 10 or 15 mm. Many varieties can be artificially grown in moist air to full development.

Myiasis Muscida

Myiasis muscida is caused by various species of Diptera, such as *Musca domestica, Fannia canicularis,* and *Calliphora vomitoria.* This is a common fly. It can lay its eggs upon inflamed or purulent wounds. The larvae wander into the cavities of the body and cause local disturbances with severe manifestations of disease. The cavities into which they have been known to wander are nose and sinuses, the ear, and the throat. They can even enter the stomach and from there go into the intestines and cause severe intestinal disturbances. In such cases, the larvae can be found in the stool. There have also been cases of larvae of *Piaphila casei* reported from the intestinal canal. These cases show severe disturbance, vomiting, pain in the abdomen, etc. The larvae are readily recognized in the stool.

Another variety is the *Cochliomyia,* or *Lucilia macellaria.* These flies are found in North and South America as well as in Asia. They enter the body of man, and have been reported in the bowels as well as in the vulva and penis.

Cordylobia Anthropophaga

Cordylobia anthropophaga are found in tropical West Africa. The larvae enter the skin of man and beast and cause considerable trouble. They cause painful pus collections in the arms, breast, head, and other places. The main symptom is itching of the skin, but severe pains are also noted. The lymph glands in the neighborhood of the larvae localization are swollen. The larvae reach their full development in eight days. According to Blacklock and Thompson, the wild rat is the principal host.

Auchmeromyia Luteola

Auchmeromyia luteola is found in West Africa, principally in the Congo. It is a blood sucker. It stays on the wall during the day and at night attacks the sleeping individual from whom it sucks blood. It appears light red from this blood content. The larvae measure about 10 mm.

Parasitic Larvae of Sarcophagidae

There is a variety of fly, the larvae of which enter ulcers and body cavities, particularly the intestinal canal and the eyes. In the eyes they produce a disease known as "ophthalmomyiasis."

Fig. 586.—Body louse of man, *Pediculus vestimenti* (×30).
Fig. 587.—Head louse of man, *Pediculus capitis* (×30).

Parasitic Larvae of Oestridae (Myiasis Oestrida)

Oestridae usually create disturbance in their larval stage. The larvae are larger than those of the ordinary fly. They enter the skin and pass into the blood. There are several varieties of these flies.

One variety, *Dermatobia cyaniventris*, is seen in North and South America. The eggs are picked up often by the bodies of other flies and thus infect individuals. In South America the larvae are known as "berne" in Brazil, "ver moyoquil" in Mexico, "torsel" in Venezuela, and "nuche" in Colombia. These larvae produce swelling in the skin of man, which rapidly goes to abscess. The larvae then fall out and develop into flies. In man, these infections are found in the head and the back.

Other varieties of Oestridae are *Hypoderma bovis* and *H. lineata.* These are seen in Africa and North America.[1] In the skin there are elevated red lines which demonstrate the paths of the invading larvae.

Another variety is *Gastrophilus.* These larvae are usually in the stomach of the horse but sometimes enter the skin of man, producing a disease known as "larva migrans," seen in Russia and described by Wohasacif. These cases show slightly elevated red lines with little nodules. There is considerable itching of the skin.

Next variety of the Oestridae is the *Oestrus ovis,* or *Rhinoestrus nasales.* These larvae enter the nasal orifices. They are often seen in sheep, but seldom infect man. When they do, they enter the eyes, producing ophthalmomyiasis. Cases of this kind have been described in Asia Minor and Siberia.

The North American Chigger

The common North American chigger is the *Eutrombicula alfreddugesi* (Oudemans). Chiggers represent the larval form of certain mites. They are not only a pest, but a certain group of the genus Trombicula, found in the Southwest and Central Pacific, as well as other regions of the Far East, closely related to our own common chigger, is a transmitter of scrub-typhus. Williams[2] has given a description of a rapid collecting method for study of this larval form. We are indebted to him and to the Williams and Wilkins Company, Baltimore, Maryland, for permission to reproduce the cuts which appear with Dr. Williams' article. Two types of localities are typical haunts of the common "red-bug." They occur in greatest numbers under and near blackberry bushes, and also in large numbers near the base of pine trees, particularly at the base of those in groups of three or more. The explanation probably lies in the fact that ground-feeding birds and perhaps certain rodents are attracted to these spots to feed during the berry season. While there feeding, chiggers which have become engorged on their epidermal cells detach themselves and drop to the ground to continue development, as is their habit when they are fully engorged. Williams stated that it required only 25 females to produce the 10,000 chiggers which he collected in one summer. His method of collection was the so-called "white dish" method, made by placing a number of white saucers, usually from five to eight, where the chiggers were found in greatest numbers. The saucers were placed several feet apart. After a minute's exposure to the grass upon which they rested, several minute red specks could clearly be seen moving about rapidly over the white background. These chiggers were "sucked" into an aspirator, constructed from a glass vial or test tube, a two-hole stopper, two small pieces of glass tubing, and two short sections of rubber tubing, and brought back to the laboratory in a living state. Williams was able to collect 105 larval mites in 4 minutes 45 seconds.

---

[1] See records of cases by Smith of Miami, Florida and Dover of the Bureau of Entomology, U. S. Department of Agriculture.

[2] Am. J. Trop. Med. 26: 243, 1946.

While chiggers do not burrow into the flesh, they attach themselves to their host in a manner similar to ticks. They evidently form a tubelike structure which extends more or less deeply into the skin from the mouth parts of the mite larvae. This tube in mammals, including man, is comparatively short, without branches, and lined by a distinct layer of cells. In parasitized mosquitoes this tube is fairly long and without branches, but in spiders, there are

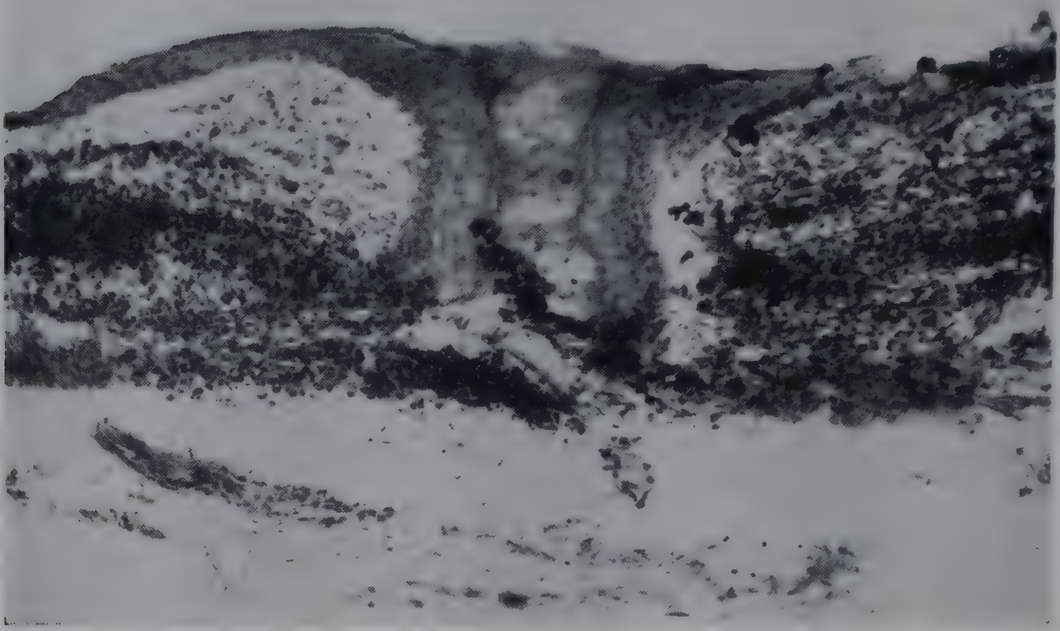

Fig. 588.—Histologic preparation of a chigger bite in a rabbit ear. Section of a bite showing the tube lined with stratum germinativum cells and containing partially digested exudate of tissue fluids and cells. (Photomicrograph by Roger W. Williams, from Am. J. Trop. Med. **26**: 2, March, 1946, by courtesy of the author and the publisher.)

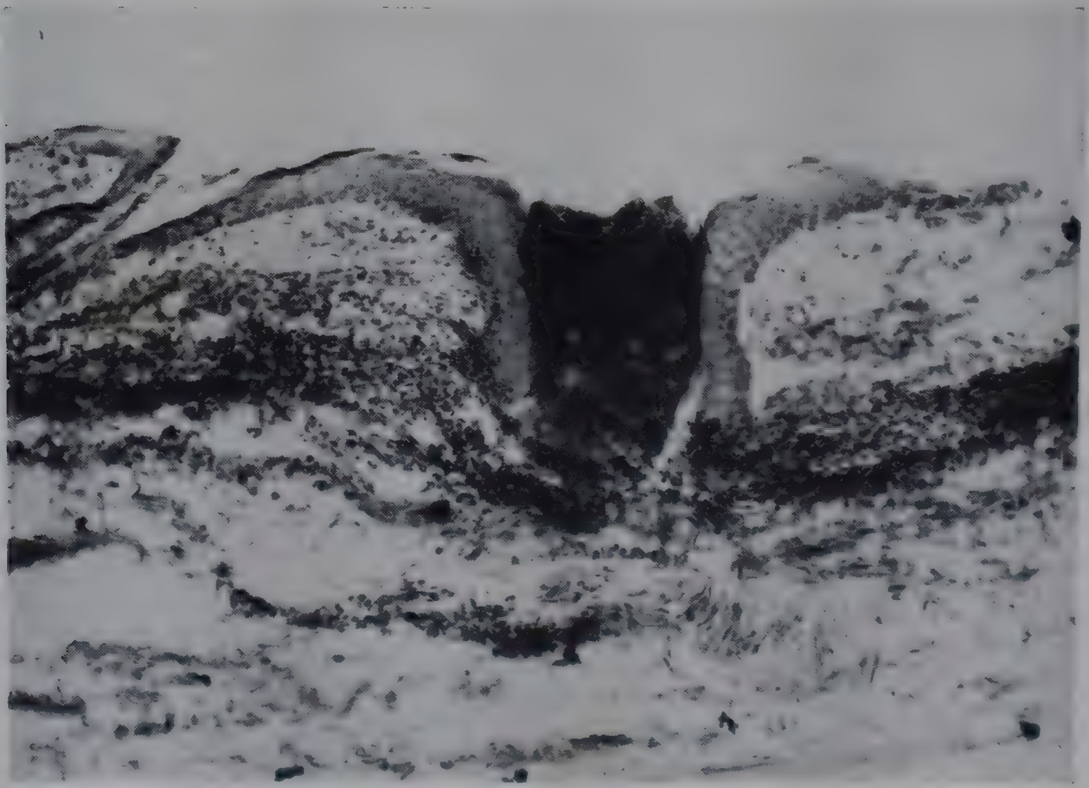

Fig. 589.—Histologic preparation of a chigger bite in a rabbit ear. An infiltration of cells and fluid being "sucked" through the inner end of the tube. (Photomicrograph by Roger W. Williams from Am. J. Trop. Med. **26**: 2, March, 1946, by courtesy of the author and the publisher.)

ramifications. Histologic preparations of chigger bites on rabbit ears show (Fig. 588) that the epidermis is completely penetrated. A tube lined with stratum germinativum cells is formed which extends to the derma and subcutis. This tube appears to represent a reaction of the host to the secretion of the parasite; its inner layer of cells is necrotic and gives evidence of digestion. There is some degree of round cell infiltration in the area of the tubelike structure. After removal of the chigger the tube contains a partially digested exudate of tissue fluids and cells. The chief source of food is derived from an infiltration of cells and fluids which are ''sucked'' through the inner end of the tube formed by the protective wall of stratum germinativum (Fig. 589). The protective wall grows and eventually closes off the opening of the inner end of the tube which it forms (Fig. 590). As the liquefied center or homogeneous zone dries and contracts, it may drop off or be pulled out as a whole from the bite (Fig. 590).

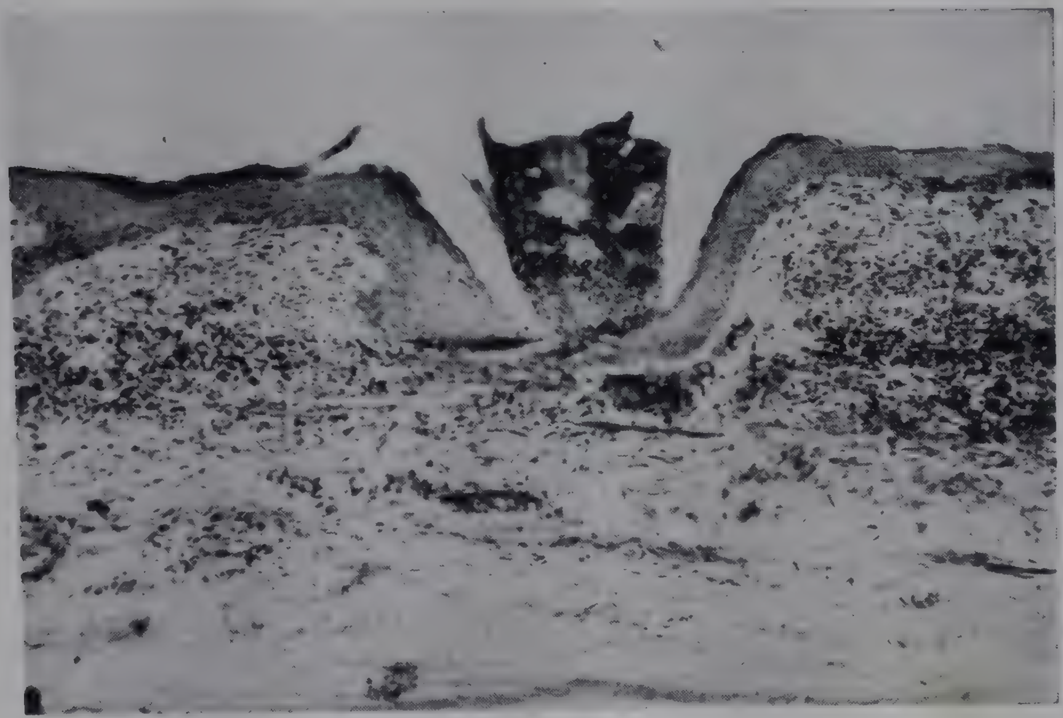

Fig. 590.—Histologic preparation of a chigger bite in a rabbit ear. The protective wall closes off the opening at the inner end of the tube which it forms and when dried the homogeneous zone may drop or be pulled out as a whole. (Photomicrograph by Roger W. Williams, from Am. J. Trop. Med. 26: 2, March, 1946, by courtesy of the author and the publisher.)

Rapidity of movement of these larval parasites is quite remarkable. At a temperature of 30.3° C. these larval mites can run, on the average, a distance of slightly better than one foot per minute.

Rarely do chiggers feed on blood and never is it their chief source of food. An extraoral digestion of epidermal cells is practiced by this parasite. Moreover, chiggers overwinter in the larval stage deep in the ears and on the eyelids of rabbits, squirrels, and possibly other animals. They are negatively geotropic and possess amazing speed for their size. Furthermore, they are frequently preyed upon by members of the mite family Bedellidae.

Latrodectus Mactans—The Black Widow Spider

The black widow spider has a widespread distribution throughout the southern half of the United States. These spiders are found in the angles

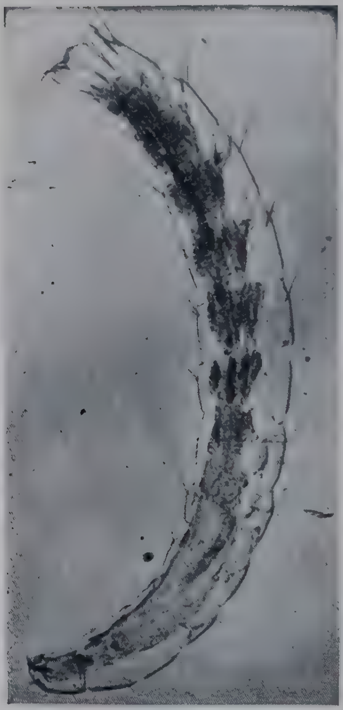

Fig. 591.

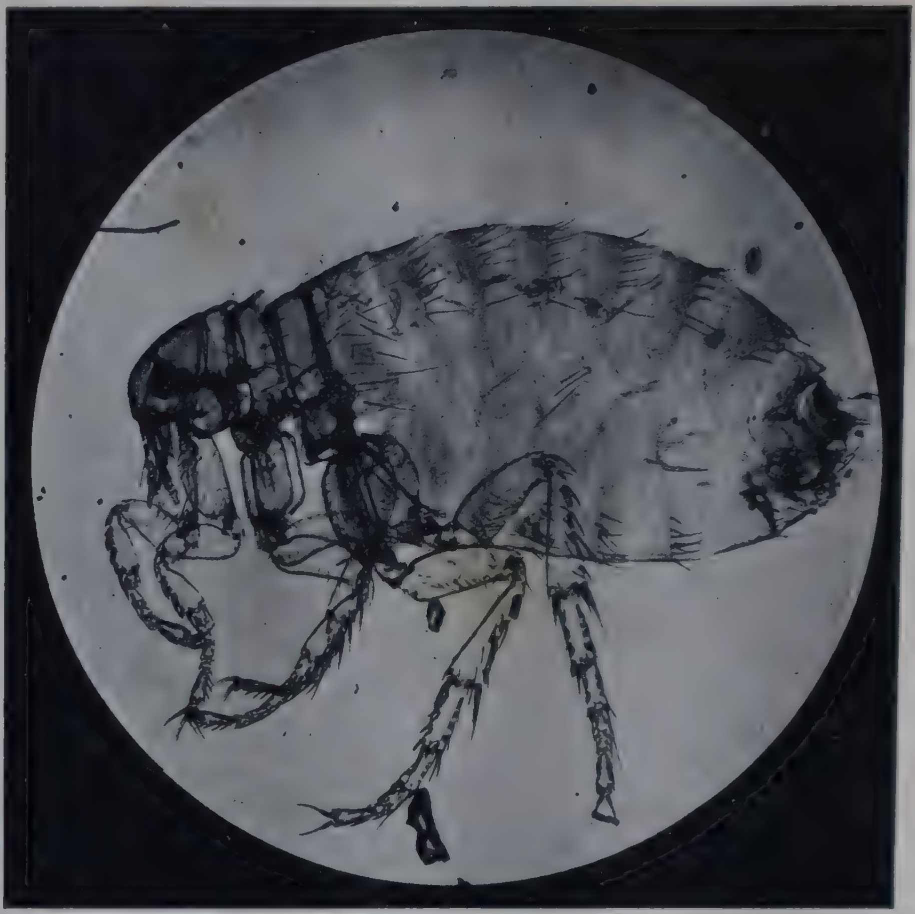

Fig. 592.

Fig. 591.—Larva of flea, *Pulex* (×30).

between the roots of trees, beneath rocks, around old stumps, in holes in the ground, in outhouses, and outbuildings. They have been found in the greatest numbers in the vicinity of human habitations. Occasionally they have been found in dark corners and in enclosed parts of dwellings. They prefer dry, dimly lit places.

The black widow is a nocturnal spider, practically all bites reported having occurred in the evenings or at night, in outdoor toilets where the spider has woven its irregular web beneath the seat, or in dry, dark corners of garages or woodsheds.

The web is so distinctive that once it has been seen it may be recognized again at a glance. It is composed of irregularly arranged, coarse threads which crisscross at various angles and in different planes. It is always found built in relation to a crevice, corner, etc., in which the spider frequently, by means of a poorly formed tunnel of silk, hurriedly retreats when disturbed. The web is relatively very strong and appears to entangle insects many times the size and weight of the spider. On many occasions, there have been observed large wood and water beetles in the web; in one case, a young mouse became entangled and was swathed and suspended in the web by these spiders. The web spun by the male is always smaller and weaker than that of the female.

Black widow spiders are capable of going without food for over a month with no recognizable harmful effects. Their fluid requirements are supplied by the body fluids of their victims. While awaiting their prey, they usually are found hanging in their webs with their ventral surface uppermost. They are cannibalistic, feeding upon each other whenever the opportunity presents itself. The common nickname, ‘‘black widow,’’ given to the female of this species, arose from her habit of capturing and feeding on the much smaller male.

The spiders are equipped with a poison apparatus for purposes of killing their prey. The poison apparatus of *Latrodectus mactans* consists of two poison sacs, each with an attached duct leading into the heavily chitinized chelicerae or horny fangs through which the poison is expelled by biting. Since the mature male does not attack prey, the poison apparatus appears to become inactive and remains small. In the female spider, on the other hand, this apparatus increases in size and strength with maturity.

The fatal dose of the poison injected subcutaneously or intravenously is extremely small. Cats are killed by quantities equal to 0.2 to 0.35 mg. per kilogram of body weight.

Effect of the Bite on Man.—The bite, itself, similar to a pinprick, is not always felt, and often there is but little evidence of a lesion. However, a slight local swelling and two tiny red spots may occur, and local redness is usually in evidence at the point of attack.

Pain in the region of the bite is felt almost immediately, and increases in intensity, reaching its maximum in 1 to 3 hours, and generally continuing for 12 to 48 hours, gradually subsiding. Rigidity and spasm of most of the larger muscle groups of the body, particularly of the abdomen, are most notable. The abdominal muscles become ‘‘boardlike,’’ but local tenderness as in appendicitis is almost always absent. There is a slight rise in body temperature, increased blood pressure, and also, as Bogen reports, a definite leukocytosis, and usually an increase in the pressure of the spinal fluid. Profuse perspiration is evident and there is often a tendency to nausea.

In man, the bite is followed, with dramatic suddenness, by a characteristic and alarmingly severe systemic reaction.

There is little doubt that the bite of the black widow spider is much more serious than that of other arachnids, and depends in effects on both the condition of the spider and the person bitten. The extract from a single spider is sufficient to kill 1,000 cats.

Diagnosis.—Diagnosis of araneism due to the bite of *Latrodectus mactans* depends upon:

(1) History of exposure to, or actual experience of, the bite of the black widow spider. There is usually little or no visible lesion at the site of the bite.

(2) Pain, beginning usually in the region of the bite but not always, and spreading until most of the larger groups of muscles of the body are involved. Except in pregnant multiparous women, the pain is usually felt most intensely in the abdominal muscles. The pain increases, reaching its maximum about an hour after the bite. It is then evidently excruciating and agonizing, usually continuous, but occasionally cramplike or intermittent, and manifested by writhing, doubling up, and screaming or moaning.

(3) Rigidity and muscle spasm occur, most notably in the muscles of the abdominal wall, which become boardlike and hard, as in general peritonitis. It should be noted, however, that this rigidity is not confined to the abdomen, but that the intercostal muscles may contract, causing backache or stiffness in the back. Spasm in muscles of the extremities may be marked, and the legs may be drawn up on the abdomen. True local tenderness, however, is usually entirely absent, or disproportionately slight compared with the intensity of the muscle spasm.

(4) Increased blood pressure, usually 20 to 40 mm. above the normal for that patient, hyperactive reflexes, especially the knee jerk, and an increase in the pressure of the spinal fluid are usually present.

(5) A mild rise in body temperature, with occasionally, but not uniformly, a slow pulse, and a definite leukocytosis, with an increased percentage of neutrophiles, is found.

(6) Profuse perspiration, restlessness, and anxiety, tossing about in agony are usually symptoms.

(7) Nausea and vomiting, localized edema, twitching or spasms of the muscles of the extremities, and urinary retention are occasionally noted.

If these considerations are borne in mind, it is not usually difficult to distinguish a case of araneism from one of an acute surgical abdominal condition, renal or biliary colic, tabetic crises, food poisoning, pneumonia or pleurisy, tetanus, or any of the other conditions that may be suggested by the clinical symptoms.

Diagnosis and Treatment of Scorpionism and Araneism[1]

Both in tropical and in subtropical countries the laboratory technician may be called upon to help clinicians either to establish a diagnosis of some rather puzzling conditions in patients or to treat them. Often patients step into physicians' offices quite hurriedly and complain of "terrible pains," or tell stories of having been bitten or stung by a "small, nonflying, secretive animal."

In such cases it is advisable to maintain a critical attitude of mind, and to think first of the possibilities of scorpion sting or spider bite.

Scorpionism.—Scorpions sting as a rule in warm weather, at night, or in dark places, such as closets, barns, storage rooms, and cellars, since these little animals like to seek shelter in boots and shoes, piles of hay or wood, among bottles, etc.

Symptoms.—In most cases the principal symptoms are:

a. **Local**: A reddish white-centered wheal surrounding the **single puncture** (caused by the sting at the tip of the scorpion's tail) and spreading into an edematous area of serous or bloody aspect; pain, very intense and sometimes excruciating, with a tendency to extend along the affected limb to the chest;

b. **General**: Slow pulse as a central nervous reflex to the pain; repeated sneezing, watery nasal and bronchial discharges; profuse lacrimation accompanied by mydriasis, nausea, vomiting and diarrhea, profuse perspiration and cold sensation, trembling and dizziness, as an effect of the venom on the sympathetic nervous system.

In some cases, particularly in nervous children or whenever the amount of the venom inoculated by the sting is large enough, there may appear a final or depression stage, represented by a marked exaggeration of the reflexes, particularly the patellar; clonic contractions, sensation of throat constriction, hiccup and convulsions, showing the direct and late action of the venom neurolysin on the central nervous system; tachycardia and low blood pressure, dyspnea, hypothermia, coma and, eventually, death. In other cases, such as those caused by the sting of the African *Buthus occitanus,* and other species, and the Brazilian *Tityus serrulatus,* these symptoms are aggravated by hemorrhages through the mucosa of the gastrointestinal duct (hematemesis and melena) or through the kidneys (hematuria), showing the destructive action of the venom proteo-hemolysin of these species on both the endothelial cells of the capillaries and the red cells of the blood.

Treatment is based on the application of a specific antivenin, either hypodermically or intravenously. Since scorpion venoms, like snake venoms, vary from species to species, it is advisable to use only an antivenin or antiserum that has been prepared from the venom of local species. The usual dose is 10 to 30 c.c., children requiring a larger amount of antivenin than adults, in view of their lower weight, to neutralize the relatively greater concentration of the venom in their systems.

---

[1] Contribution by Afranio do Amaral, B.Sc. & Lit, M.D. (Bahía) D. Hyg. & Trop. Med. (Harvard), Founder and Director, Antivenin Institute of America (Pa., U. S. A.), Co-Founder and Professor, Escola Paulista de Medicina (São Paulo, Brazil) Lecturer, Harvard University School of Public Health, Reorganizer and former President, São Paulo Red Cross, Member, International Commission on Zoological Nomenclature (London), Director, Instituto Butantán, São Paulo, Brazil.

Whenever a specific antivenin is not available, it is recommended to take into consideration the neurotropic and sympathico-mimetic effects of scorpion venoms in order to attempt to counteract them. Therefore, at the invasion period of the poisoning, the patient should receive, about the sting puncture, an ampule of 1 or 2 c.c. of magnesium sulphate solution with Novocain (magnesium sulphate 25%, distilled water 74.5%, Novocain 0.50%) so as to relieve pain. In the excitation period, in order to neutralize the adrenergic effects of venom, injections of acetyl-choline, by acting on the postganglionic fibers of the para-sympathetic system, usually bring the patient some comfort. In the depression period, the administration of stimulants and cardiotonics is advisable particularly when supplemented by liberal amounts of normal saline *given warm and slowly* by the venous route and glucose solution or Ringer-sodium acetate solution, also intravenously, given warm and slowly.

In mild cases it suffices to give the patient an intravenous injection of 10 c.c. of a 10 per cent calcium gluconate solution in order to relieve pain. In rare instances, whenever there is some reason to believe that an acute pancreatitis is complicating the clinical feature, 5 to 10 units of insulin are indicated to complete the treatment.

In view of the sympathicomimetic action of scorpion venoms, administration of any strong heart stimulant is contraindicated during the excitation period of the envenomation. Applications of tourniquet, bleeding, and suction are of no avail whatsoever. Use of potassium permanganate does not help the patient in any way.

Araneism.—Spider bites as a rule may occur at any time, both in tropical or subtropical countries and in temperate regions. Spiders, being secretive, unsociable animals which seek shelter under dead trees, dry leaves, and piles of hay, sometimes invade toilets, closets, kitchens, cellars, stables, and barns to catch insects, mice, and other small forms on which they feed. In some places they spin their webs under the cover of outdoor toilets where they can frequently capture flies. In this case they may bite humans at or around the genitalia; otherwise, their bites usually take place on the feet or hands and, eventually, under the arm or elsewhere.

Leaving aside the Mygales or crab-spiders (*Mygalomorphae*), which in general are not very dangerous, the true spiders (*Aranomorphae*) are provided with a pair of fangs moving horizontally (so as to converge at the moment of the bite), each fang corresponding to an elongated poison gland.

For this reason the bite caused by any spider usually leaves on the patient's skin a double marking or **two punctures**, the symptoms that follow the introduction of the venom varying from species to species according to the chemical composition of this secretion.

From a physiopathologic standpoint, spider venoms may be grouped into the following categories: (a) neurotropic; (b) hemolytic and icterogenic; (c) dermotropic or necrotic.

Virtually all spider venoms are neurotropic, some being more so than others. The species whose venoms are most typically neurotropic are, for instance, *Ctenus nigriventer,* the "armadeira" of Brazil and *Latrodectus mactans,* the "black widow spider" of the United States, also called "casampulga" in Mexico and Central America, "lucacha" in Peru, "guina" in Chile, and "araña-deliño" in Argentina.

The venom of *Lycosa raptoria* of Brazil, Uruguay, and Argentina, is characteristically dermotropic or necrotic.

The venom of *Epeira diadema,* of the West Indies, is both neurotropic and hemolytic, although devoid of any icterogenicity. That of *Araneus audax,* of the meridional section of South America is necrotic, hemolytic, and icterogenic, while that of *Glyptocranium gasteracanthoides,* the "podadora" of Peru, is hemolytic, necrotic, and slightly neurotoxic.

From the above it is clear that besides the double puncture, which is their only common feature, clinical symptoms of araneism vary quite widely from species to species

Latrodectus Mactans.—Local red wheal, pain, swelling and numbness, followed by fever, depression, shivering, restlessness, convulsions, spasms and rigidity of the muscles of the abdominal wall and other regions; vomiting, hypothermia; sexual excitation and anuria and death in severe cases.

L. Hasselti.—Some of the *L. mactans* signs of poisoning followed by internal hemorrhages and icterus.

Ctenus Nigriventer.—Acute pain, muscular spasms, chills, cold perspiration, salivation and lacrimation, followed by dysuria, tachycardia and arterial hypotension, sometimes terminating in death especially among children.

Lycosa Raptoria.—Extensive edema with phlyctenules and destruction of the derma at the site of the bite, followed by sloughing of the affected tissue and an irregular scar.

Epeira Diadema.—Pain followed by bloody swelling at the site of the bite and hemorrhages through mucous membranes; hyperthermia and nervous depression.

Glyptocranium Gasteracanthoides.—Red wheal and papula surrounding the punctures, spreading phlegmonous edema with phlyctenules, sloughing of the derma and necrosis of the affected tissue followed by deep scar; tachycardia, dyspnea and depression; hematuria sometimes complicated by anuria.

Treatment of such a complex symptomatic picture must of necessity be directed by a correct diagnosis and by the evolution of each case as well.

Specific therapy by means of antivenin must be applied whenever it is possible or in severe cases especially in children. Unfortunately only very few laboratories have considered the necessity of producing antivenins specific for local spiders.

Should a specific antivenin be available it must be given, either locally (intradermal injection) in case of a dermotropic poisoning, or hypodermically in other cases, and intravenously in children or in any severe case, a dose of 5 to 20 c.c. usually being sufficient.

Nonspecific therapy consists of the following: (a) against pain and local swelling: warm dressing with concentrated solution of magnesium sulphate;

sometimes an intravenous injection of 5 or 10 c.c. of a 10 per cent calcium gluconate solution causes a lasting relief; (b) against depression and arterial hypotension: cardiotonics and general stimulants such as caffein and epinephrin; (c) against hemolysis (and icterus): liver extract and blood transfusions; (d) against spasms (and cramps): an injection of atropine to block the parasympathetic, followed by neostigmine to cause muscular relaxation.

CHAPTER XIII

SEROLOGY

This chapter will take up the subject of the diagnosis of disease by those serologic methods known as complement fixation and precipitation technics. Complement fixation technic really had its beginning with the discovery of Pfeiffer in 1894 of what has been termed the "Pfeiffer phenomenon" or bacteriolysis. Pfeiffer showed that, with the development of immunity by an animal to bacteria, its body fluids develop the property of dissolving these bacteria. He immunized guinea pigs to cholera organisms. After immunizing these animals, he injected the same cholera vibrios into their peritoneal cavities and found, when he punctured the abdominal cavity with sterile glass capillary tubes and withdrew peritoneal fluid, that this fluid dissolved the cholera vibrios. Nonimmunized pigs did not show this phenomenon. This was an example of bacteriolysis. Metchnikoff further proved that this same phenomenon could be detected in the test tube; i.e., by mixing cholera vibrios in a test tube containing the peritoneal fluid of an immunized guinea pig, the same bacteriolysis could be observed. Bordet showed that upon heating the cholera-immunized serum to 56° C., adding fresh unheated blood serum, plus cholera organisms, bacteriolysis occurred; upon heating the immune serum, not adding blood or serum, and adding cholera organisms, there followed no bacteriolysis. Thus he demonstrated that there were two substances concerned with the bacteriolytic test; viz., a specific thermostable antibody which could withstand heating to 56° C., and another which could not withstand such heating—and this latter substance which is thermolabile could be replaced by fresh normal blood or blood serum. He first showed that the thermolabile substance is present at all times in normal blood and is not a product of the immunization injections, but the substance which is thermostable is a product of immunization injections and is not normally found in blood or blood serum. This phenomenon of bacteriolysis was found similar to that of hemolysis which was first noted by Bordet and Gengou[1] in their classic article, entitled, "Sur l'éxistence de substances sensibilatrices dans la plupart des sérums antimicrobiens." In this article they showed that hemolysis could be developed by the interaction between a substance, such as sheep cells, and a corresponding "substance sensibilatrice" produced by injecting a rabbit with repeated quantities of sheep cells in the presence of a third substance called *complement*. In other words, an antibody formed by the organism in response to the injection of the sheep cells, the "substance sensibilatrice" now called generally hemolysin (or amboceptor), would hemolyze the sheep cells in the presence of a sufficient amount of *complement*—an unknown species-specific substance found in various quantities in practically all animals. It was further shown that the heating of the serum containing hemolysin, at 56° C.

---

[1] Ann. Inst. Pasteur 15: 289, 1901.

for one-half hour destroyed the complement substance but did not affect the antiserum or hemolysin in any way. It was upon this so-called hemolytic system, which was only mildly interesting to research workers for a number of years, that Wassermann, Neisser, and Bruck[2] based the famous test, now named after the first one of these investigators, which is commonly considered the classic serologic test for the diagnosis of syphilis. Wassermann, Neisser, and Bruck believed that in the blood of all syphilitic patients there was an antigenic substance, or antibody, which in the presence of a specific extract of the *Treponema pallidum* was sufficient to so bind or fix complement that the later addition of the hemolysin and the homologous cell (sheep cell) was followed by no hemolysis or lack of hemolysis; furthermore, that if the blood serum came from a patient who was not syphilitic, the antigenic extract supposedly derived from a suspension of *Treponema pallidum* would not bind complement, which would be free later to hemolyze the specific hemolysin and cellular mixture (sheep cells). This was a very valuable application of the well-known Bordet-Gengou phenomenon and has served exceedingly well throughout the years since 1906 to assist us in the diagnosis of syphilis. Strange to say, the theoretical assumption by Wassermann and his co-workers that the blood serum of the syphilitic contained the syphilitic antibody and was bound by a supposed extract of the *Treponema pallidum* has been found to be in no sense theoretically correct. The original extract of the *Treponema pallidum* introduced into the Wassermann system by the originators of the test was a tissue extraction of liver substance derived from congenital (stillborn) syphilitics. It was found soon after the announcement and use of their test that equally specific results could be obtained with the use of liver tissue extract not derived from syphilitic tissue at all. The use of tissue extracts in alcohol or ether derived from normal organs, such as human heart, ox heart, ox kidney, etc., yielded excellent antigenic extracts for the performance of the Wassermann test. The diagnostic value of the Wassermann test cannot be attacked, yet the theory which led to its discovery has been shown to be completely erroneous. The Wassermann reaction and its modifications are quite specific diagnostic tests, yet the substance in the syphilitic serum which is responsible for the fixation of complement, or for precipitation flocculation, is not definitely known. The term **reagin,** or the substance which reacts, was applied by Citron[3] to the active factor of syphilitic serum. It is a very useful term to so designate the substance which is found in syphilitic blood serum and spinal fluid and which is responsible for the specific reaction. Soon after the discovery of methods of cultivating *Treponema pallidum* by Noguchi, an attempt to make a specific antigenic extract from cultures of the supposedly growing organism failed to produce a laboratory reagent which in any way compared in efficiency with the various types of alcoholic extracts of mammalian tissues.

It is sufficient to say at this point, therefore, that the serologic methods which we employ in the diagnosis of syphilis are quite useful and reliable although the theory which truly explains the specificity of these reactions still remains to be promulgated.

---

[2] Deutsch. med. Wchnschr. 32: 19, 745, 1906.
[3] Berl. klin. Wchnschr. 44: 1370, 1907.

The methods of making a serologic diagnosis of syphilis consist in the main of two types of tests, the complement fixation type and the precipitation type. There are many modifications of the original Wassermann and many types of precipitation tests. There are adherents of both the complement fixation and the precipitation methods. There has been much dispute regarding the value of each type of test and also as to priority of discovery. It seems to the author that the most valuable opinion on the value of the various types depends largely upon the experience of the worker. It has been quite interesting since my early days in Wassermann's laboratory in 1908 to view the various developments of the test, the improvements in the technic, the eradications of faults, and development of precipitation methods. The modifications of the Wassermann test now in use are quite specific and the various types of precipitation tests are equally specific. Those methods will be detailed which, in our hands and in the hands of other standard workers, have proved most efficient and reliable.

EXPLANATION OF TERMS USED

1. Blood Serum

Blood serum is the fluid part of the blood which separates from clotted blood. It is usually straw colored, and is free of cells. It is this part of the blood which is used in serologic diagnosis. Certain facts about this material must be taken into account in a consideration of complement fixation tests. Patient's serum (unheated) contains variable amounts of complement and hemolysin. Normally, it shows naturally no syphilitic substance. It may or may not show syphilitic substance during an infection with syphilis, or rather, the amount varies under various conditions and under the influence of treatment. The heating of blood serum to 56° C. destroys complement, but does not destroy hemolysin. It has also been proved that this heating, which is called ''inactivation'' in the technic, has a destructive effect on syphilitic substance in certain individuals. This is due to the fact that the syphilitic substance is composed of two kinds of material, one ''thermolabile'' and one ''thermostable.'' The relative proportions of these two different kinds of syphilitic substances are variable, so that in order to retain the maximum amount of both substances, the serum should preferably be examined for complement fixation in an unheated state. Since the Wassermann technic entails the use of heated serum, necessarily, at times, the process of inactivation, or heating, will destroy the very substance the presence of which we are trying to prove. In technic such as Hecht-Gradwohl, where unheated serum is used, the entire amount of unaltered syphilitic substance is determined.

2. Physiologic Saline

Physiologic saline is an 0.85 per cent solution of sodium chloride in water.

3. Inactivation

Inactivation is the heating of blood serum in a water-bath at 56° C. for one-half hour for the purpose of destroying complement.

4. Complement

Complement is a thermolabile, nonspecific, enzyme-like substance contained in the blood serum of all animals. The quantity of complement varies from time to time in the bodies of animals, and may disappear altogether after removal from the animal tissues. It takes part in the reaction between antibodies and antigen, and between hemolysin and its specific cells. It is present in particularly large amount in the blood of guinea pigs.

5. Antigen

The term "antigen" is an immunologic expression which actually means any substance "foreign" to the animal into which it is injected and which stimulates antibody formation by the injected animal. Originally, Wassermann advised the use of an antigen made from the liver of a congenital syphilitic child; that is, from the stillborn children of syphilitic parentage. In the Wassermann technic, the term "antigen" has come to mean an extract supposedly of substances referable to the *Treponema pallidum,* which are specific in their reaction with the antibody or immune body found in syphilitic blood serum; i.e., antigen and syphilitic immune body of homologous materials are mutually attracted in the presence of complement and are bound by complement, thus producing the phenomenon of "complement fixation." As a matter of fact, in the Wassermann reaction, the antigen used is not made from a syphilitic spirochete but is made from lipoidal material. It is for this reason that the Wassermann test is not really an antigen-antibody reaction but rather a very important test which is dependent upon factors other than the binding of complement by true antigen and true antibody. The term "antigen" in this sense is, therefore, a misnomer, but has been retained with this understanding.

The antigens used today in the Wassermann test are made by alcoholic extraction of normal organs, from alcoholic extraction of normal organs reinforced with cholesterin, from acetone-insoluble lipoids, from cholesterinized and lecithinized alcoholic extracts of heart muscle, and from cardiolipin.

A true antigen as prepared by Noguchi, using pure cultures of *Treponema pallidum,* is not as serviceable as any of the foregoing. The *T. pallidum* immobilization test is described on page 2085.

Antigens for complement fixation tests other than tests for syphilis are extracts of the organisms which cause the disease. For example, the complement fixation test for gonorrhea utilizes an extract of gonococci as an antigen.

In making serologic tests, new lots of antigen should be checked against old lots on two different days before using the new antigen. If comparable results are not obtained, the new antigen should not be used.

The Chemical Nature of Syphilis Antigen—Cardiolipin.—

Fischer and Velasco,[1] School of Anatomy and Physiology, University of Chile, Santiago, reported their results on various methods of purifying the syphilis antigen. In 1942 Pangborn[2] described a method of purifying the syphilis antigen of alcoholic beef heart extract by precipitating the phosphatides with cadmium chloride, suspending the precipitate in petroleum ether, and eliminating the lecithin-cadmium chloride complex by extractions with 80 per cent alcohol. The remaining solution contained cephalin-cadmium chloride complex and antigen. After eliminating the cadmium by ammonia, and cephalin by precipitations with alcohol, the antigen was further purified until a substance which Pangborn claimed to be the pure syphilis antigen was obtained. According to this author, this substance, called **cardiolipin,** is a nitrogen-free, sugar-containing phospholipid, with 4.11 per cent phosphorus.

---

[1] Science 103: 455, 1946.

[2] J. Biol. Chem. 143: 247, 1942.

In further publications,[3, 4] Pangborn described another method of purifying the syphilis antigen, based on the precipitation of the cephalin fraction together with the antigen by barium chloride, and eliminating cephalin by alcohol. After purification a substance was obtained with the characteristics of syphilis antigen. This second ''cardiolipin'' contained no sugar but approximately the same amount of phosphorus as the ''cardiolipin'' of the first publication.

Between 1931 and 1936,[2] one of the authors and his co-workers elaborated several methods of purifying the syphilis antigen. Having applied two of these methods successively, a purified antigen preparation was obtained from the phosphatid fraction of alcoholic beef heart extract. The process of purification consisted of adsorbing the antigen on specially prepared aluminum hydroxide and eluting it in benzene. The antigen was then further purified by extracting it with petroleum ether from an acidulated 80 per cent alcohol solution. From 207 grams of phosphatides 1 gram of a purified antigenic preparation was obtained, with only 0.01 per cent phosphorus, 0.25 per cent reducing substances (liberated by acid hydrolysis), and 40 per cent fatty acids (liberated by alkaline hydrolysis).[5]

It was shown in 1936[6] that by extracting an 80 per cent alcoholic solution with petroleum ether, only a part of the antigen could be obtained in the petroleum ether solution, another part still remaining in the hydroalcoholic phase. Only after acidulating this phase with hydrochloric acid did the antigen disappear completely from it, entering into the petroleum ether phase. It may be assumed, therefore, that the antigen occurs in two different forms in the alcoholic organ extract; i.e., acid and salt.

In a later experiment, these authors worked on the phosphatid fraction of 10 beef hearts, obtained by extraction with alcohol and precipitation with acetone. The antigen was adsorbed on aluminum hydroxide and eluted in benzene. The substance obtained in this way was dissolved in 80 per cent alcohol and extracted at first without, and then with, acidulation.

They obtained in this way two fractions, which they called ''petroleum ether fraction before acidulation'' (P.E.N.) and ''petroleum ether fraction after acidulation'' (P.E.A.). Both fractions reacted with strongly positive sera. P.E.N. weighed 39 mg., and no phosphorus could be detected in it. P.E.A. amounted to 22 mg. with 0.1 per cent phosphorus. Both fractions were yellow oils which hardened rapidly, forming a transparent, soft film.

They assumed that the small quantities of phosphorus found in their preparations correspond to impurities, as was the case with the reducing substances in the former experiment.

6. Complement Fixation ("Wassermann Reaction")

The laboratory diagnosis of syphilis comprises mainly two methods: first, the dark-field demonstration of the *Treponema pallidum,* for the diagnosis of primary sores; and, second, the serologic or serum diagnosis of syphilis. The dark-field examination has been described on pages 11 ff. The serum diagnosis of syphilis may be divided into two parts: first, the complement fixation, or Wassermann, reaction; and second, the flocculation, or precipitation, test.

Regarding complement fixation methods, of historical interest is Bordet's discovery of the hemolysins in 1898 and his demonstration of the roles of the antibody and alexin in the process. Bordet's discoveries were confirmed by Ehrlich and Morgenroth. Later, Bordet and Gengou brought out the "Bordet-Gengou Phenomenon."* Bordet showed that the complement in a normal serum would unite with either a bacteriolytic or a hemolytic amboceptor, and that, by furnishing sufficient of either amboceptor, all the complement may be "fixed." Prior to this Bordet had shown that the addition of a small amount of normal serum to an immune hemolysin would result in lysis of the homologous corpuscles, and that the process could not take place without the alexin. In their researches Bordet and Gengou gave the results attained with three different antigens and their respective antisera—pest, typhoid, and *Proteus vulgaris.* Gengou[1] later showed that not only cellular antigens, such as bacteria and red cells, are capable of stimulating the production of amboceptors, but that the proteins in solution, such as serum and milk, may produce complement-binding amboceptors in addition to precipitins. Widal and Lesourd[2] applied the Bordet-Gengou reaction to the diagnosis of typhoid fever, using an emulsion of typhoid bacilli and the serum of a typhoid fever patient; they found that a positive reaction occurred more frequently and earlier than the agglutination test. Wassermann, Neisser, and Bruck[3] applied the complement fixation method to the study of syphilitic infections and published their epoch-making report of their work on May 10, 1906. Later they applied the complement fixation test to a large number of cases of syphilis in Neisser's clinic. Aqueous extracts of syphilitic liver, placenta, glands, chancres, and gummata were used as antigens. Of 257 cases in all stages of the disease, only 49 reacted positively. Obviously, this small percentage of positive results is an indication of the poor technic originally employed. It was originally thought by Wassermann and his co-workers that the antigen in this reaction must be made from syphilitic material, but later work showed this to be erroneous. In 1907, Weygandt reported that he had obtained a positive reaction in tabes with an extract of normal spleen. Later in 1907, Landsteiner[4] and others showed that an alcoholic extract of guinea pig heart yielded results equal to those

obtained with an aqueous extract of syphilitic liver. These results indicated that the antigenic principle was soluble in alcohol, and a prolonged series of investigations on the various lipoids and their relation to the reaction was begun. This work apparently upset the theory of the Wassermann reaction. Modern work, however, shows that while Wassermann's original idea of the mechanism was incorrect, there is no doubt about the specific nature of the reaction. We believe now that the reaction is dependent upon a particular antibody, and that these can be demonstrated by suitable lipoidal substances. The method is diagnostic of syphilis, with the exception of yaws (see Chapter X). Assuming that yaws and syphilis are identical diseases, certainly the Wassermann reaction and its modifications are diagnostic of syphilis.

It has been affirmed and denied that the Wassermann test is specific, that it is found positive in diseases other than syphilis, notably malaria.

A complete study of the question of the Wassermann test in giving rise to nonspecific positive reaction was made by Saunders and Turner.[2] Sutherland and Mitra,[3] Di Natale,[4] Lloyd,[5] Fischer and Gunsberger[6] and Curth[7] in their writings suggested that malaria alone might cause a positive or partly positive Wassermann reaction. On the other hand, Johnson,[8] Iyengar,[9] Clark,[10] and Kolmer[11] indicated that malaria alone does not cause positive reactions. Altounyan[12] contended that acute malaria had an undoubted effect in increasing the anticomplementary powers of the serum.

Their report is based upon the findings among a total of about 2,000 persons studied carefully in a yaws clinic in Jamaica in 1932. Seventeen per cent of these people were listed as having malaria.

Some important work on this subject was reported by Saunders and Bianco,[*] based upon observations made at the U. S. Naval Hospital at Bethesda, Maryland, during the year 1945. Serologic tests were recorded at least once on all malaria patients admitted to the Tropical Disease Service of that hospital, and results of tests made on 411 consecutive admissions to the Service were analyzed. Most of the patients were admitted with acute malaria in the first few days of the attack, but a number were seen during remissions, several weeks after the last febrile attack. Some had as many as two to twenty-five attacks. They were all cases of vivax malaria. Positive or doubtful[†] Kahn reactions were found in 10.4 per cent. Some cases showed negative[‡] results with the first samples and positive results with the second or third sampling. Of 508 separate samples of blood examined, 43, or 8.5 per cent, gave doubtful or positive serologic reactions.

All reports indicate that malaria profoundly influences the serologic test for syphilis. A diagnosis of syphilis should not be made without eliminating the possibility of a concurrent malarial infection. This precaution becomes more important because of the large number of veterans who have contracted malaria overseas, especially since many are required to have premarital serologic tests to detect syphilis.

Conclusions by Saunders and Bianco were as follows:

1. Serologic tests for syphilis are frequently positive in nonsyphilitic persons following an attack of malaria.
2. Some studies indicate that when a variety of tests are made at intervals during and after an attack, one or more positive reactions can be demonstrated in every case.
3. The proportion of cases giving positive tests appears to be greater when clinical activity of malaria has persisted for more than a week.
4. The largest number of positive reactions appears first during the second to fourth weeks following onset of acute malaria.
5. Positive serologic tests resulting from malaria revert to negative in most cases within four weeks and in practically all cases within ten to twelve weeks following the acute attack.
6. Of 411 presumably nonsyphilitic malaria cases, doubtful or positive serologic tests were found in more than 10 per cent. Tests became positive for the first time in 10 per cent during the first week, 21 per cent during the second week, and 5 per cent during the third week, but a total of 29 per cent gave positive reactions during the second week, and 24 per cent during the third week following the onset of acute malaria.

The question of positive Wassermann or positive flocculation test in malaria in nonsyphilitic persons has been investigated by Burney, Mays, and Iskrant.[1] They selected eleven patients with functional psychoses. Syphilis was excluded by means of history, physical examination, two negative blood serologic tests, and one negative spinal fluid. Four controls were selected, two with syphilis and two without. The laboratories of Eagle, Hinton, Kahn, Kline, and Kolmer performed the tests on all specimens collected in the course of this study. Three patients were inoculated with 10 c.c. of blood containing *Plasmodium vivax*. The other eight patients were infected directly by the bite of an infected mosquito. The infected blood was obtained from functional psychotics with malaria who did not have syphilis as proved by negative history, physical examination, and blood and spinal fluid serologic reactions. Inasmuch as there is no evidence that the mosquito may transmit the spirochete of syphilis, it can reasonably be stated that these patients were inoculated only with *Plasmodium vivax*. Enough blood was withdrawn from each patient to send a comparable amount to each laboratory in the form of whole blood. Of these eleven patients, all cases had at least one positive reaction to the Kahn standard, and the Kline diagnostic tests. Our of eleven cases, positives were returned on nine according to the Kline diagnostic; one case returned three doubtfuls; and one case was never positive or doubtful. Out of ten cases the

[1] Am. J. Pub. Health 32: 39, 1942.

Kolmer (Mahoney) complement-fixation test was positive on nine, and the other patient had one doubtful reaction. Only seven cases were positive to the Kolmer (Kolmer) complement fixation, and four cases were never positive. Five cases were positive out of eleven according to the Eagle Wassermann, and of the six that were never positive, one had a doubtful reaction. Only four patients out of eleven tested according to the Eagle microflocculation test were positive, and one of the other seven had two doubtful reactions. None of the ten patients were positive to the Hinton test, but three of them showed one doubtful reaction. According to this investigation, the duration of clinical activity, highest temperature reached, time of withdrawal of blood in relation to an individual paroxysm, or density of parasites, did not seriously influence the serologic reactivity of the blood. It is the opinion of these workers that, from the evidence presented, a diagnosis of asymptomatic syphilis based upon positive serology alone should not be made in an area where malaria is endemic without first eliminating the possibility of coincident malarial infection. This work seems to prove that malarial infections may give rise to positive complement fixation and flocculation tests.

In the years that have elapsed since the announcement of Wassermann and his coworkers, much work has been done in the direction of standardization of technic. There have been many discussions as to just what kind of antigen should be used, whether the patient's serum should be active or inactive, just how much complement should be used, etc. Out of this wealth of literature have come the standard methods which are discussed in this chapter.

We now believe that a *positive* Wassermann reaction is rather good evidence for the existence of a syphilitic infection, but that a *negative* reaction does not by any means exclude the probability of syphilis. We know that the reagin of syphilis is inconstant in any given case for any given period of time. We know that in primary syphilis a certain degree of tissue change must occur before the specific reagin appears in the blood. We do not expect the presence of a syphilitic reagin in the primary stage before the tenth day, after which time we are likely to find a positive reaction. In the primary latent period, that is, when the chancre is healing or in the pre-eruptive stage, a positive reaction is obtained in about 92 per cent of the cases. In the secondary, or eruptive stage, positive reaction is obtained in 100 per cent of the cases. In the latent stage of syphilis after the secondary symptoms have subsided, our experience has been that possibly 80 per cent of all syphilitics show a positive Wassermann. In the tertiary stage, about 90 per cent of all individuals show a positive Wassermann reaction. In the tertiary stage with lesions of the central nervous system, we find, in general paresis of the insane, from 90 to 100 per cent positives in the blood serum and nearly 100 per cent positives in the spinal fluid. In tabes, our personal experience has been about 60 per cent positives in the blood serum and about 90 per cent in the spinal fluid. In the active prenatal or first year, we find practically 100 per cent of congenital syphilitics show positive Wassermann reactions, and in the second year, about 80 per cent.

The cerebrospinal fluid of individuals with primary syphilis is usually negative. The cerebrospinal fluid, according to Wile, in secondary syphilitics gives a positive reaction in about 30 per cent of all cases. It is probably in tertiary syphilis that the Wassermann reaction has its greatest value. In untreated and active tertiary syphilis, the reaction is positive in about 95 per cent of all cases.

The effect of treatment on the Wassermann test has been much discussed. It is the *last* symptom to disappear under treatment and the *first* to reappear if complete sterilization has not been accomplished. In some cases, the Wassermann reaction seems to disappear with a rather moderate amount of treatment. This is, of course, no proof that the individual has been cured. A single negative reaction of the blood serum following the institution of treatment is simply evidence that the treatment has probably been partially successful, but certainly is no criterion of the probable outcome of the case. Only a succession of negative Wassermann reactions over a long period of time with a knowledge of the institution and amount of treatment is of advantage in drawing conclusions as to the probable results of the treatment. Successive examinations must be made over a period of at least two years and off and on during the remainder of life. Questions are frequently asked by patients as to how many negative Wassermann tests they must have before they can be considered cured. The answer is practically no different from that given by the celebrated syphilologist, Fournier, who was once asked by a student just how he determined the patient was ''cured'' of syphilis: the answer of the master was, ''Treat the case for three years and have him return in twenty-five years. If he has no symptoms at that time, I consider that he has been cured.'' There are several facts which must be considered in summing up conclusions as to cure, the advantage of treatment, and why the reaction disappears quickly in one individual and not in another. There are different strains of spirochetes varying in virulence. There are different degrees of individual resistance to this disease. Assuming that we have a patient with a high degree of resistance and an infection of a mildly virulent strain of spirochetes, we should find mild symptoms and a rapid disappearance of the Wassermann reaction. Taking a patient with low resistance and an organism of high degree of virulence, we find a persistence of the Wassermann reaction and the onset of very severe symptoms. Again, there may be a strain which has a predilection for nervous tissue. This has been said by some authors to explain why some individuals have certain lesions of the nervous system and others never develop such lesions. It is rather interesting that many cases of syphilis of the nervous system, such as paresis, are recruited from the more intelligent ranks. Is it possible that these individuals are prone to this infection because of their more highly developed nervous systems, which are more susceptible because of this higher organization?

Blood and Spinal Fluid Tests for Reagin After Treatment of Neurosyphilis

Clinicians are frequently disturbed by the persistence of a positive test for reagin after long-continued and persistent treatment. This is particularly true with respect to neurosyphilis. This question has been thoroughly studied by Thomas.[1] His conclusions are based upon a follow-up of patients treated by malaria or penicillin, with data obtained in a 5- to 14-year period on 181 patients with neurosyphilis treated with malaria therapy, and a 5- to 8½-year follow-up of 213 patients treated with penicillin. It was found that positive results from serologic tests for syphilis persisted in 80 to 84 per cent of patients followed for five years, and in 70 per cent of patients followed for ten years after treatment. Positive results from tests for spinal fluid reagin were found in 63 per cent of patients followed for five years, and in 27.7 per cent of patients followed for ten years after treatment. It is futile to re-treat patients solely because of the persistence of reagin in blood serum and spinal fluid. In cases in which treatment was given to note the effect on high titers in blood serum and spinal fluid reagin, no appreciable effect in titers was obtained (Thomas).

One must remember that reagin in blood serum is a complex substance consisting of more than one presumed antibody, and that factors other than syphilis may influence the production of one or more of these ''antibodies'' in known syphilitic patients as well as in persons who have biologically false positive results in tests for syphilis. One must also consider that relapses in neurosyphilis, as determined by increases in spinal fluid cell count and in results of other quantitative spinal fluid tests, never occur later than two years after treatment has inactivated the infection.

It is obvious, in the light of our present knowledge, that erroneous conclusions must not be drawn about a persistent positive test for reagin in either blood serum or spinal fluid. Unnecessary treatment of these positive persons should be avoided.

We find, too, a certain type of infection which is ''Wassermann-fast''; that is, no matter how much treatment is given, the Wassermann remains positive. No explanation has been given in the literature for this condition. Some have claimed that the Wassermann reaction is an indicator of resistance and that these individuals have a high degree of resistance. No facts of an experimental nature have been brought forward to explain this. It is paradoxical that at times syphilitic treatment may convert a negatively reacting serum into a positive one. It is also true that some cases of latent syphilis which give a negative reaction at first will become positive under the influence of injection of mercury or salvarsan. At times, attempts are made to utilize this phenomenon in the form of the *provocative* Wassermann; that is, for the purpose of confirming the diagnosis of syphilis where previously a negative reaction would seem to exclude it. Our experience with this method has been disappointing.

Craig and others have reported that the *ingestion of alcohol* by a patient with a positive Wassermann will tend to diminish the reaction or cause it to disappear. Our experience does not confirm this statement. In a general way, we can state that the Wassermann reaction serves two important purposes: first, it is an invaluable aid in the diagnosis; and second, it is a guide in the treatment of syphilis. Negative reactions do not exclude syphilis, but positive reactions include it. In all cases where any suspicion exists as to the presence of syphilis of the central nervous system, a spinal puncture and an examination of the spinal fluid should be performed. A positive reaction occurring in women about to abort is an indication for treatment and may protect the fetus. A positive reaction in either parent of a seemingly healthy infant is an indication for treatment of the child, especially if the mother reacts positively. Another point which must be borne in mind is that although a positive reaction indicates that the patient is syphilitic, it does not necessarily mean that a particular lesion is syphilitic. For instance, we had a very interesting case of a lesion of the tongue in which we obtained a four-plus positive Wassermann. This was in the early days of the Wassermann test before we had had an opportunity to weigh it in the balance after years of experience. Immediate treatment by injections of arsphenamine clearly stimulated the growth of the cancer of the tongue, for such it was, and in a few months the patient died from this condition.

---

[1] J. A. M. A. 153: 718, 1953.

Just how long the reaction may remain positive after the patient is cured and all spirochetes are dead, of course, is a matter of conjecture. Experimental studies on rabbits and monkeys have shown that the reagin disappears very completely and quickly under therapeutic control. In a general way, it can be stated that a positive reaction is of great value, while a negative reaction is of comparatively little value in clinical medicine.

In regard to the *comparative value of the various tests* for syphilis, in other words, the *complement fixation* and the *precipitation methods,* our own opinion inclines strongly to the belief that the complement fixation methods are superior to the precipitation methods. We therefore urge that the complement fixation methods be continued as the methods of choice, rather than that they be abandoned, as some have already done. We are ready to admit, however, that precipitation methods are simpler and easier to control. They seem to yield more false positives than do complement fixation methods.

Summary: A Negative or Nonreactive Report.—A negative or nonreactive report is evidence that the patient has not active syphilis but does not mean that he never has had syphilis or that syphilis is not present at this time. It may also mean that he has a syphilitic infection too recently acquired to produce the substances which give the positive reaction.

The Weakly Reactive or Doubtful Reaction.—No weakly reactive test should be used as a diagnostic measure or as a measure of control of treatment. A borderline reaction is a finger of suspicion only, pointing at the individual, and must be verified and checked over by repetitions. In this connection, the provocative treatment by injection of arsphenamine may be attempted, testing the blood on the second and seventh days after the injection. If the reaction is still borderline, or negative, in a negative sense we may be emboldened further in our belief that syphilis is not present. Our experience with this has been disappointing.

The Positive or Reactive Reaction.—This is a very positive indication of syphilis. If the clinical symptoms are at variance with the positive serologic findings, this by no means eliminates the question of syphilis. Syphilis may be coincidental with other diseases, such as malignancy or tuberculosis. Positive Wassermann tests indicate tissue response to syphilitic infection. The cerebrospinal fluid is positive in all cases of general paresis and in about 60 per cent of tabes. Other writers give figures as high as 80 per cent for tabetics. In latent syphilis, the spinal fluid may show a positive reaction while the blood Wassermann is negative. So far as a positive reaction in tuberculosis is concerned, if this occurs, it indicates a coexistent disease with syphilis.

If possible, the positiveness or negativeness of Wassermann reactions should not be discussed with patients because of the difficulty of explanation of all these facts. In order to get good results in any case, the patient should have perfect confidence in his medical adviser. It is foolhardy for him to discuss serum reactions with patients where a medical training is vital to a perfect understanding of the facts. These patients should be told, of course, all the facts about the diagnosis and their manner of life under treatment, but under no circumstances should any discussion of the vagaries of the serum reaction be undertaken with the interested patient.

No attempt should be made to make any statement as to how long a patient should be treated before he is considered well, nor how many negative Wassermanns should be obtained before he is considered cured. If, after a lapse of several years of treatment, the Wassermann test is negative, and if, year after year, it remains negative, one might tell the patient that each negative which he obtains is better and better evidence of the probability of cure. No statement stronger than this should be made to the patient.

Reporting Results of Serologic Tests

It was recommended in the 1953 report of the National Serology Advisory Council to the Surgeon General of the U. S. Public Health Service that the following terms be used in reporting the results of serologic tests: *Reactive* instead of positive, *weakly reactive* in place of weakly positive or doubtful, and *nonreactive* to replace negative.

When reporting results of quantitative reactions, the end-point titer should be reported in terms of the greatest dilution in which the tested specimen produces a reactive (positive) result, and that the term "dils," a contraction of "dilution," be used to identify these dilution reactivity end points.

The Biologic False Positive Reaction for Syphilis

Refer to the treponemal immobilization test, page 2085.

Out of the many contributions which have been published on this point is an excellent article written by Stokes, Boerner, Hitchens, and Nemser.[1] This report gave the result of the fourteen-month period spent in studying the problem of the nonspecific positive, so-called "biologic false positive" reaction for syphilis. The bloods of Red Cross donors at the Philadelphia Blood Donor Center supplied the material. In all, 210,261 blood specimens were tested in a nine months' period and 79 of the donors, showing definite positive reactions, were subjected to subsequent clinical and laboratory examinations. Of 210,261 Red Cross donor blood specimens, 489 gave definite positive reactions to serologic tests for syphilis. This incidence of 0.23 per cent positives is substantially below even the low reported prevalence rates for the disease (0.5 per cent) in the Northwestern and Northeastern rural sections of this country as reported by serologic surveys. In this evaluation, the diagnosis of syphilis was reached in three months in 69.2 per cent; in nonspecific positive cases in only 22 per cent. Of the nonsyphilitic positive cases, 78 per cent required more than three months for decision. Only 40.5 per cent of the Red Cross donors with syphilis-positive bloods were finally adjudged to have syphilis. The remainder, 59.5 per cent, were finally adjudged to have actual or probable biologic false or nonspecific positive reactions.

---

[1] J. A. M. A. 130: 57, 1946.

In evaluating this work, it was found that the clinician's history and examination of this group as a means of differentiating syphilis from nonsyphilis was, in contrast to its usual claims to ''court of last resort'' status, disappointing. The final resort was perforce too often serologic. With respect to history, there was a slight preponderance of recent vaccination, upper respiratory infection, inoculations, recent febrile illness, and infection in nonspecific positive cases. In the physical examination for ''landmarks'' of syphilis and ''suspicion arousers,'' the yield of definite findings was small, though better than from the history.

There was a fertile field of disagreement among both examiners and consultants about questions of physical examination—opinion on the level of the liver, presence or absence of true enlargement, the configuration of teeth and bones, the shape and height of the palate, the interpretation of pupillary reactions, and the interpretation of murmurs over the precordium. In the physical examination, evidence for the presence of syphilis was found largely in examination of the eyes, including slit lamp study for vascularization of the corneas, characteristic teeth in congenital syphilis, the skeletal changes of congenital syphilis, the facies, and the reflexes.

Special studies were made in response to apparent indications in the individual case but these had a rather small positive yield. The high points in the examination were spinal fluid examinations, heterophile antibody tests, radiographic examinations of the chest, and examinations for congenital stigmas.

The serologic studies devised for the purpose of this investigation were the Boerner classification procedure, an interpretation of simultaneously performed, exceptionally sensitive tests for the detection of flocculating and complement fixing reagin.

These workers found that all of the precipitation tests show quite high proportions of strong positives and of strong and moderate positives obtained in nonspecific blood sera. The Kolmer complement fixation test, as performed in Mahoney's laboratory, on the other hand, while less sensitive in the detection of syphilis, is a notably safer resort than any of the precipitation tests except the Kline diagnostic for the avoidance of strong positives in the nonspecific field. Broadly speaking, one would be inclined to infer that a precipitation test should either not be used or should be paralleled by a dependable and sensitive complement fixation procedure in any and every serologic survey of a mass material in which nonspecific positives may appear.

This study does not solve all of the difficulties intrinsic in both the identification and the exclusion of syphilis in any individual case. It indicates that a disconcerting serologic proportion obtained by a routine test procedure on a large scale sampling of blood in a population group will yield a high proportion of nonspecific positives. Many people have been subjected to treatment for nonsyphilitic or, rather, nonexistent syphilitic infection. The diagnosis of syphilis by history and physical examination is difficult to make as the infection passes into latency and even into the period of late manifestations. Therefore, recourse must be had to serologic procedure. The clinician may expect to identify indubitable symptoms and signs of the disease in a proportion of cases of seropositiveness depending on the type of material with which he is dealing. Many times he will throw a weight of suspicion, disappointingly small and based on slender and debatable evidence, into the scales with the serologic test. He sometimes is compelled to diagnose syphilis on the basis of repeated nonspecific positive reactions. Stokes and associates stated that the outright diagnosis of a nonspecific positive at the present time is laboratory rather than clinical—a consistent weak or doubtful positive reaction, its decline to negative within a reasonable time, currently estimated in the literature as approximately three months. A suggestion but certainly not a presumption in favor of nonspecific positiveness, in the majority of cases such as Stokes and associates had, may be raised by a record of intercurrent or recently antecedent infection, especially of the upper respiratory tract, accompanied by fever. The special test procedures to determine the character and location of such infection will usually be applied too late to be of material value in sustaining a diagnosis of nonspecific positive reaction. They therefore, at best, establish little more than a suspicion-arousing type of reaction in the mind of the consultant, and the final decision again falls to the serologic test procedure and in the future, let us hope, to a specific physiochemical test for nonspecificity.

He further stated that the serologic warnings of nonspecificity are again (1) consistent weak or doubtful positiveness, punctuated with occasional high titer precipitation reactions, (2) serologic fluctuation and discord, i.e., disagreement between tests and among laboratories, and (3) negative complement fixation with positive flocculation reaction. For the simplified and yet increasingly accurate differentiation of syphilitic from nonspecific positive sera on repeated testing, by a procedure easily available to well-equipped serologic laboratories, this investigation offered the Boerner classification procedure as deserving of widespread trial even though it may presently be overtaken by a contribution from the physical chemists.

Our own experiences are in complete agreement with Stokes' conclusions. We, too, had several cases of nonspecific reaction referred to us during the American Red Cross campaign for blood plasma. We believe that routine tests for syphilis in the laboratory should consist of both the complement fixation and the precipitation tests. In cases where speed is essential, we have used the Kline test and found it very satisfactory.

Test for False Positive Serologic Reaction for Syphilis.—

In connection with the false positive serologic reaction for syphilis, Brown, Kolmer, and Lynch[2] reported the results of an investigation of a method whereby the reagin responsible for false positive reactions in the test for syphilis occurring in individuals with certain diseases could be inactivated or destroyed without inactivating or destroying the syphilis reagin.

---

[2] Am. J. Syph., Gonor. & Ven. Dis. 29: 200, 1945.

Technic.—Treat the serum chemically by adding 0.1 c.c. of carefully titrated N/3 or N/4 sodium hydroxide solution to 1 c.c. of serum. Then inactivate at 55° C. and proceed with the test.

Results were given following the application of this method to normal rabbit serum and that of nonsyphilitic human beings with malaria, infectious mononucleosis, leprosy, virus pneumonia, and certain other diseases, as well as to sera of patients with syphilis.

The method proved effective in preventing biologic falsely positive Kolmer, Kahn, and Mazzini reactions in sera of normal rabbits and in a large percentage of sera of presumably nonsyphilitic individuals with malaria and infectious mononucleosis. In each of these sera, N/3 sodium hydroxide was more effective than the N/4 solution. Less effective results were observed with the sera of presumably nonsyphilitic lepers, and in leprosy the N/4 solution was found to produce results superior to those following the use of N/3 sodium hydroxide.

It was found that this treatment applied to syphilitic sera results in the inactivation or destruction of some syphilis reagin, but according to Brown and associates, falsely negative Kolmer complement fixation reactions are likely to occur only in the case of sera containing small amounts of reagin.

Furthermore, the addition of N/3 or N/4 sodium hydroxide solution to rabbit and human sera has prevented the occurrence of anticomplementary reactions in the Kolmer complement fixation test. There was some loss of syphilis reagin, but again the authors noted that falsely positive negative reactions are not likely to occur except in the case of sera containing small amounts of reagin.

In Venereal Disease Information for March, 1945, further consideration was given to this question of biologic false positive serologic reactions for syphilis. Such false positives are common in leprosy, malaria, infectious mononucleosis, vaccination against smallpox, rat-bite fever, relapsing fever, lupus erythematosus, and possibly atypical pneumonia. There is no reliable evidence that the tests are affected by pregnancy, menstruation, scarlet fever, jaundice, subacute bacterial endocarditis, tuberculosis, or hyperproteinemia. Inadequate data are available on measles, mumps, infectious hepatitis, lymphogranuloma venereum, and chancroid.

In this communication it was stated that transient false positive reactions may occur in apparently normal individuals without recent illness and in cases of some diseases the incidence of which is so low as to suggest that the relationship may be coincidental. It has been suggested that even persistently positive reactions may occur in nonsyphilitic patients. In widespread serologic surveys the number of innocent victims may be large.

Since low titer syphilitic sera may show discrepancies between the results obtained with various test antigens and fluctuation in apparent reactivity of successive sera, these are not adequate criteria for considering a positive reaction true or false.

The various complement fixation and flocculation tests for syphilis are antigen-antibody reactions. The lipid antigen is widely distributed in human and other mammalian tissues, and is an effective antigen for forming antibodies if mixed with a foreign protein before inoculation. It is not clear whether the Wassermann antibody is formed in response to Wassermann antigen from the organisms or to tissue antigen rendered active by the spirochete. If the latter hypothesis is correct, no difference would be expected to exist between the Wassermann antibodies in syphilis and in other diseases.

Some of the false positive reactions may be eliminated in the future by purification and improvement in specificity of lipid antigens of the Wassermann group, but there is no reason to expect all false Wassermann antibodies to differ in any given respect from the true antibody. Attempts to find consistent empirical physicochemical differences betwen syphilitic and false positive sera have thus far failed. The most promising approach to the problem is the detection of antibodies to antigens of the spirochete other than Wassermann antigen. See the treponemal immobilization test, page 2085.

7. Hemolysis

By "hemolysis" is meant the digestion or dissolution of blood cells by various agents. Hemolysis may be caused by chemical or bacteriologic factors. For instance, blood cells are hemolyzed by the addition of distilled water and mineral acids. A specific blood cell, for example the sheep cell, would be hemolyzed or digested in the presence of the specific antisheep hemolysin and sufficient complement. Excessive or prolonged heat, toxins of certain bacteria, undue agitation, age, and other factors cause hemolysis of blood cells.

8. Hemolysin or Amboceptor

Hemolysin is a substance, either present normally, or artificially produced, in the blood serum of animals, that is capable of dissolving the blood cells against which it has a specific action. This reaction does not take place unless complement is used. Hemolysin is artificially produced by the injection of blood cells of one species of animal into the blood stream of another animal, at definite intervals. The blood serum of the animal injected contains the hemolysin which is specific in dissolving the blood cells of the species of animal the cells of which were used for injection.

For example, if sheep cells are injected into the blood stream of a rabbit, the rabbit blood serum develops antisheep hemolysin. This hemolysin is capable of dissolving sheep cells (if complement is present in the reaction). Any other type of hemolysin is produced in a similar fashion.

9. Sheep Cells

The washed blood cells of a sheep are used in complement fixation tests if antisheep hemolysin is used. If antichicken hemolysin is used, chicken cells are used in the test.

10. Hemolytic Index

Hemolytic index refers to the amount of hemolytic action (or blood cell digestion) the blood serum has naturally against a given species of blood cells. For example, if 0.1 c.c. unheated patient's serum is capable of causing hemolysis of 0.8 c.c. sheep cell suspension (without the addition of hemolysin or complement from another animal) the hemolytic index is 0.8 c.c. This term is used particularly in the Hecht-Gradwohl test.

11. Anaphylaxis (see page 1339)

Anaphylaxis is shock produced by the injection of a foreign protein into an animal whose tissues are sensitized to the protein injected. It may be natural or acquired. It is produced by injecting the foreign protein the second time into an animal after a period of time long enough to permit sensitization to develop.

12. Antigen-Antibody Reaction

An antigen-antibody reaction is the reaction which takes place between an antibody and a specific antigen. In the Wassermann reaction, it is seen in the production of complement fixation. The reaction in the Wassermann test for syphilis does not utilize a true antigen (that is, an extract of *Treponema pallidum*) but is an extract of lipoidal substances. A true antigen-antibody reaction is illustrated in the tuberculosis complement fixation test where the blood serum contains the true antibody of tuberculosis, and the antigen is made by extracting tubercle bacilli.

13. Reagin

The term ''reagin,'' originated by Coca, is employed to designate what in respect to other microbic diseases would be called the ''antibody of syphilis.'' No one has found antispirochetal antibodies in the blood sera of syphilitic patients. Syphilitic serum does not agglutinate the spirochetes in material from lesions and does not contain treponemacidal substances. Syphilitic serum does not agglutinate cultures of *Treponema pallidum.* Rabbits injected with these cultures develop agglutinins for the culture spirochetes but these sera have no protective action when injected into rabbits along with virulent organisms. It is generally believed that humoral antibodies have no significance in immunity in syphilis. Nevertheless, we speak of ''antigen-antibody'' reactions in syphilis purely in a theoretical sense. The term is incorrect in view of the foregoing statements, but is used purely in an artificial sense.

14. Anticomplementary

The meaning of the term ''anticomplementary'' is as follows: any condition which arises in a complement fixation test which, by itself, causes destruction of complement. A serum may **become** anticomplementary, or it may be naturally anticomplementary. It becomes anticomplementary through age. bacterial contamination, or other unknown factors.

15. Thermolabile

Any substance which is affected or destroyed by heat is thermolabile. Complement, for example, is thermolabile.

16. Thermostable

Any substance which is unaffected by heat. Hemolysin, for instance, is thermostable.

17. Hypertonic

A hypertonic solution is one that contains an excessive amount of chloride over the physiologic amount, 0.85 per cent, or which has a higher osmotic pressure than the blood.

18. Hypotonic

A hypotonic solution is one that contains chloride under the physiologic amount, 0.85 per cent.

19. Cholesterinization

Cholesterinization is the rendering of an antigen more sensitive by the addition of a small amount of cholesterol.

THE WASSERMANN TEST OF BLOOD

Preparation of Glassware

New glassware should be immersed in a freshly prepared weak solution (1:1,000) of nitric acid overnight. The following day, rinse thoroughly in tap water to remove the acid. Rinse thoroughly in distilled water. Wrap in paper, and sterilize in the dry heat oven at 170° C. for two hours.

After use, the glassware should be rinsed thoroughly to remove any blood or serum that may adhere to the glass, then wrapped and sterilized.

Do not allow the pipettes or tubes to become brownish. This can be avoided by removing all traces of blood serum or blood corpuscles from the glassware before sterilizing.

Do not use soap or strong chemicals, as it may produce artificial hemolysis of the blood during the performance of the test.

The glassware should be cooled to room temperature before use.

All glassware used in the Wassermann test, including the graduated cylinders, must be clean, sterile, and dry. If glassware shows even a trace of water, it should not be used.

Patient's Serum—Method of Venepuncture

There are certain details about venepuncture which should be borne in mind. The same principles apply whether we are obtaining blood for bacteriologic or serologic purposes. It is first necessary to find a suitable vein on the arm, usually the median basilic vein where it crosses the anterior flexus of the elbow. In babies, we have used the jugular vein of the neck or have simply plunged a large needle into the heel. The patient should be placed in a comfortable position, preferably lying down on the operating table. This facilitates ease of puncture and prevents shock. The instrumentarium should be either the 19-gauge needle described below or a needle attached to a glass syringe. Necessarily, both syringe and needle should be previously sterilized at the proper dry heat sterilization temperature, 170° C. for two hours. Sterilization by boiling is objectionable because it is desired not to have any water in contact with the specimen of blood which is obtained.

With the vein selected and with the arm placed in a comfortable position (on the side arm connected to the operating table) and covered with a sterile towel, one prepares the skin by rubbing with tincture of iodine. Remember that fairly fresh tincture of iodine should be used because it tends to concentrate when it becomes old or if the stopper of the bottle is left out. This concentration is likely to burn the skin of the patient. We now apply a tourniquet; either a flat band of rubber may be used or, preferably, the cuff of a blood pressure apparatus. The cuff of the blood pressure apparatus should be adjusted to the upper arm and applied so as just about to hear the diastolic pressure around 90 to 100. After a deep mahogany color is produced by the application of the iodine, a minute or two is allowed, and then the puncture is started. The selection of the needle is important. One with a rather short bevel is preferred. Be sure that the stylet has been moved back and forward in the needle so that there is no obstruction. Insert the needle almost parallel to the skin. The tendency of most beginners is to plunge the needle directly downward, which perforates both anterior and posterior walls, fails to get blood, and produces an objectionable hematoma in the surrounding tissue. The technic of entering the vein is very much like that of picking up a stitch in a piece of goods, namely, sliding along the anterior wall with a slight dipping motion, penetrating only the anterior wall. The process should be rather swiftly performed so as to produce the minimum of pain. The pain is practically negligible provided the needle is sharp and the operator is swift, and swiftness will come with experience.

Having obtained sufficient blood, the tourniquet or blood pressure cuff is rapidly removed and the needle is then withdrawn. Do not withdraw the needle before the pressure above is relieved, otherwise a hematoma is likely to occur. A pledget of alcohol-soaked cotton is held in the hand and pressed down over the puncture point while the needle is withdrawn.

After the needle is removed, cover the puncture with a small piece of adhesive tape.

If the blood is to be used for serologic work, expel it into a sterile test tube and allow it to clot. If it is to be used for bacteriologic purposes, it should be ejected into a sterile flask or large sterile test tube with a tightly fitting sterile cork and defibrinated to prevent clotting. If it is to be used for serologic purposes immediately, place the clotted blood in the incubator and wait a few minutes before centrifugalization. If it is not to be used until later, place in refrigerator.

Fig. 326 shows various types and sizes of needles used in laboratory procedures. Needles of gauges 19 and 20 are used for venepuncture; gauges 23 and 24 for subcutaneous injections; gauges 15 and 17 are useful in connection with obtaining blood for blood transfusion purposes or for use with the Baxter vacuum outfit.

Needles for taking the blood are the hose-type 19 gauge 1 inch needle (Becton-Dickinson Company). Place a wire in the needle, thrust the point into a cork test tube stopper and place the cork containing the needle into the test tube that is to be used for collecting the patient's blood. The whole is sterilized at 170° C. for two hours.

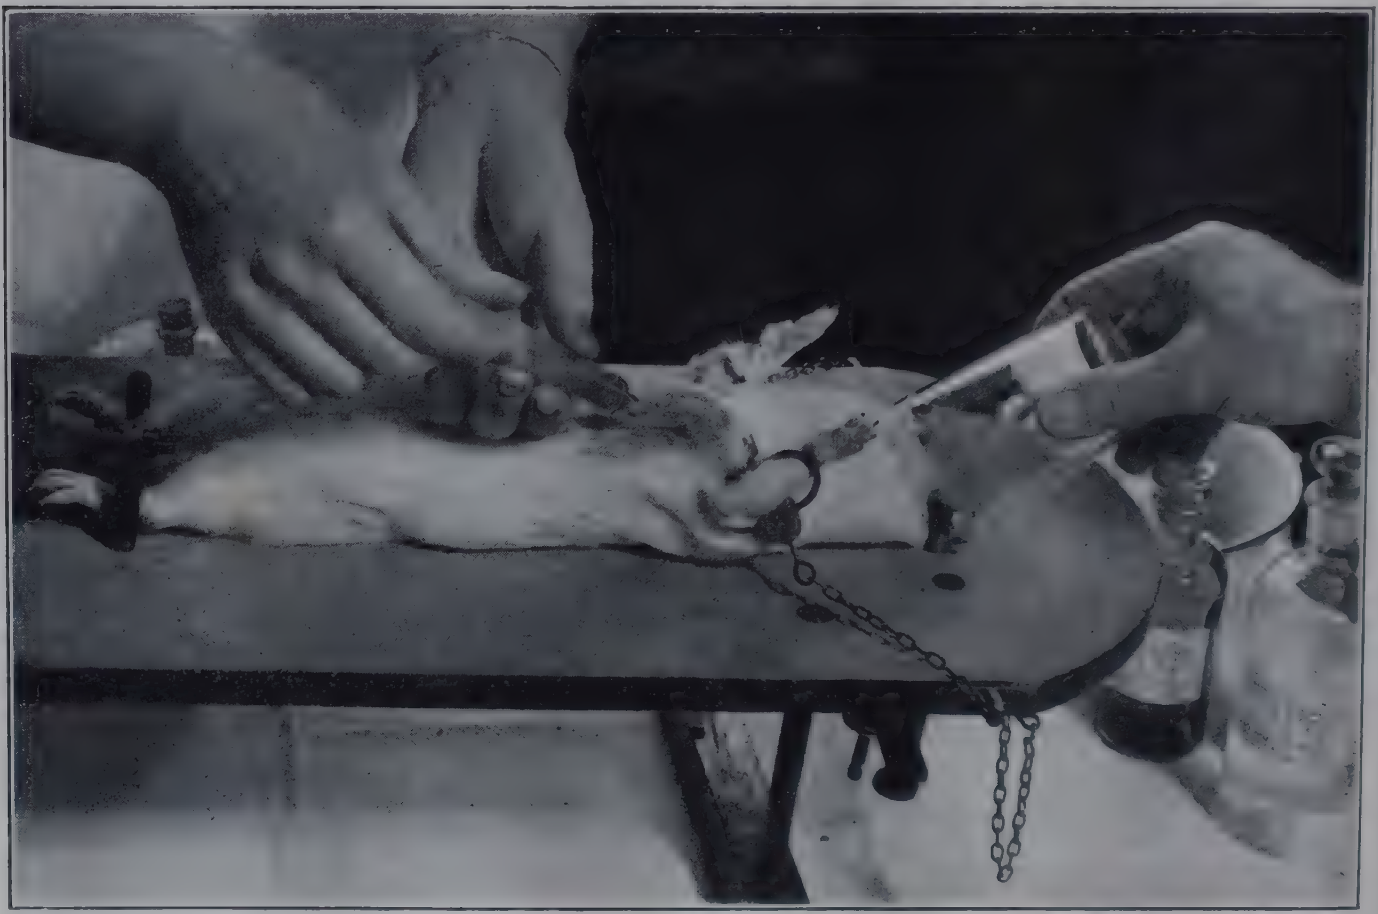

Fig. 594.—Withdrawing blood from the heart of a guinea pig. This is the Friedberger-Gradwohl apparatus. After the guinea pig is anesthetized, this is an excellent position for cardiac or carotid artery work.

Each blood, after it has been entered into the laboratory specimen book, and given a number, should be recorded on a sheet of paper representing the blood specimens of the day. After recording on the record sheet, loosen the clot from the side of the tube with a sterile wooden applicator. Centrifuge at high speed for 15 minutes to separate the serum from the clot.

Using a sterilized dropper, remove the clear supernatant fluid, placing it in a sterile test tube. If the serum is to be used for the Hecht-Gradwohl test, as well as for the Wassermann test, it is divided between two test tubes.

The serum for the Wassermann, Kahn, Kline, and Kolmer tests is placed in the inactivator at 56° C. for thirty minutes. The serum for the Hecht-Gradwohl test is ready for use; i.e., it is not heated.

It is customary to use letters of the alphabet as markers for the various sera in each day's work. The sera are then tested as A, B, C, etc.

When a serum has been tested, and is to be saved as a serum-control, a sterile cork stopper is placed in the tube, the tube labeled and dated, and placed in the refrigerator.

Physiologic Saline

This is 0.85% sodium chloride solution in water.

Dissolve 8.5 grams sodium chloride, c. p., in 1,000 c.c. distilled water in a large bottle.

The sodium chloride must be very accurately measured, and the quantity of distilled water must be exactly 1,000 c.c.

Mix thoroughly until the sodium chloride is dissolved and equally distributed throughout the solution by thoroughly shaking the large bottle.

Filter through filter paper into brown bottles of 500 c.c. capacity.

Fill these bottles about two-thirds full. Plug with nonabsorbent cotton. Cover with paper. Autoclave for sterilization at 15 pounds pressure for thirty minutes.

Do not use before the solution has cooled to room temperature.

Saline solutions should be made at least once, and preferably twice, a week.

If brown bottles are not used, keep the saline solution in a dark cabinet when not in use.

Preparation and Titration of Complement for the Wassermann Test

The blood serum of guinea pigs is used in the Wassermann test to supply complement.

Assemble the following materials:

Guinea pig and animal board.
Five c.c. Luer syringe with 1½ inch 21 gauge needle, sterilized in the dry heat oven at 170° C. for two hours.
Test tube for collecting the blood.
Sterile sponges.
Alcohol or iodine.
Ether anesthetic.
Sterile saline in test tubes for emergency injection, or for opening needle if it becomes plugged.

Place the animal on the animal board. (Fig. 594.)

Shave the skin over the area of the heart.

Locate the heartbeat (left ventricle) by palpation.

Give the animal a light anesthetic.

Disinfect the skin with alcohol or iodine.

Plunge the needle attached to the syringe into the heart, taking care that the needle is in the left ventricle.

Slowly withdraw 5 or 10 c.c. blood from the heart.

Eject the contents of the syringe into a sterile test tube.

Inject 5 c.c. saline into the abdominal wall of the guinea pig, and release it from the board.

Allow the blood to clot. Loosen the clot from the side of the tube with a sterile wooden applicator. Centrifuge at high speed to separate the serum from the clot. Remove the clear supernatant serum from the clot by means of a sterile dropper, placing it in a sterile test tube. If there are any blood cells in the serum, recentrifuge it and decant the cell-free serum.

The serum is now ready for dilution and titration preliminary to use in the Wassermann test.

Technic of Dilution and Titration of Complement for the Wassermann Test

Place 7 c.c. physiologic saline in a sterile cylinder. (This should be measured with a 10 c.c. graduated pipette.)

Add 1 c.c. guinea pig serum.

Dilute the hemolysin as for the Wassermann test.

Use the suspension of sheep cells which is to be used in the day's work.

Set up four Wassermann tubes in a rack and carry out the titration as in Table 186.

TABLE 186

TUBES	1	2	3	4
Saline	1.2 c.c.	1.1 c.c.	1.0 c.c.	0.9 c.c.
Complement	0.1 c.c.	0.2 c.c.	0.3 c.c.	0.4 c.c.
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.
Sheep Cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Total Volumes	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.

Place in the water-bath 37°-40° C. for five minutes.

Accurate timing is important.

The saline is placed in each of the four tubes, then the complement, then the hemolysin, then the sheep cells.

After the tubes are ready for the water-bath, they are shaken thoroughly to mix the contents. The quantity in each tube should be the same.

At the end of five minutes' incubation, observe for hemolysis of the sheep cells.

If all tubes show hemolysis, 3 c.c. physiologic saline should be added to the diluted complement, and the titration repeated.

The tube containing the smallest amount of complement that shows complete hemolysis is the unit tube. Add 0.1 c.c. to the unit to find the titer for the day's work.

For example: Tube 1 shows no hemolysis.
Tubes 2, 3, and 4 show complete hemolysis.
Tube 2 contains the smallest amount of complement that will completely hemolyze 1 c.c. of diluted sheep cells. The amount in Tube 2 is 0.2 c.c.
0.2 c.c. + 0.1 c.c. = 0.3 c.c., or the titer of complement for the day's Wassermann tests.

If all four tubes show no hemolysis, either the complement is too weak, or the other reagents are not in perfect condition. If the complement is fresh, it is reasonable to assume that the fault is in the saline, hemolysin, or sheep cells.

If the saline is at fault from high concentration, a new solution will have to be made.

If the hemolysin is too weak, a stronger solution of hemolysin must be diluted, and another titration made.

If the sheep cells are in too heavy suspension, dilute further, and retitrate the complement.

Lack of hemolysis in any tube, when the complement is fresh, is frequently due to too weak a hemolysin.

If the mixture in Tube 1 is not hemolyzed, in Tube 2 is half or partially hemolyzed, and in Tube 3 is completely hemolyzed, we assume that the smallest amount of complement that will cause complete hemolysis is 0.25 c.c., the quantity midway between 0.2 c.c. and 0.3 c.c. The titer in such a case is 0.25 c.c. + 0.1 c.c., or 0.35 c.c.

If the first three tubes show no hemolysis, and Tube 4 shows complete hemolysis, we usually discard the complement for a fresh complement, as 0.5 c.c., the titer in this case, is too large a quantity to use in the test.

The titration of complement not only determines the volume of diluted guinea pig serum to be used in the test, but a successful titration is a check of the reagents, saline, hemolysin, and sheep cells which are also to be used in the day's Wassermann tests. This titration should always be carried out immediately before any Wassermann tests are made. No further check of these reagents is necessary.

Complement may be saved for several days, provided a titration is made prior to the Wassermann test. It usually deteriorates after two or three days. It should be kept in a corked container in the refrigerator.

The pooled blood serum of several guinea pigs is usually higher in complement than the blood serum of a single guinea pig.

The titration of complement is the same whether it is to be used in the Wassermann test, or in the titration of hemolysin or antigen.

If the titration of complement shows that the saline used was stronger than 0.85 per cent, all reagents will have to be rediluted with fresh saline before a test can be made.

NOGUCHI'S ETHER-SOLUBLE ACETONE-INSOLUBLE ANTIGEN

Preparation

Obtain beef heart and beef kidney from the abattoir.

Remove all fat and fibrous particles, cutting the meat into very small pieces so that there is no difficulty in finding and removing all undesirable material.

Grind in a meat grinder.

Add 50 grams beef heart, finely ground, and 50 grams beef kidney, finely ground, to 1,000 c.c. 95% ethyl alcohol.

Place all in a large bottle, stopper with a rubber stopper, shake thoroughly and place in the incubator at 37° C. for ten days, shaking twice a day during this period.

Filter through filter paper into a large, flat, clean, white porcelain pan.

Cover the pan with a thin layer of gauze to prevent contamination by flies or other insects.

Evaporate to dryness by means of an electric fan. This process may take from twenty-four hours to ninety-six hours.

A yellowish sticky residue remains in the pan.

Take up the residue in 75 c.c. ether. This is accomplished by marking a wide-mouth colorless bottle at 75 c.c., then adding ether to the pan, a small amount at a time, pouring into the bottle, adding more ether, etc., until all the residue has been dissolved or suspended in exactly 75 c.c. total quantity of ether.

Stopper the bottle tightly, holding the stopper in place with adhesive tape. Place in the refrigerator for twenty-four hours. The temperature of the refrigerator should be from 0 to 5° C. The insoluble substances will precipitate during the twenty-four hours.

Decant the supernatant fluid in which the ether-soluble substances of the meat are dissolved. Place the fluid in a casserole.

Evaporate the liquid in the casserole to 20 c.c. This can be judged approximately by placing 20 c.c. water in another casserole of the same dimensions, and comparing the two quantities.

Add 40 c.c. chemically pure acetone, free of methyl alcohol. (A very satisfactory acetone is Merck's reagent grade.) A precipitate will form immediately. This precipitate contains those lipoidal substances from the meat which are both soluble in ether and insoluble in acetone.

Cover the casserole with a thin layer of gauze, and allow it to remain at room temperature for an hour.

Pour off the supernatant fluid, keeping the sediment.

Place sediment in a wide test tube. Remove all traces of the acetone by pressure with a glass rod, pour off, leaving a sediment of a resinous consistency.

Cork the test tube tightly, label "stock antigen," and place in a cool box for at least two weeks to one month before diluting for titration.

This **Stock Antigen** can be kept indefinitely, unless it becomes contaminated with molds.
Prepare a **Stock Antigen Solution** from this stock antigen.

Stock Antigen Solution

Dissolve 0.3 gram stock antigen accurately measured on analytical balance

in 1.5 c.c. ether. The 0.5 c.c. ether is added to take care of loss by evaporation. When larger quantities of the stock dilution of antigen are made, it is not necessary to figure 0.5 c.c. for evaporation for each quantity.

Add 9.0 c.c. chemically pure methyl alcohol, free of acetone. (The methyl alcohol of the National Aniline and Chemical Company is excellent for this purpose.)

Mix thoroughly. A slight precipitate will form. The supernatant fluid is used.

To use in the Wassermann test, the antigen must be diluted with physiologic saline.

The exact dilution of each antigen varies but seldom.

From our experience in making hundreds of bottles of antigens in our laboratories, it has been found that in almost every case a dilution of 1 part of stock antigen solution with 9 c.c. physiologic saline gives a titer of 0.2 c.c. Nevertheless, each new quantity of antigen must be titrated before use. Since 0.2 c.c. is the titer of antigen that is desired, the titration of antigen is usually made first with a dilution of 1:10. Any subsequent dilutions of antigen are made if this dilution is insufficient, or if the exact strength of the antigen is desired.

Titration of Antigen

The dilution of the antigen may vary. It is, however, as previously stated, usually 1 part of antigen solution to 9 parts of physiologic saline.

In the titration of antigen, that quantity is used which gives (1) a strong (++++) positive reaction on a known positive (++++) serum when ½ the quantity to be used in the Wassermann test is employed; and (2) a clear negative reaction on a known negative serum when double the quantity to be used in the Wassermann test is used.

Example:

If 0.2 c.c. of antigen is to be used in the Wassermann test, 0.1 c.c. of antigen must give a ++++ positive reaction on a known ++++ positive serum; and 0.4 c.c. antigen must give a negative reaction on a known negative serum.

Prepare and titrate fresh complement.

Dilute the hemolysin and sheep cells.

Have on hand about 5 c.c. known ++++ positive serum and 5 c.c. known negative serum.

Make three dilutions of the stock antigen solution:

1:10, made by adding 1 c.c. stock antigen solution
to 9 c.c. physiologic saline
1:15, made by adding 1 c.c. stock antigen solution
to 14 c.c. physiologic saline
1:20, made by adding 1 c.c. stock antigen solution
to 19 c.c. physiologic saline.

The diluted antigen will be opalescent.

Carry out the titration of antigen according to the following chart, using each antigen dilution. It requires three Wassermann racks for the full titration.

Rack up the tubes so that there are four Wassermann tubes in the front row of holes at the left of the rack, and four at the right of the rack.

Place one tube behind the four tubes at the left, and one tube behind the four tubes at the right of the rack. The back row (two) of tubes are the serum controls. These are always used to be sure that the serum employed in the titration has not become anticomplementary.

TABLE 187.—TECHNIC OF TITRATION OF THE ANTIGEN WITH A KNOWN ++++ POSITIVE SERUM

TUBES	1	2	3	4	CONTROL
Known ++++ serum	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.
Saline	0.7 c.c.	0.6 c.c.	0.5 c.c.	0.4 c.c.	0.8 c.c.
Complement	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.
Antigen	0.1 c.c.	0.2 c.c.	0.3 c.c.	0.4 c.c.	------
Place in the water-bath at 37°-40° C. for 30 minutes.					
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.
Sheep cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Place in the water-bath at 37°-40° C. for 30 minutes.					
Total quantity	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.

TABLE 188.—TECHNIC OF TITRATION OF THE ANTIGEN WITH A KNOWN NEGATIVE SERUM

TUBES	1	2	3	4	CONTROL
Known negative serum	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.
Saline	0.6 c.c.	0.4 c.c.	0.2 c.c.	------	0.8 c.c.
Complement	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.
Antigen	0.2 c.c.	0.4 c.c.	0.6 c.c.	0.8 c.c.	------
Place in the water-bath at 37°-40° C. for 30 minutes.					
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.
Sheep cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Place in the water-bath at 37°-40° C. for 30 minutes.					
Total in each tube is	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.

The complement varies according to the previous titration result.

The quantity of saline in each tube varies according to the amount of complement used.

The control tubes should always show complete hemolysis.

If these tubes show no hemolysis, the serum used is anticomplementary, and another serum must be substituted.

Tubes 1 and 2 are the two tubes which are of importance if a titer of 0.2 c.c. is desired. If any other titer is preferred, Tubes 3 and 4 are the important tubes. In the titration with a known positive serum, if Tube 1 shows complete inhibition of hemolysis (cloudy tube with precipitate of cells), then 0.1 c.c., or ½ the desired titer, gives a strong positive reaction on a known ++++ positive serum. If this tube shows no hemolysis, the other tubes (2, 3, and 4) will show the same result.

If this tube shows complete, or partial hemolysis, the titer of the antigen cannot be 0.2 c.c.

If all tubes show complete hemolysis, the antigen must be discarded, as it is too weak in its action to be of any value in the Wassermann test.

In the titration with a known negative serum, Tube 2 contains 0.4 c.c. antigen, and is, therefore, the tube in which the titration result is determined. If this tube shows complete hemolysis, 0.2 c.c. antigen may be used as a titer, since double the quantity, or 0.4 c.c., gives a clear negative reaction on a known negative serum. The titer depends, obviously, on the result in the titration with a known positive serum also.

If all tubes show complete hemolysis, the antigen is such that the worker can be absolutely sure that no false positive reactions will occur. False positive reactions may be due to too strong an antigen.

If all tubes show complete, or partial, inhibition of hemolysis, the antigen must not be used in this dilution. If this occurs, the titration results with a 1:15, or a 1:20, dilution of the antigen must be studied for the purpose of determining the exact dilution of the antigen to be used in the subsequent Wassermann tests.

It is well, in the titration of antigen, to test its action on many known positive and negative sera before using it in the Wassermann tests. In this way, false reactions due to faulty antigens can be avoided.

The antigen is a very important reagent in the Wassermann test, and like all other reagents, great care must be used in its manufacture and titration.

In the preparation of any antigen for any complement fixation or precipitation test for syphilis, the titration should always be carried out on known positive and negative sera. Any other method of titration, if employed, is inadequate in judging the action of an antigen. In the titration just described, if ½ the titer used in the Wassermann gives a positive reaction on a strongly positive serum, it is reasonable to assume that the antigen is capable of detecting antibodies in weakly positive serums when 0.2 c.c. are used. The reaction on sera of this type are not false positives, since false positive reactions are guarded against by titrating against a negative serum, in which it is shown that quantities of antigen as high as 0.4 c.c., or in many cases, as high as 0.8 c.c., do not give positive results.

After antigen has been diluted in saline, it is not stable, and must be discarded after the Wassermann tests are made.

It is well to dilute only the quantity needed in the day's work. This is a definite saving of stock antigen.

Preparation of Cholesterinized Antigen from Noguchi's Ether-Soluble, Acetone-Insoluble Antigen

Make 10 c.c. **Stock Antigen Solution** (page 2035).

Add 100 mg. cholesterol, c. p., and dissolve.

If placed in the refrigerator, the cholesterol may precipitate. Before use, place in a water-bath at 37° C. until the cholesterol is again in solution.

When this antigen is diluted 1:10, the cholesterol present is in the proportion of 1:1,000.

Obviously, if the final dilution of the antigen with saline is to be 1:15, instead of 1:10, 150 mg. of cholesterol are used instead of 100 mg. Similarly, if the dilution is to be 1:20, 200 mg. cholesterol are added to the stock solution.

The cholesterol is added to the stock solution, since it is soluble in the methyl alcohol present but not in saline.

Preparation and Titration of Antisheep Hemolysin

Select large, healthy rabbits for injection purposes. The animals should be quarantined for several weeks before using until the condition of their health is established.

Use washed sheep cells for injection to prevent anaphylaxis. The sheep cells should be warmed to body temperature before use.

Use 1 c.c. tuberculin syringes so that the quantity of cells injected is accurately measured.

Remove the hair over the area of the marginal ear vein.

Disinfect the skin with alcohol.

Rub xylol into the skin to dilate the vein.

Select a point for the first injection near the tip of the ear; a point higher up or more proximal for the second; etc.

Inject 1 c.c. of washed sheep cells into the vein. See Figs. 597 and 598.

Tag the animal and record its number and the date of inoculation.

Repeat the injections at four-day intervals until 4 injections have been given.

Allow three days to elapse before withdrawing blood from the animal to test the amount of hemolysin produced.

Withdraw about 5 to 10 c.c. blood from the ear vein of the injected rabbit after the three-day interval has passed.

This is accomplished either by using a syringe to withdraw the blood from the marginal vein, prepared as above, or by making an incision into one of the ear veins, and allowing the blood to run into a test tube.

Allow the blood to clot.

Loosen the clot from the side of the tube with a sterile wooden applicator.

Centrifuge at high speed for fifteen minutes.

Decant the clear supernatant serum, placing it in a clean dry test tube.

Inactivate at 56° C. for thirty minutes to destroy the natural complement in the serum.

The quantity of hemolysin in the serum is then *roughly estimated* as follows:

Make the following dilutions of the rabbit blood serum:

1 drop of serum in 80 c.c. sterile saline (physiologic)
1 drop of serum in 100 c.c. sterile saline (physiologic)
1 drop of serum in 140 c.c. sterile saline (physiologic)
1 drop of serum in 160 c.c. sterile saline (physiologic)
1 drop of serum in 200 c.c. sterile saline (physiologic)
1 drop of serum in 250 c.c. sterile saline (physiologic)
1 drop of serum in 300 c.c. sterile saline (physiologic)
1 drop of serum in 400 c.c. sterile saline (physiologic)

Mix the serum dilutions very thoroughly, since the quantity of serum in saline is extremely small.

Measure the drops with a 1 c.c. pipette, holding the pipette in a horizontal position, and allow the drop to collect on the under side of the pipette.

The physiologic saline is added to the containers first. The serum is placed in each container with the same pipette to insure uniformity of the drop.

After the dilutions have been made, prepare the dilution of sheep cells in the same manner as for the Wassermann test.

Dilute and titrate the complement (which must be fresh), using for this titration a hemolysin which has previously been titrated, and the strength of which is known. After the titration of the complement, the diluted hemolysin used in it may be discarded.

Rack up 8 Wassermann test tubes.

Carry out the rough titration in Table 189.

TABLE 189

TUBES	1	2	3	4	5	6	7	8
Dilution of hemolysin	1 drop in 80 c.c. saline	1 drop in 100 c.c. saline	1 drop in 140 c.c. saline	1 drop in 160 c.c. saline	1 drop in 200 c.c. saline	1 drop in 250 c.c. saline	1 drop in 300 c.c. saline	1 drop in 400 c.c. saline
Saline	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Complement*	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.
Sheep cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Total quantity	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.

*The quantity of complement varies according to the previous titration results.

Place in the water bath at 37° to 40° C. for fifteen minutes.

The quantity of saline will vary according to the quantity of the complement, so that the total will remain 2.8 c.c. The saline is placed in the tubes first. The amount of saline is figured after the previous titration of complement.

Tube 1 received 0.5 c.c. hemolysin diluted 1 drop in 80 c.c. saline; Tube 2, 0.5 c.c. hemolysin diluted 1 drop in 100 c.c. saline, etc.

A different pipette is used for measuring each different quantity of hemolysin.

Shake the rack thoroughly before placing in the water-bath.

Observe at the end of every five minutes for hemolysis.

If no hemolysis occurs in any tube, an insufficient amount of hemolysin has been produced to warrant bleeding of the rabbit. Further injections may be given followed by titrations just described, or the animal may be discarded, and other animals injected.

If hemolysis occurs in the first two tubes only, the hemolysin is too weak to justify the bleeding of the animal.

If, however, hemolysis occurs in any tube higher than Tube 2, the animal should be bled to the point of exsanguination and the final titration made.

The rough titration just described gives an index of the quantity of hemolysin present, so that the final titration may be made with dilutions suggested by the results of the first titration. For example, if hemolysis occurs in the tube containing hemolysin diluted 1 drop to 300 c.c. saline, and partial hemolysis occurs in the tube containing hemolysin diluted 1 drop in 400 c.c. saline, the final dilution lies between 1 drop in 300 c.c. and 1 drop in 400 c.c. The final titration would, in this case, be made with dilutions of 1:280; 1:300; 1:320; 1:340; 1:360; 1:380; 1:400.

If the rough titration of hemolysin warrants the bleeding of the rabbit, the animal is bled to exsanguination[1] and the blood collected in sterile 50 c.c. Rockefeller tubes with corks.

Allow the blood to clot, keeping the tubes slanted.

Loosen the clot by striking firmly against the palm of the hand.

Centrifuge at high speed for fifteen to thirty minutes to separate the serum from the clot.

---

[1] See p. 2040.

Decant the supernatant serum into sterile Rockefeller tubes, using all sterile precautions.

Cork the tubes to prevent bacterial contamination.

Inactivate at 56° C. for thirty minutes.

Place the hemolysin in 5 c.c. quantities in sterile ampules, using a sterile syringe. Seal the ampules in the flame.

Leave enough of the hemolysin in a sterile test tube, corked, to allow for the final titration.

Keep the ampules in the refrigerator until ready for use.

After the final dilution of the hemolysin is determined, label all ampules with the dilution just determined, the titer (0.5 c.c.), and date of manufacture.

The final titration of hemolysin is carried out according to Table 190.

The complement must be obtained fresh, and diluted and titrated, using a known hemolysin for the titration. The hemolysin to be titrated is diluted in saline in the quantities given in the preceding paragraph, or other dilutions are made, as the case may be.

TABLE 190.—CHART FOR THE FINAL TITRATION OF HEMOLYSIN IN THE EXAMPLE CITED

TUBES	1	2	3	4	5	6	7
Dilutions of hemolysin	1 drop in 280 c.c. saline	1 drop in 300 c.c. saline	1 drop in 320 c.c. saline	1 drop in 340 c.c. saline	1 drop in 360 c.c. saline	1 drop in 380 c.c. saline	1 drop in 400 c.c. saline
Saline	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Complement*	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.

Sheep cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Total quantity	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.

*The quantity of complement varies according to a previous titration.

Place in the water-bath at 37°-40° C. for fifteen minutes.

The last tube in which hemolysis occurs is the unit.

The final dilution of hemolysin to be used in the Wassermann reaction will be four times the strength of the hemolysin in the last tube showing hemolysis.

If no tube shows hemolysis, the dilutions are too high, and lower dilutions of the hemolysin will have to be made.

If all the tubes show hemolysis, the dilutions are not high enough, and the titration will have to be carried further.

Example: If the last tube showing complete hemolysis at the end of fifteen minutes' incubation is Tube 4, containing hemolysin diluted 1 drop to 340 c.c. saline, the final dilution of the hemolysin is 1 drop to 85 c.c. saline. After the dilution has been determined, retitrate the same complement used in this titration of hemolysin, using the new hemolysin diluted according to the dilution just determined (in this case 1:85). The titer of the complement should be the same as it was with the old hemolysin. In this manner, each new hemolysin is standardized in its action with complement against the previously titrated hemolysin.

Method of Bleeding Rabbit From the Carotid Artery

Prepare the following sterile instruments:

1 pair sharp pointed small scissors.
1 pair sharp pointed long scissors.
2 seraphine clamps.
2 fine pointed hemostats.
1 pair tissue forceps.
Several pieces of linen thread about 8 inches long.
3 or 4 Rockefeller centrifuge tubes with corks.
Gauze sponges.
2 groove directors, or probes.

Assemble, also, material for anesthetic, iodine, shaving material, rabbit board.

Place the animal on the rabbit board, and give a light anesthetic. Ether is preferable to chloroform.

Shave the hair over the entire front area of the neck.

Pour on a generous quantity of iodine. If too small a quantity of iodine is used, the blood may become contaminated from bacteria on the rabbit's skin. Make a long incision through the skin over the neck. The incision should be at least 4 inches in length, and extend in a lateral line in the center of the neck.

Grasp the probes at the center, and probe down into the muscles until the carotid artery is visible. It will be easily recognized by the arterial beat, and the vagus nerve which is adjacent to it. Do not mistake the jugular vein for the carotid artery.

Lift the artery on the probes, placing the probes sidewise under the artery to lift it.

Separate the artery from the nerve.

Tie off the upper end of the artery with linen thread which has been previously dipped in iodine. Do not tie too tightly, or the arterial wall may be broken. Tie tightly enough so that the artery does not retract through the suture.

Clamp the other end of the artery, about 1½ inches below the thread, with a seraphine clamp.

Cut the thread so that about one-quarter of an inch remains protruding from the double knot.

Pick up one wall of the artery between the thread and the clamp with the hemostat. Be sure not to close the entire artery during this process.

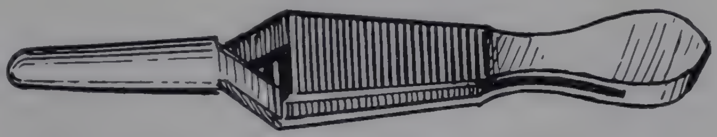

Fig. 595.—Seraphine clamp.

Cut the artery in about the center of the space between the thread and the clamp.

Place a small amount of iodine on the end of the cut artery nearer the clamp. This procedure must not consume too much time.

Direct the end of the artery into a sterile Rockefeller tube, and loosen the seraphine clamp.

The blood spurts through the artery into the tube. Be sure to keep the animal under a light anesthetic during this process. Do not give too heavy an anesthetic.

Allow the blood to run from the artery, filling as many tubes as necessary, until the animal is dying, then give a heavy anesthetic, sacrificing the rabbit.

The bottle is stoppered with a sterile cork immediately after the blood is obtained.

Shipley[1] has devised a board for studies requiring repeated injections into the ear veins of rabbits. It has the advantage of effectively holding rabbits and immobilizing their ears for bleeding or injection procedures.

The significant feature of the apparatus is a mask, shaped to accommodate the anterior three-fourths of the rabbit's head. An inverted, U-shaped collar holds the head firmly in the mask so that the position of the ears is correspondingly stabilized. The head holder is made by molding a liquid thermō-setting plastic[2] around a plaster-of-Paris model which has been shaped to conform to that of the head of a rabbit weighing about 2.5 kilograms. Provisions are made for leaving a hole from the nose to the outside. Within the two horizontal, tubular supports which are included in the plastic casting run two 3/16 inch ball chains 12 inches long. The anterior three-fourths of the rabbit's head is held in the cast by a horse-collar-shaped neckpiece to which are attached the ball chains. Once the rabbit's head is placed in the cast, the operator exerts traction on the chains, and under moderate tension the latter are secured by fitting them into two narrow vertical slots on the ends of the horizontal support tubes.

---

[1] Proc. Soc. Exper. Biol. & Med. 63: 75, 1946.

[2] "Catavar 101" (cream colored) or "Catavar 1001" (clear), Catalin Corporation of America, New York, N. Y. Plaster of Paris may also be used.

The body of the rabbit is confined in a 5 by 5 by 12 inch metal box with a hinged lid and clasp. Two flanges fastened to the front of the box prevent the rabbit's legs from reaching the area about the ears. All parts are mounted on a piece of 12 by 27 by ¾ inch plywood, the top and edges of which are covered with sheet metal 0.050 inch thick. For maximum rigidity, durability, and ease in cleaning, stainless steel, chrome-plated brass, and plastic were used. In using this box, by transilluminating the rabbit's ear from below, locating and visualizing particularly the smaller veins is greatly facilitated.

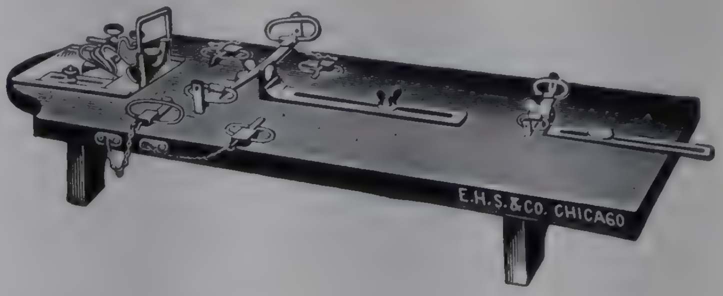

Fig. 596.—Animal board, Latapie. (Courtesy E. H. Sargent & Co.)

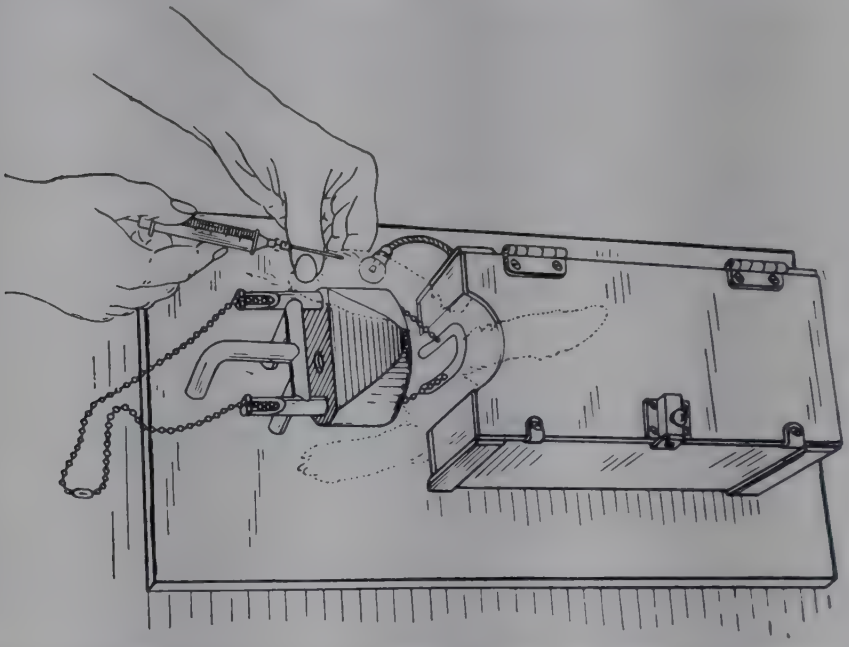

Fig. 597.—The Shipley rabbit board. (Courtesy Dr. R. E. Shipley, Eli Lilly and Company.)

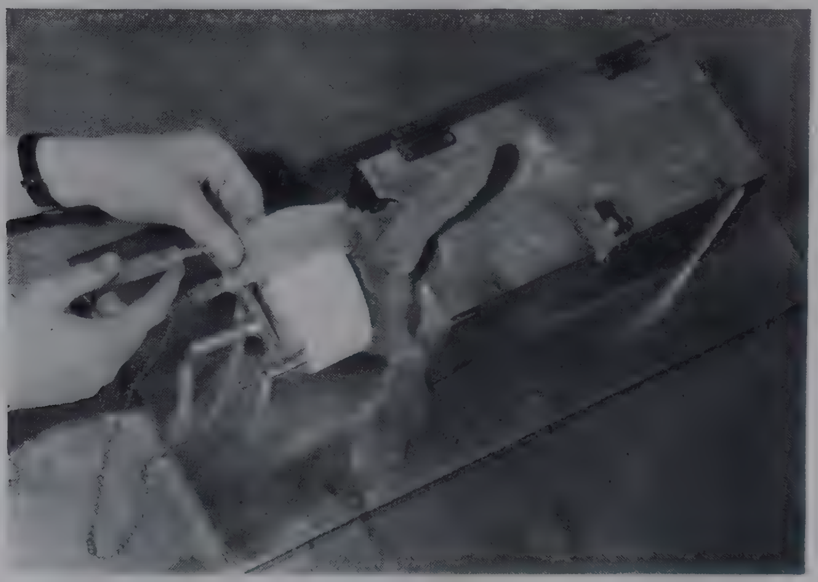

Fig. 598.—Injecting into the marginal ear vein of a rabbit, using the Shipley rabbit board to hold the animal. (Courtesy Dr. R. E. Shipley, Eli Lilly and Company.)

It is rarely necessary to clip or shave the hair over the vein in preparation for injection. A flexible arm with a small socket and bulb attached may be brought into any desired position beneath either ear.

Preparation and Dilution of Sheep Cells for the Wassermann Test

Prepare a 500 c.c. colorless wide-mouth bottle with numerous glass beads. The glass beads are made by breaking up stirring rods to about 1-inch lengths, and rounding the ends in the flame. Cork and sterilize in the dry heat sterilizer at 170° C. for two hours.

Obtain sheep blood from the abattoir, filling the bottle to about two-thirds its capacity. (Sheep may be kept on the premises. In this case, the blood is withdrawn with a syringe from the jugular vein, and defibrinated in the same manner.) Shake vigorously for about fifteen minutes, or until defibrination is complete.

Filter through gauze to remove all particles of fibrin, collecting the filtrate in 50 c.c. sterile Rockefeller tubes with corks. A sterile funnel is used.

Cork tightly.

Place a mark with a wax pencil at the top of the sheep cells.

Centrifuge at high speed for fifteen to thirty minutes to throw down the cells.

Using a sterile transfer pipette (urethral syringe), remove and discard the supernatant fluid.

Fill to the wax pencil mark with sterile physiologic saline.

Recentrifuge.

Decant the supernatant fluid, replacing it with fresh saline, and recentrifuge.

Continue this process until the supernatant fluid is colorless. This is usually accomplished in five or six washings.

After the last centrifuging, remove the clear, colorless supernatant fluid, and replace with fresh saline.

Cork the tubes and keep in the refrigerator.

Fresh sheep cells should be prepared in this manner at least once or twice a week. In summer, the sheep cells will rapidly undergo hemolysis unless unusual care is exercised in keeping them cold.

For use in the Wassermann test, no accurate dilution can be made, since each new quantity of sheep cells may contain more or less cells than the blood previously obtained. It is well, therefore, to dilute to a definite color. About a 3% suspension of the washed cells is used.

Since the diluted sheep cells are used in the titration of complement, no error enters the Wassermann reaction from slight variations in the dilution of the sheep cells. This is part of the hemolytic system of the reaction, and does not take part in the antigen-antibody, or complement fixation, reaction which gives a positive Wassermann test.

Technic of the Wassermann Test

All sera for the Wassermann test are arranged in chronologic order, and the numbers recorded after a letter which represents their place in the day's work. After recording, each blood is prepared in the manner described under **Patient's Serum.** (Page 2032.)

Obtain guinea pig serum, as described above and titrate.

Dilute the hemolysin, antigen, and sheep cells. In diluting the antigen always add the antigen to the saline slowly.

All tests on bloods for the Wassermann reaction are made at the same time. The sera are carried through the day's work with a letter, or a number, or both, according to the routine of the laboratory.

Have on hand known + + + + positive serum and known negative serum.

The water-bath for carrying out the test must be regulated at 37°-40° C. before the tests are made.

The inactivator is set up and regulated at 56° C. before the serum is prepared.

Fresh saline is used in the tests.

In Table 191, the test on only one serum is given. Tubes A and A^1 represent the unknown serum, Tubes Positive and Positive^1 receive known + + + + positive serum,

TABLE 191.—THE WASSERMANN REACTION ON ONE SERUM, AND THE CONTROLS

TUBES	A	A^1	POS.	POS.^{1}	NEG.	NEG.^{1}	X	Y	Z
Patient's serum	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	------	------	------
Saline	0.6 c.c.	0.8 c.c.	0.6 c.c.	0.8 c.c.	0.6 c.c.	0.8 c.c.	0.8 c.c.	1.1 c.c.	1.3 c.c.
Complement	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	------	------
Antigen	0.2 c.c.	------	0.2 c.c.	------	0.2 c.c.	------	0.2 c.c.	0.2 c.c.	------
Place in the water-bath at 37°–40° C. for 30 minutes.									
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.

Place in the water-bath at 37°–40° C. for 30 minutes.									
Total quantity	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.	2.8 c.c.
Results expected	?	Hem.	No hem.	Hem.	Hem.	Hem.	Hem.	No hem.	No hem.

and Tubes Negative and Negative^1 receive known negative serum. It will be noted that the quantity of patient's serum in these tubes is the same as that used in the test.

A different pipette is used for measuring each new serum.

Since Tube A represents the unknown serum, the result is not anticipated.

Tube A^1 should always show hemolysis, positive shows no hemolysis, etc.

In carrying out the test, all sera are placed in the tubes. Then the saline, then the complement, etc.

The quantity of complement varies according to the previous titration result.

The quantity of saline varies according to the titer of the complement.

In racking up the tubes, place all of the serum control tubes (represented in the chart as A^1, Pos.^{1}, Neg.^{1}) in the back row of the double holed rack. In this way, all serum tubes which do not receive antigen are in the back row.

X, Y, and Z are placed in the front row.

After taking the racks from the water-bath, observe the back row of tubes first, since these are the anticomplementary controls. They should all show hemolysis.

Next, observe all the control tubes, Pos., Neg., X, Y, Z.

If the controls are as they should be, record the results of the Wassermann tests. No hemolysis represents a ++++ positive reaction. Complete hemolysis is a negative reaction. Degrees of positive reaction are judged by the amount of hemolysis; thus if half of the cells are hemolyzed, it is ++, etc.

If the controls give any reaction other than that desired, proceed in the correction of the tests before making reports.

Explanation of Tubes

Tube A represents a Wassermann test on an unknown blood serum. A tube similar to this, together with its serum control, is used for each serum tested. Since it is the patient's blood, the reaction is not known until the racks have been removed from the water-bath the last half hour. If complete hemolysis has occurred, the blood is negative. If complete or partial inhibition of hemolysis has occurred, compare with the result in the test on the known positive and negative sera to judge the degree of the reaction. The report is made on the result in this tube.

Tube A^1 is a test on the serum used in Tube A to determine whether or not it is anticomplementary. Complement is present, but antigen is omitted. No reaction should take place between the patient's serum and the complement unless the serum is anticomplementary. If such is the case, the result in this tube will be complete inhibition of hemolysis, and the report on the result of the Wassermann test of this blood will read: "Test cannot be made, since the serum is anticomplementary." If the serum is not anticomplementary the result in this tube will be complete hemolysis of the sheep cells. A tube corresponding to Tube A^1 is used for each serum introduced into the Wassermann reaction.

Tube Positive is an actual Wassermann test on a known ++++ positive serum. All the reagents are used. This tube, together with Tube Negative, serves as a rough titration of the antigen used in the day's work. The result in this tube checks the reaction of the day's antigen with a positive serum, showing by the result (complete inhibition of hemolysis) that the antigen used is capable of detecting antibodies when they are present in the serum. It, therefore, is a control over a **negative reaction** on an unknown blood. Only one known positive serum is needed to check the antigen each day. If the result in this tube is complete hemolysis of the sheep cells, instead of inhibition of hemolysis, either the serum has deteriorated, or the antigen is not of the correct strength. Before changing the antigen, and making all the tests anew, it is wise to make another positive test using another serum.

Tube Positive¹ is an anticomplementary control over the serum used in Tube Positive. It corresponds (in its relation to Tube Positive) to Tube A¹.

Tube Negative is an actual Wassermann test on a known negative serum. All the reagents are used. This tube, together with Tube Positive, serves as a rough titration of the day's antigen. Since it is a test on a known negative serum, the result should be complete hemolysis, or a negative Wassermann reaction. It is a control over a **positive reaction** on an unknown serum, since it definitely proves that were the serum negative, the reaction between complement, hemolysin, and sheep cells would not be interfered with.

Tube Negative¹ is an anticomplementary control over the serum used in Tube Negative. It corresponds to Tube A¹.

Tube X is a control over the action of antigen with complement. Occasionally an antigen will become anticomplementary. In such case, every tube containing both complement and antigen will show inhibition of hemolysis. Manifestly such a result is incorrect. If an antigen is anticomplementary, a new antigen must be employed in the Wassermann test. This tube should show complete hemolysis, since patient's serum is omitted, and there should be nothing to interfere with the action of complement, hemolysin, and sheep cells.

Tube Y is a control over the action of antigen with hemolysin and sheep cells. It should not cause hemolysis of the sheep cells. The result will, therefore, be inhibition of hemolysis. If hemolysis occurs, every tube containing antigen will likewise show complete hemolysis, and this antigen cannot be used in the Wassermann reaction.

Tube Z is a control over the saline used in the day's work. When the reaction is as it should be, there should be complete inhibition of hemolysis. The saline used should not be so weak as to cause hemolysis of the cells. Too strong a saline solution was guarded against in the titration of complement which was carried out just prior to the making of the Wassermann tests. If the saline solution had been too strong, no titer would have been obtained. The action of hemolysin with complement and sheep cells was likewise checked in the preliminary titration of complement.

If all reagents are as they should be, the results of the Wassermann tests, as shown in Tubes A, B, C, etc., may be reported.

Tubes Positive and Negative are used for comparative purposes in judging the degree of a positive reaction. Complete inhibition of hemolysis with a deposit of sheep cells on the bottom of the tube is ++++. Complete hemolysis of the sheep cells is negative. Any degree of positive reaction between ++++ and borderline must be judged by the worker.

THE WASSERMANN TEST OF SPINAL FLUID

The spinal fluid should be clear and free from blood. If blood is present, obtain a new specimen preferably, or centrifuge the fluid and decant the clear supernatant fluid for the test.

The same reagents are used for this test as for the Wassermann tests on blood serum.

Complement is titrated in the usual manner.

If the spinal fluid is tested along with blood serum, the same set of controls, namely, Tubes Positive, Positive¹, Negative, Negative¹, X, Y, and Z, are used. These tubes represent reagent controls, and consequently one set controls all reagents used either for blood serum or for spinal fluid. If the spinal fluid is tested alone, a set of controls is made. Blood serum is used in Tubes Positive, Positive¹, Negative, Negative¹.

The quantity of complement varies according to the titer.

The amount of saline varies according to the amount of complement used in the test.

TABLE 192

TUBES	1	2	3	4	5	6	CONTROL
Spinal fluid	1.0 c.c.	0.8 c.c.	0.6 c.c.	0.4 c.c.	0.2 c.c.	0.1 c.c.	1.0 c.c.
Saline	0.0 c.c.	0.2 c.c.	0.4 c.c.	0.6 c.c.	0.8 c.c.	0.9 c.c.	0.2 c.c.
Complement	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.	0.3 c.c.
Antigen	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	0.2 c.c.	------
Place in the water-bath at 37°-40° C. for 30 minutes.							
Hemolysin	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.	0.5 c.c.
Sheep cells	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.	1.0 c.c.
Place in the water-bath at 37°-40° C. for 30 minutes. **Total in each tube is 3.0 c.c.**							
Results expected	?	?	?	?	?	?	Hemolysis

Tube 7 is placed behind the six "test" tubes in the rack. It is the anticomplementary control. Antigen is omitted. If complete hemolysis of the sheep cells does not occur in this tube, the spinal fluid is anticomplementary, and no Wassermann test can be made.

The tube in which the strongest reaction will occur is Tube 1, in which 1.0 c.c. of spinal fluid is used. In many cases, this is the only tube which will show a positive reaction. This is true especially of treated cases. If the quantity of spinal fluid submitted to the laboratory is small, Tube 1 must always be made. Other tubes may be omitted, since the result in each tube is reported.

Any quantity between 0.2 c.c. and 1.0 c.c. of spinal fluid may be used in the control tube, but if there is sufficient spinal fluid to permit it, use 1.0 c.c. in this tube. If smaller quantities are used, make up the difference with saline.

Report the result in each tube, as follows:

Example:

1.0 c.c.—positive.
0.8 c.c.—positive.
0.6 c.c.—positive.
0.4 c.c.—negative.
0.2 c.c.—negative.
0.1 c.c.—negative.

A negative reaction is complete hemolysis in each tube.

A positive reaction is inhibition of hemolysis in all tubes, or in all but Tube 6, or in all tubes except 6 and 5, etc. If Tube 1 is the only tube showing inhibition of hemolysis, this is a positive reaction, since frequently the quantity of syphilitic substance in spinal fluid is so small that no quantity less than 1.0 c.c. will give a positive reaction.

THE KOLMER COMPLEMENT FIXATION TESTS FOR SYPHILIS[1]

JOHN A. KOLMER, M.D.*

Two methods are commonly used: (1) the qualitative test with serum and spinal fluid; and (2) the quantitative test.

Equipment.—

Pipettes (Fig. 599).—The following pipettes are recommended:

1 c.c. graduated in 0.01 c.c. to tip
5 c.c. graduated in 0.10 c.c.
10 c.c. graduated in 0.10 c.c.

Three 1 c.c. pipettes certified by the Bureau of Standards are recommended for measuring hemolysin, corpuscles, and antigen and a 2 c.c. pipette graduated in 0.10 c.c. for complement.

---

*Personal communication, furnished by Dr. John A. Kolmer. Revised according to 1955 Manual, Serologic Tests for Syphilis, U. S. Department of Health, Education, and Welfare, Public Health Publication No. 411.

[1] Kolmer, J. A.: Am. J. Syph. 6: 82, 1922.

Test Tubes.—For the routine quantitative and qualitative tests, which have a total volume of 3.0 c.c., test tubes measuring 8.5 by 1.5 cm. (inside diameter) with rounded bottoms and no lips are employed.

Cylinders.—Glass stoppered, graduated (100 and 500 c.c. capacity) to be used for measuring amounts over 50 c.c.

Test Tube Racks.—Galvanized wire racks carrying 12 rows of 6 tubes each (Fig. 600).

Water Bath.—Any easily regulated water bath is suitable, or a simple galvanized pan carrying water to a depth of 8 centimeters can be used satisfactorily at 55° or 37° C. (Figs. 601 and 602).

Refrigerator.—Any refrigerator maintaining a temperature of 6° to 8° C. is satisfactory.

Method of Cleaning Glassware.—All glassware should be chemically clean and preferably sterile. To clean tubes and flasks, empty and rinse in running tap water; wash inside and outside in soapy water; rinse several times in running tap water and invert in wire baskets. Dry in dry heat sterilizer at about 160° C.

Pipettes should be placed after use in a jar or cylinder of clean water with a pad of cotton in the bottom. To clean pipettes, rinse thoroughly in running tap water, place in a metal box or wire basket, and sterilize in the oven.

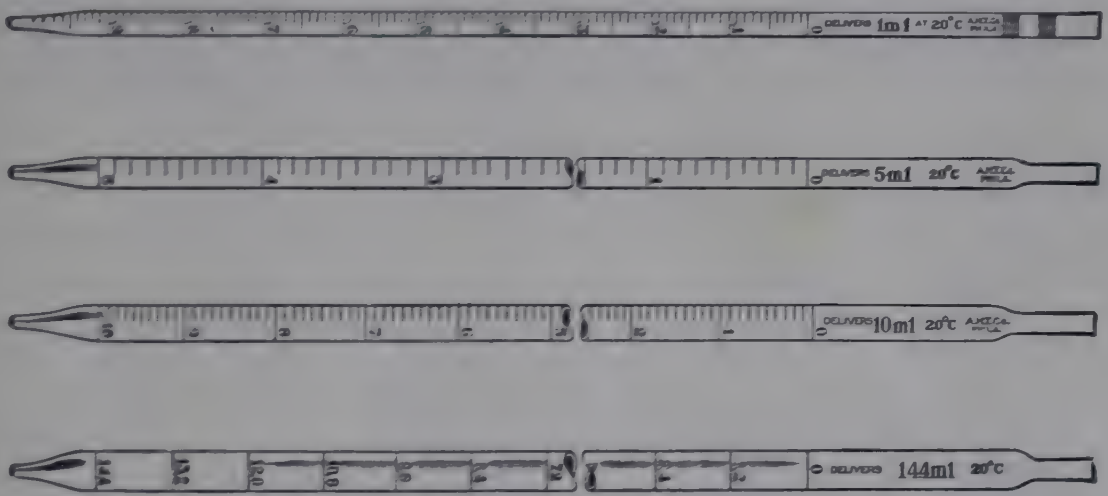

Fig. 599.—Pipettes recommended for the Kolmer complement fixation test.

Flasks should be plugged with cotton and sterilized in the oven for 30 minutes at 160° C.

If glassware becomes cloudy, immerse in bichromate cleaning fluid (2 parts potassium bichromate, 3 parts commercial sulphuric acid, and 25 parts water) for 24 hours. Rinse thoroughly in running tap water and proceed with the washing as described.

Reagents.—

Saline Solution.—Dissolve 8.5 gm. of dry, C.P., sodium chloride and 0.1 gm. magnesium sulphate in 1,000 c.c. of freshly distilled water. If the salt has absorbed moisture it should be dried in the dry heat oven for 10 or 15 minutes before weighing. Filter solution through paper into a flask fitted with a gauze-covered cotton stopper. Sterilize by heating in an Arnold sterilizer for 1 hour before use (not essential if immediately used).

A satisfactory saline solution should not of itself be hemolytic when 1 or 2 drops of washed corpuscles are added to 5 c.c. of the solution in a test tube followed by water bath incubation for 1 hour. Neither should it be antihemolytic as determined by the hemolysin or complement titrations. The antisheep hemolysin should give a unit of at least 0.5 c.c. of a 1:4,000 dilution when titrated with 0.3 c.c. of 1:30 complement and 0.5 c.c. of a 2 per cent suspension of washed sheep corpuscles with a water bath incubation of 1 hour. It is possible that failure of hemolysis may be due to defective hemolysin or complement or to the use of corpuscles of increased resistance to serum hemolysis.

When unusually low complement titers are obtained, Kolmer recommends adding 40 mg. $CaCl_2 \cdot 2H_2O$ to each liter of saline. When this is done, the complement should not be used at a dilution higher than 1:37 (for 2 full units).

Preparation of Sheep Corpuscles (Indicator Antigen).—Sheep blood may be obtained at an abattoir or by bleeding a sheep from the external jugular vein. In a clean (but not necessarily sterile) quart-sized Mason jar, place 30 c.c. of a 10 per cent solution of sodium citrate in saline solution and 2 c.c. of Formalin. At the abattoir have the jar almost filled with *fresh* blood (blood kept over in buckets is unsatisfactory), screw on the top, mix well with the citrate-Formalin solution, and keep in a refrigerator. Ordinarily it is fit for use over a period of 2 to 3 weeks at least, but as soon as the corpuscles become too fragile a fresh supply should be secured. Boerner and Lukens advise keeping blood for 48 hours in the refrigerator before using.

If preservation is not desired, glass beads alone may be placed in the jar, and after filling with blood, it should be thoroughly shaken for defibrination. Blood collected in this manner will keep at a low temperature (jar placed on a block of ice) for about a week.

Filter a small quantity of blood through cotton into a *graduated* centrifuge tube (Fig. 603). Allow twice as much blood as the amount of cells required. Add 2 or 3 volumes of saline solution. Centrifuge at a moderate velocity until it is ascertained that all the corpuscles are thrown down.

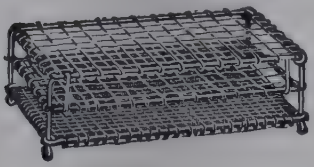

Fig. 600.

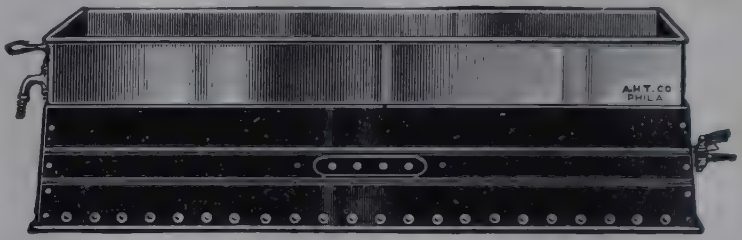

Fig. 601.

Fig. 600.—Test tube rack for use in the Kolmer complement fixation test.
Fig. 601.—Water bath for use in the Kolmer complement fixation test.

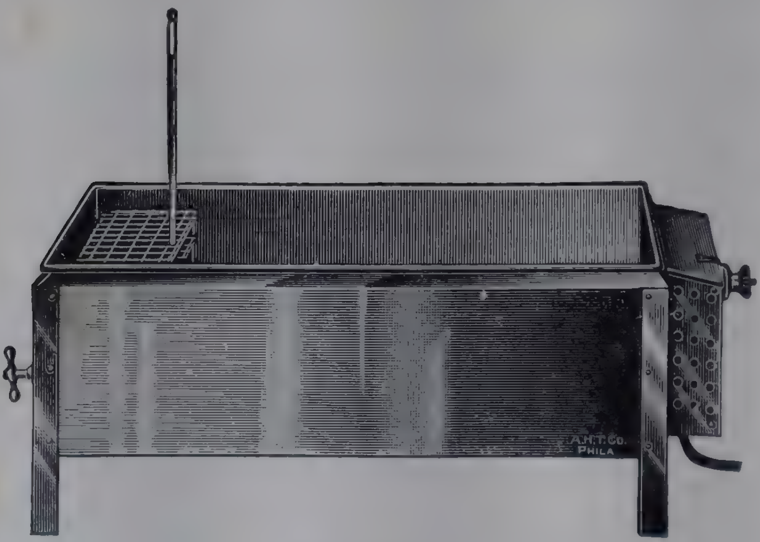

Fig. 602.

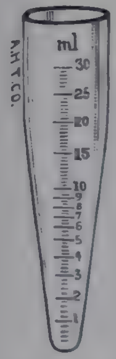

Fig. 603.

Fig. 602.—Water bath for use in the Kolmer complement fixation test.
Fig. 603.—Graduated centrifuge tube used to wash sheep corpuscles.

Remove the supernatant fluid with a capillary pipette or by suction. Add 3 or 4 volumes of saline solution; mix by inverting and centrifuge again for the same length of time.

Repeat the process for a third time but centrifuge twice as long as in the first washing in order to pack the cells evenly and firmly.

Cells should be washed until the supernatant fluid is almost colorless. Three washings are usually sufficient. (If more than four washings are necessary, the cells are too fragile for use.)

Read the volume of cells in the centrifuge tube, carefully remove the supernatant fluid, and prepare a 2 per cent suspension by washing the corpuscles into a flask with 49 volumes of saline solution or dilute 2 c.c. of corpuscles with 98 c.c. of saline solution. *Always shake before using to secure an even suspension, as the corpuscles settle to the bottom of the flask when not in use.*

Preparation of Antisheep Hemolysin.—Give a rabbit 5 or 6 intravenous injections of 5 c.c. of a 10 per cent suspension of washed sheep corpuscles every 5 days. Bleed the rabbit 7 to 9 days after the last injection if a preliminary titration gives a unit of 0.5 c.c. of 1:4,000 or higher. Separate the serum (it need not be inactivated) and preserve with an equal part of best grade neutral glycerin. Keep in a refrigerator.

Preparation of Complement.—The pooled sera of at least 3 healthy male guinea pigs should be used. Select large, well-nourished animals that have not been fed for 12 hours; avoid pregnant animals.

Anesthetize the pig lightly with ether. Collect the blood from the heart (page 2033) in a sterile test tube, and allow to clot. Loosen the clot with a sterile applicator and centrifuge. Remove the clear supernatant serum and place in a clean, dry, sterile test tube. *Keep in the refrigerator when not in use.*

If but a small amount of serum is required, 4 or 5 c.c. of blood may be obtained from each pig by bleeding from the heart with a 5 c.c. syringe fitted with a short needle, gauge 20.

Complement serum may be preserved for several weeks by adding 0.3 gm. of c. p. sodium chloride to each c.c. of serum. Keep in a dark glass bottle at or near the *freezing point.* To prepare for use, dilute 1 c.c. of serum with 29 c.c. of distilled water. This gives a 1:30 dilution in 1 per cent salt solution. Complement may also be preserved for at least 2 weeks by adding and dissolving 1 gm. of chemically pure sodium acetate in each 10 c.c. of serum (Rhamy). *Sonnenschein's solution* is also recommended:

Sodium acetate (c.p.)	12.0 gm.
Boric acid	4.0 gm.
Sterile distilled water	100.0 c.c.

Equal parts of serum and solution are mixed giving a 1:2 dilution of complement from which a 1:30 dilution is prepared by diluting 1 c.c. with 14 c.c. of saline. By whatever of these chemical methods complement is preserved, it is important to keep the serum frozen or at a temperature not exceeding 2° C. As preserved complement loses first in fixability by syphilis antigen and antibody, it should not be kept for more than 3 or 4 weeks.

Lyophil Complement.[2]—The most satisfactory method for preserving complement is by evaporation in the frozen state in vacuo by the method of Flosdorf and Mudd.[3] It retains both hemolytic activity and fixability for 8 to 12 months and has proved satisfactory. It has the great advantage of being prepared of the pooled sera of a large number of guinea pigs with uniform hemolytic activity and fixability by antigen and antibody. It may be obtained from Sharp and Dohme, Philadelphia, and is dispensed in vacules containing the equivalent of 5 c.c. of fresh serum. These should be kept in a refrigerator until used. By adding 5 c.c. of distilled water the material goes into immediate solution and is ready for use in the same manner as fresh serum. Preservation by the *cryochem process* is also recommended and is more economical.

Preparation of Antigen.—The antigen for the Kolmer test is an alcoholic solution containing 0.03 per cent cardiolipin, 0.05 per cent lecithin, and 0.3 per cent cholesterol. Each new lot must be tested along with a standard antigen before use. It is best to purchase antigens which have been standardized.* Kolmer[4] states that such antigens are preferred as a mixture of maximum sensitivity consistent with specificity in tests with sera and spinal fluids.

Preparation of Antigen Dilution.—Place the required amount of saline in a flask and add the antigen drop by drop while continuously shaking the flask. Calculate the amount needed for the day's work.

The test dose constitutes 0.5 c.c. of the antigen dilution indicated on the label of the bottle, which is usually 1:150.

Keep the antigen dilution at room temperature in a stoppered flask.

Allow to stand at room temperature for at least 1 hour before use.

---

*Kolmer cardiolipin antigen may be purchased from Sylvana Chemical Company, Orange, N. J.

[3] J. Immunol. 29: 389, 1935.

[4] Kolmer, J. A., and Lynch, E. R.: J. Ven. Dis. Inform. 29: 166, 1948.

Preparation of Sera.—All specimens are lined up and properly labeled.

The sera are removed from the clots with capillary pipettes to test tubes properly labeled. Great care is required to prevent errors in labeling and confusion of sera. Each serum should be free of corpuscles, otherwise it is necessary to break up the clots with wooden applicators (one for each serum) and centrifuging for clear serum. Slight tinging with hemoglobin does no harm. Sera containing large amounts of hemoglobin are likely to be anticomplementary and unsatisfactory for both complement fixation and precipitation tests.

Removal of Natural Antisheep Hemolysin From Sera.—

It is not necessary to remove the natural antisheep hemolysins by absorption with *thoroughly washed sheep corpuscles* although this tends to increase the sensitiveness of complement fixation reactions and especially in the case of sera containing small amounts of syphilis antibody. Kolmer recommends the routine removal of natural hemolysins when conditions permit in order to secure reactions of maximum sensitiveness, but when large numbers of sera require testing it may be omitted.

To each is added *a drop of washed sheep corpuscle sediment for approximately each 2 c.c. of blood and serum* as gauged by inspection.

Each specimen is then thoroughly mixed with a wooden applicator (one for each serum).

All are then placed in a *refrigerator for 15 minutes* to enable the sheep corpuscles to absorb the hemolysins with none or but a minimum and harmless amount of hemolysis.

All specimens are now centrifuged and the sera separated into test tubes properly labeled.

The tubes of plain or absorbed sera are now placed in a water bath at 55° C. for *15 to 20 minutes,* when they are ready for testing.

Preparation of Spinal Fluids.—*These are usually tested without any preliminary preparation* as they do not contain enough natural antisheep hemolysin to require removal or enough complement to require inactivation by heating at 55° C. If a specimen contains considerable blood which has not had time to settle out, it should be centrifuged. Otherwise no preparation is required as spinal fluids are tested as delivered without preliminary heating unless they are more than 3 days old, in which case they may be heated at 55° C. for 15 minutes to remove thermolabile anticomplementary substances. As a general rule, however, spinal fluids are not anticomplementary unless heavily contaminated with bacteria (cloudy). If a large amount of blood is present, the spinal fluid cannot be used.

The Regular Quantitative Kolmer Complement Fixation Test

TITRATION OF HEMOLYSIN

It is advisable to make this titration each time the complement fixation test is conducted.

Prepare a **stock dilution** of 1:100 hemolysin:

Saline solution	94.0 c.c.
Phenol, 5% in saline solution	4.0 c.c.
Glycerinized hemolysin (50%)	2.0 c.c.

Mix the phenol and saline solution well before adding the glycerinized hemolysin. This may be kept in a refrigerator for several months, unless a precipitate develops, in which case it must be discarded.

For titration: Dilute to 1:1,000 by adding 0.5 c.c. of the 1:100 dilution to 4.5 c.c. saline solution.

Prepare higher dilutions in a series of 10 tubes as in Table 193.

TABLE 193

TUBE	0.5 C.C. HEMOLYSIN: DILUTION:	C.C. SALINE SOLUTION	DIRECTIONS	FINAL DILUTION OF HEMOLYSIN
1	1:1,000	—	—	1:1,000
2	1:1,000	0.5	Discard 0.5 c.c.	1:2,000
3	1:1,000	1.0	Transfer 0.5 c.c. to tube 6. Discard 0.5 c.c.	1:3,000
4	1:1,000	1.5	Transfer 0.5 c.c. to tube 7. Discard 1 c.c.	1:4,000
5	1:1,000	2.0	Transfer 0.5 c.c. to tube 8. Discard 1.5 c.c.	1:5,000
6	1:3,000	0.5	Transfer 0.5 c.c. to tube 9	1:6,000
7	1:4,000	0.5	Transfer 0.5 c.c. to tube 10	1:8,000
8	1:5,000	0.5	Discard 0.5 c.c.	1:10,000
9	1:6,000	0.5	Discard 0.5 c.c.	1:12,000
10	1:8,000	0.5	Discard 0.5 c.c.	1:16,000

Mix the contents of each tube thoroughly.

Carry out the titration in these tubes, each containing 0.5 c.c. of diluted hemolysin.

Prepare a 1:30 dilution of complement for hemolysin and complement titration by diluting 0.2 c.c. of complement serum with 5.8 c.c. saline solution.

Prepare a 2 per cent suspension of sheep corpuscles.

In the series of 10 tubes, Table 193, add to all tubes:

0.3 c.c. of 1:30 complement
1.7 c.c. saline solution
0.5 c.c. sheep corpuscles.

Mix the contents of each tube and incubate in the water bath at 37° C. for 1 hour. Read the unit of hemolysin. The *unit is the highest dilution of hemolysin that gives complete hemolysis.*

Two units are used in the complement and antigen titrations and in the complement fixation tests. Hemolysin is so diluted that 0.5 c.c. contains 2 units. For example, if the unit equals 0.5 c.c. of 1:6,000, two units equal 0.5 c.c. of 1:3,000. Dilute just enough hemolysin for the complement titration and the complement fixation tests. *Keep hemolysin and corpuscles in suspension in the refrigerator when not in use.*

Table 194 shows how the dilutions are made so that 0.5 c.c. carries two units.

TABLE 194

1 UNIT 0.5 C.C. OF—	2 UNITS WOULD BE 0.5 C.C. OF—	PREPARED BY DILUTING 1 C.C. OF STOCK 1:100 WITH FOLLOWING AMOUNTS OF SALINE C.C.
1: 1,000	1: 500	4
1: 2,000	1:1,000	9
1: 3,000	1:1,500	14
1: 4,000	1:2,000	19
1: 5,000	1:2,500	24
1: 6,000	1:3,000	29
1: 8,000	1:4,000	39
1:10,000	1:5,000	49

High titer hemolysin is recommended and the unit should be 0.5 c.c. of 1:4,000 or higher.

In practice the hemolysin titration may be placed in the water bath at the same time as the complement titration; at the end of the first incubation of the complement titration the unit of hemolysin is available and two units are added to all tubes of the complement titration, etc.

TITRATION OF COMPLEMENT

For the complement titration use 1:30 dilution of complement prepared above. *Dilute antigen so that the dose employed in the main tests is contained in 0.5 c.c.* This dilution is made by placing the required amount of saline solution in a flask and adding antigen drop by drop. Shake the flask after each addition of antigen. Prepare enough antigen dilution for the complement titration and the complement fixation tests.

In a series of 8 test tubes set up, the complement titration is as in Table 195.

TABLE 195

TUBE	COMPLEMENT, C.C. (1:30)	ANTIGEN DOSE, C.C.	SALINE SOLUTION, C.C.		HEMOLYSIN C.C. (2 UNITS)	CORPUSCLES, C.C. (2 PER CENT)	
1	0.2	0.5	1.3	Water bath 37° C. for 1 hour	0.5	0.5	Water bath 37° C. for 1 hour
2	0.25	0.5	1.3		0.5	0.5	
3	0.3	0.5	1.2		0.5	0.5	
4	0.35	0.5	1.2		0.5	0.5	
5	0.4	0.5	1.1		0.5	0.5	
6	0.45	0.5	1.1		0.5	0.5	
7	0.5	0.5	1.0		0.5	0.5	
8	None	None	2.5		None	0.5	

The smallest amount of complement just giving complete sparkling hemolysis is the *exact unit.* The next higher tube is the *full unit* which contains 0.05 c.c. more complement. In conducting the antigen titration and complement fixation tests, *two full units* are employed and so diluted as to be contained in 1 c.c. as per the following example:

Exact unit:	0.3 c.c.
Full unit:	0.35 c.c.
Dose (two full units):	0.7 c.c.

To calculate the dilution to employ so that 1 c.c. contains the dose of two full units, divide 30 by the dose: $\frac{30}{0.7} = 43$ or 1 c.c. of 1:43 dilution of serum.

Table 196 gives additional examples:

TABLE 196

EXACT UNIT, C.C.	FULL UNIT, C.C.	TWO FULL UNITS, C.C.	DILUTION TO USE	PREPARATION
0.2	0.25	0.5	1:60	1 c.c. serum + 59 c.c. saline
0.25	0.3	0.6	1:50	1 c.c. serum + 49 c.c. saline
0.3	0.35	0.7	1:43	1 c.c. serum + 42 c.c. saline
0.35	0.4	0.8	1:37	1 c.c. serum + 36 c.c. saline
0.4	0.45	0.9	1:33	1 c.c. serum + 32 c.c. saline
0.45	0.5	1.0	1:30	1 c.c. serum + 29 c.c. saline
0.5	0.55	1.1	1:27	1 c.c. serum + 26 c.c. saline

It is always advisable to dilute complement serum with cold saline solution instead of with saline kept at room temperature. Undiluted and especially diluted complement serum should always be kept in a refrigerator when not in use. Exposure of diluted complement to room temperature for over an hour may result in some deterioration.

Occasionally hyperactive complement yields a unit of 0.2 to 0.25 c.c. of 1:30, but when this occurs it is necessary to take arbitrarily 0.3 c.c. as the exact unit as less complement falls below the absolute minimum and is likely to be unsatisfactory.

KOLMER QUANTITATIVE TEST ON SERUM AND SPINAL FLUID

(A) Serum:

Place 8 tubes for each serum in a rack.

Include 3 tubes for reagent controls and several tubes for graded known positive sera and 1 tube for negative serum for the day's work.

For each serum add saline in the following amounts:

0.9 c.c. into tube 1 and 0.5 c.c. saline in tubes 2 through 8.

Place the indicated amounts of saline in each reagent control as follows:

Antigen control	0.5 c.c.
Hemolytic control	1.0 c.c.
Corpuscle control	2.5 c.c.

Place 0.6 c.c. inactivated serum in tube 1.

Mix and transfer 0.5 c.c. to tube 8 (serum control) and to tube 2.

Mix the contents of tube 2 and transfer 0.5 c.c. to tube 3.

Continue in this manner through tube 7. Mix the contents of tube 7 and discard 0.5 c.c.

The tubes now contain 0.5 c.c. serum diluted, respectively, 1:1, 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, and no serum.

Add 0.5 c.c. diluted antigen to the first 7 tubes of each serum test, and to the antigen control.

Shake the racks to mix thoroughly.

Allow to stand at room temperature for 10 to 30 minutes.

Prepare the diluted complement during this interval.

Add 1 c.c. of diluted complement, containing 2 full units, to each tube of the serum tests and to the control serum tests.

Add 1 c.c. diluted complement to the antigen control and the hemolytic system control.

Mix by shaking the racks well, and place in a refrigerator at 6° to 8° C. for 15 to 18 hours.

Prepare the volume of diluted hemolysin needed for the test, allowing 0.5 c.c. containing 2 units for each tube. Prepare a slight excess.

Remove the racks from the refrigerator and place immediately in a water bath at 37° C. for 10 minutes.

Remove from the water bath and add 0.5 c.c. of the diluted hemolysin to all tubes of the test except the corpuscle control.

Add 0.5 c.c. of 2% sheep red cell suspension, prepared the previous day, to all tubes. Agitate the cell suspension occasionally to insure even suspension of cells while adding to the tests.

Shake the rack thoroughly and return to the water bath at 37° C.

Examine the controls at 5-minute intervals. The period of secondary incubation will be determined by the length of time necessary to reproduce the predetermined reactivity pattern of the control sera.

The reading time should be at least 10 minutes more than that required to hemolyze the antigen and hemolytic system controls, but must not exceed a total of 60 minutes.

When control sera are not available, the secondary incubation period should be terminated 10 minutes after the hemolytic system control and the antigen control hemolyze. This period must never exceed 1 hour.

Record hemolysis and degrees of hemolysis as indicated in Tables 197 to 199.

The serum control must show complete hemolysis.

Quantitative tests may be reported in terms of the highest dilution giving a reactive result. If a reactive result is obtained with a 1:64 dilution of the serum, higher dilutions may be made and tested.

TABLE 197.—REPORTING KOLMER QUALITATIVE TESTS

TEST READING	CONTROL READING	REPORT	TEST READING	CONTROL READING	REPORT
4+	–	Reactive	3+	3+	Anticomplementary

2 – – – – – –	2+	Nonreactive

(B) Spinal Fluid:

Use 6 tubes for each spinal fluid. If these tests are made at the same time as tests on the sera are made, no further controls need be made. If made alone, include the controls given above.

Place 0.5 c.c. of saline in tubes 2, 3, 4, 5, 6.

Place 0.5 c.c. spinal fluid in tube 1, and 0.5 c.c. in tubes 2 and 6.

Mix the contents of tube 2 and transfer 0.5 c.c. to tube 3, and continue in this manner through tube 5. Discard 0.5 c.c. from tube 6. The dilutions of spinal fluid in their respective tubes is now 1:1, 1:2, 1:4, 1:8, and 1:16. Tube 6 is the control, and contains 0.5 c.c. undiluted spinal fluid.

Add 0.5 c.c. of diluted antigen to the first 5 tubes of each spinal fluid test.

Shake the racks.

Allow to stand at room temperature for 10 to 30 minutes.

Continue with the test from this point, as in the Kolmer quantitative test for serum, pages 2052 ff.

Read as directed for the Kolmer quantitative test of serum, Tables 197, 198, and 199.

KOLMER QUALITATIVE TEST ON SERUM AND SPINAL FLUID

Set up tubes in a rack, 2 tubes for each serum, and 2 tubes for each spinal fluid. Use, also, control sera of graded reactivity and negatively reacting sera, 2 tubes for each. Set up 4 additional tubes for reagent controls.

Arrange the tubes for the sera and sera controls in two rows.

Place 0.5 c.c. saline into each tube of the second row.

Add saline to the reagent controls as follows:

Antigen control for serum tests	0.2 c.c.
Antigen control for spinal fluid tests	0.5 c.c.
Hemolytic system control	1.0 c.c.
Corpuscle control	2.5 c.c.

Place 0.2 c.c. of each serum in both their tubes, 1 and 2 (front and back rows).

Add 0.5 c.c. spinal fluid to its tubes 1 and 2 (front and back rows).

Add 0.2 c.c. of each control serum to its tubes 1 and 2.

Add 0.5 c.c. antigen dilution to the front tubes of each test (tube 1), and to the 2 antigen control tubes.

Allow to stand at room temperature for 10 to 30 minutes.

Prepare the diluted complement during this interval. The amount needed is equivalent to 1 c.c. for each tube of the test plus a slight excess.

Add 1 c.c. diluted complement containing 2 full units to all tubes of the serum, control serum, and spinal fluid tests, including the antigen control and the hemolytic system control.

Shake the racks well and place in a refrigerator at 6° to 8° C. for 15 to 18 hours.

Prepare the diluted hemolysin needed for the test, allowing 0.5 c.c. containing 2 units for each tube. Prepare a slight excess.

Remove the racks from the refrigerator at regular intervals and place immediately in a water bath at 37° C. for 10 minutes. The interval is determined by the time necessary to add the hemolysin and sheep cell suspension to each rack.

Remove from the water bath and add 0.5 c.c. of diluted hemolysin to all tubes except the corpuscle control.

Add 0.5 c.c. of 2% sheep red cell suspension, prepared the previous day, to all tubes. Agitate the cell suspension occasionally to insure even suspension of the cells during the period when they are being added to the test.

Shake the racks thoroughly and return to the 37° C. water bath for secondary incubation. Examine the controls at 5-minute intervals. The period of secondary incubation is determined by the length of time necessary to reproduce the predetermined reactivity pattern of the control sera. The reading time must be at least 10 minutes longer than that required to hemolyze the antigen and hemolytic system controls, but must not exceed 60 minutes. If control sera are not available, terminate the secondary incubation period 10 minutes after the hemolytic system control and the antigen control hemolyze. This secondary incubation period must not exceed 1 hour.

Read results by comparison with the reading standards and report.

PREPARATION OF READING STANDARDS

Heat tubes of hemoglobin solution, saved from the titration or obtained from control tubes of the day's tests, in a water bath at 56° C. for 5 minutes.

Prepare a 1:6 dilution of 2% sheep corpuscle suspension by adding 5 c.c. of saline solution to 1 c.c. of the 2% suspension.

Prepare reading standards by mixing hemoglobin solution and cell suspension as in Table 200.

TABLE 200

1:6 CORPUSCLE SUSPENSION C.C.	HEMOGLOBIN SOLUTION C.C.	EQUIVALENT FIXATION PER CENT	COMPLEMENT REPORT
3.0	0.0	100	4+
1.5	1.5	50	3+
0.75	2.25	25	2+
0.3	2.7	10	1+
0.15	2.85	5	±
---	3.0	0	–

READING AND REPORTING RESULTS

All serum and spinal fluid controls should show complete hemolysis.

Estimate the individual tube readings by comparison with the reading standards at the end of the secondary incubation period, and record the degree of complement fixation noted, except when the specimen shows inhibition of hemolysis in the control tube.

Read the tubes that have been returned to the 37° C. bath for a full hour's secondary incubation, estimating and recording the degree of complement fixation of each tube and control tube by comparison with the reading standards. See Table 197, page 2053.

Preparation of Anticomplementary Sera for Kolmer Complement Fixation Tests (Modified Sachs Method)

Heat 0.5 c.c. of serum at 55° to 56° C. in a water bath for 15 minutes. If the serum has been previously heated and is being re-tested, heat for 5 minutes.

Add 4.1 c.c. of accurately titrated N/300 hydrochloric acid and mix thoroughly.

After standing ½ hour at room temperature, centrifuge for 10 minutes and discard the sediment.

To the supernatant fluid add 0.4 c.c. of 10% sodium chloride solution. The acid is fixed by the precipitate of globulin; hence neutralization is unnecessary.

This gives a 1:10 dilution of original serum ready for testing as follows:

Arrange 2 rows of 5 test tubes each, and number them 1 to 5. The second row contains the serum controls.

Place 0.5 c.c. of saline in tubes 3, 4, and 5 of both rows.

Add to both rows:

1 c.c. of treated serum to tube 1.

0.5 c.c. of treated serum to tubes 2 and 3.

Mix tube 3 and transfer 0.5 c.c. to tube 4.

Mix tube 4 and transfer 0.5 c.c. to tube 5.

Mix tube 5 and discard 0.5 c.c.

The 5 tubes of each row contain 0.1, 0.05, 0.025, 0.012, and 0.006 c.c. of serum, respectively.

Add 0.5 c.c. of antigen dilution to each tube of the first row.

Add 0.5 c.c. of saline to each tube of the second row.

Shake the rack and allow to stand at room temperature for 10 to 30 minutes.

Add 1 c.c. of diluted complement to all tubes of both rows.

Shake the rack and place in a refrigerator for 15 to 18 hours at 6° to 8° C.

Continue the test as described under the Kolmer Qualitative Tests with Serum and Spinal Fluid, pages 2054 ff.

Record the degree of hemolysis in both the test and the control tubes. All the tubes of the rear row may show complete hemolysis; however, the first and second tubes of the rear row may show slight inhibition of hemolysis.

With nonreactive sera, the corresponding front tubes show the same degree of inhibition of hemolysis, and if the degree is slight, a nonreactive report may be rendered. With reactive sera, inhibition of hemolysis is much more marked in tubes of the front row. Report results as reactive, weakly reactive, and nonreactive.

RETESTING ANTICOMPLEMENTARY SPINAL FLUIDS

Heat the spinal fluid for 15 minutes at 56° C.

Arrange 2 rows of 5 tubes each and number 1 to 5.

Add 0.5 c.c. of saline to tubes 2, 3, 4, and 5 of both rows.

To both rows:

Add 0.5 c.c. of spinal fluid to tubes 1 and 2.
Mix tube 2 and transfer 0.5 c.c. to tube 3.
Mix tube 3 and transfer 0.5 c.c. to tube 4.
Mix tube 4 and transfer 0.5 c.c. to tube 5.
Mix tube 5 and discard 0.5 c.c.

Add 0.5 c.c. of antigen dilution to each tube of the first row.

Add 0.5 c.c. of saline to each tube of the second row.

Shake the rack and allow to stand at room temperature for 10 to 30 minutes.

Add 1 c.c. of diluted complement to all tubes of both rows. Shake the racks and place in a refrigerator for 15 to 18 hours at 6° to 8° C.

Complete the tests as described under Kolmer Qualitative Tests with Serum and Spinal Fluid, pages 2054 ff.

Interpret the results as follows:

FIRST ROW	SECOND ROW	REPORT
4 4 4 1 –	4 1 – – –	Reactive
4 3 2 – –	4 1 – – –	Reactive
4 1 – – –	1 – – – –	Reactive
4 4 2 – –	4 2 1 – –	Nonreactive
3 2 – – –	3 1 – – –	Nonreactive

Analysis of Difficulties

Due to Complement.—When difficulties are observed, the trouble is usually first thought to be due to defective hemolysin or antigen but, since both of these keep very well, they are seldom responsible. In the great majority of instances, difficulties are due to the complement because too low in hemolytic activity or too sensitive to what may be called the occult anticomplementary effects of antigen or serum and particularly a summation of both. This is especially likely to occur during the hot months of the year and likewise when the sera of underweight or pregnant guinea pigs are used as well as those of guinea pigs previously employed for various inoculation tests.* When the unit is higher than 0.5 c.c. of 1:30 dilution, the complement should not be used.

Due to Hemolysin.—As previously stated, this is usually first suspected but probably least likely to be a cause of trouble, especially if the hemolysin has been previously used with success. The unit of antisheep hemolysin should be at least 0.5 c.c. of 1:4,000 and serum of this and higher strengths are so easy to prepare that it is a mistake to use weaker products. If the saline solution and complement are satisfactory, a good hemolysin is rarely responsible even when shipped over long distances.

Due to Corpuscles.—When blood is obtained from an abattoir one is almost sure sooner or later to encounter the corpuscles of occasional animals possessing *increased resistance* to serum hemolysis. The cause of this phenomenon is unknown; fortunately it is rare. The remedy is to discard the corpuscles and secure a fresh supply of blood.

Due to Antigen.—Providing no mistakes have occurred in dilution and dosage, this is very rarely a cause of trouble. When the antigen control shows incomplete hemolysis it is almost surely due to some component of the hemolytic system, especially the complement.

Due to Anticomplementary Sera and Spinal Fluids.—Sera and spinal fluids may be found to be anticomplementary, as shown by incomplete hemolysis of the controls. After experience has been gained some of these reactions may be safely read, as previously stated, but as a general rule it is safer and wiser to repeat the tests with fresh serum or spinal fluid, especially in the case of those technicians lacking experience in complement fixation work. It is infinitely better to repeat the tests than to run the slightest chance of error, especially the regrettable and almost unpardonable error of rendering a falsely positive report. Sometimes the majority of sera and spinal fluids of a day's work show incomplete hemolysis of the controls, but this trouble is not due to anticomplementary effects on their part but rather to the use of a defective supersensitive complement. Under these conditions the tests may have to be repeated and for this reason the *unused portions of all sera and spinal fluids should be routinely kept in a refrigerator until the tests are completed in case repetitions are required.* In case difficulties are due to the presence of thermostable anticomplementary substances in sera, they can usually be satisfactorily tested after preparation by the modified method of Sachs.

---

*Use only male pigs.

THE HECHT-GRADWOHL COMPLEMENT FIXATION TEST FOR SYPHILIS

The method of performing the Wassermann test described on pages 2031 ff. entailed the use of ''inactivated'' serum, complement derived from a guinea pig, and specific hemolysin developed as a result of repeated injections of washed sheep cells into rabbits. In the years following the original announcement of Wassermann, Neisser, and Bruck of complement fixation as a method of diagnosing syphilis, it was found that many cases of syphilis failed to give a positive Wassermann reaction. It was believed that this failure to obtain a positive Wassermann reaction was due to errors inherent in the performance of the test. Noguchi early determined that the syphilitic substance, or reagin, which gives rise to the positive Wassermann, was partly thermolabile and partly thermostable. In other words, a part of the syphilitic reagin resisted the temperature of 56° C., to which blood serum was subjected in inactivation, and some of it did not. He also showed that in certain syphilitic individuals the thermolabile factor might constitute the larger percentage of the syphilitic antibody. Therefore, in those cases, inactivation would completely render the following Wassermann test negative.

For this reason, efforts were made to utilize active serum so as to keep both the thermolabile and thermostable factors inviolate in the test. The principal methods using active serum that have appeared in the literature are those of M. Stern,[1] Hecht,[2] Gradwohl,[3] Laredde,[4] Levaditi and Latipie, Famulener and Hewitt, McIntyre, Worth and McIntyre, Fernandez, Perilmann, Boas, Mutermilch and Latapie, Plaut, Müller and Lansteiner,[5] and Noguchi.[6]

I began my serological work in 1907 in Wassermann's laboratory, and soon discovered that many cases of syphilis were not detected by the original Wassermann test. I therefore interested myself in the use of active sera for complement fixation and, after trying out a number of methods worked out a modification of the original tests advocated by Hecht, Weinberg, and Laredde. This work, which was begun in 1910, was published in 1914. A number of reports on this work were made and can be found in the literature.[7] Briefly, the method employs blood serum which is not inactivated, and utilizes the native complement and native antisheep hemolysin present in practically all human bloods. Fullest advantage is taken of the fact that the thermolabile and thermostable factors of blood serum are preserved in this method. From 1913 until the present time, that is, over a period of forty years,

[7] Gradwohl, R. B. H.: J. A. M. A. 63: 240, 1914; Lancet-Clinic 112: 624, 1914.

I have used the test that I originated as a routine method, together with the Wassermann test as standardized by Kolmer, and the Kahn precipitation test, later to be described. As a result of an experience with over 100,000 blood sera, I firmly believe that this method affords the most reliable and satisfactory measure for the estimation of the presence of syphilitic reagin in a given blood serum. It presents no difficulties in technical performance nor does it give false positives. It might be added that this work has been confirmed in a number of other laboratories. Some have objected to the test on the grounds that it utilizes fourteen tubes and therefore considerable additional work is necessary. But this, in itself, is not objectionable in view of the fact that information is afforded which is not obtainable with any other method, so far as my experience is concerned.

A rather valid objection, however, is found in the fact that sera that have stood over twenty-four hours may lose their native complement, under which circumstances the Hecht-Gradwohl technic, as outlined below, must be changed; namely, one must add sufficient complement, determined by titration, to offset the disappearance of the native complement. In a few cases where native antisheep hemolysin is absent, this, too, may be added so that these objections are thus overcome.

So far as the results of this test are concerned, as compared with the classical Wassermann, we may state that we have frequently seen a strong positive Hecht-Gradwohl reaction when a negative Wassermann was found. In our own cases which have been all checked over very carefully, undeniable history and symptoms of syphilis were obtained. It is also a fact that this test gives a positive reaction in a given case of syphilis earlier than the standard Wassermann test. It is also true that under treatment the Wassermann test becomes negative much more quickly than the Hecht-Gradwohl test. In other words, as a guide or measure of the efficacy of treatment, this test may be used with greater advantage than the classical Wassermann or many of the modern modifications.

Preparation of Glassware

The glassware is prepared in the same manner as for the Wassermann test. Great care must be exercised in cleaning the small Hecht-Gradwohl test tubes, as small quantities of blood and serum tend to remain in the tubes. This causes the tubes to become brown, or cloudy, and unfit for use.

Patient's Serum

The blood is procured in the same manner as for the Wassermann test.

After removing the serum, it is ready for use. The serum for the Hecht-Gradwohl test is not inactivated, as the complement naturally present is used instead of complement procured from guinea pig blood. The natural hemolysin present in human serum is also employed in the reaction.

Physiologic Saline

The saline solution used in the Hecht-Gradwohl test is the same as is used in the Wassermann reaction.

Antigen

Noguchi's ether-soluble, acetone-insoluble antigen is used.

After the dilution for the Wassermann reaction is determined (see titration of Noguchi's Antigen, page 2036), the antigen is diluted to double volume for use in the Hecht-Gradwohl test. For example, if the dilution for the Wassermann test is 1 part of antigen

TABLE 201

THE HECHT-GRADWOHL COMPLEMENT FIXATION TEST FOR SYPHILIS

TUBES	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Patient's serum (unheated)	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.	0.1 c.c.
Saline	1.0 c.c.	0.9 c.c.	0.8 c.c.	0.7 c.c.	0.6 c.c.	0.5 c.c.	0.4 c.c.	0.3 c.c.	0.2 c.c.	0.1 c.c.	0.2 c.c.	0.15 c.c.	0.1 c.c.	0.3 c.c.
Antigen	------	------	------	------	------	------	------	------	------	------	0.1 c.c.	0.15 c.c.	0.2 c.c.	------
Sheep cells	0.1 c.c.	0.2 c.c.	0.3 c.c.	0.4 c.c.	0.5 c.c.	0.6 c.c.	0.7 c.c.	0.8 c.c.	0.9 c.c.	1.0 c.c.	------	-------	------	------

Place in the water-bath at 37°–40° C. for 30 minutes.
At the end of the 30 minutes, add sheep cells to the last four tubes according to the index chart below.
Place again in the water-bath at 37°–40° C. for 30 minutes.

If the index is 0.1 c.c., 0.2 c.c., 0.3 c.c., or 0.4 c.c., Add 0.1 c.c. sheep cells to the last 4 tubes.
If the index is 0.5 c.c., 0.6 c.c., or 0.7 c.c., Add 0.15 c.c. sheep cells to the last 4 tubes.
If the index is 0.8 c.c., 0.9 c.c., or 1.0 c.c., Add 0.2 c.c. sheep cells to the last 4 tubes.
If the index is 1.1 c.c., 1.2 c.c., 1.3 c.c., or 1.4 c.c., Add 0.25 c.c. sheep cells to the last 4 tubes.
If the index is 1.5 c.c., 1.6 c.c., 1.7 c.c., Add 0.3 c.c. sheep cells to the last 4 tubes.
If the index is 1.8 c.c., 1.9 c.c., or 2.0 c.c., Add 0.35 c.c. sheep cells to the last 4 tubes.

After the first half hour in the water-bath, no further treatment of the first ten tubes is necessary. They are the index tubes; that is, the hemolytic activity of the patient's serum is determined in this titration.

Tube 14 is the control over the first ten tubes, especially when there is a low index. If Tube 14 is cloudy instead of clear, the result of the test cannot be reported. This tube does not receive antigen, and is, therefore, an anticomplementary control. If none of the first ten tubes show hemolysis after the first half hour's incubation, the serum has no natural hemolytic activity, and a Hecht-Gradwohl test cannot be made. About 2% of all bloods show no index.

to 9 parts of saline, the dilution of the same antigen for the Hecht-Gradwohl test is 1 part of antigen to 19 parts of saline. The antigen is added slowly to the saline solution. If both Wassermann and Hecht-Gradwohl tests are made on the same bloods, the antigens for the two reactions may be diluted as follows:

Make the dilution of the antigen for the Wassermann test as usual.

Add 4 c.c. of the diluted antigen to 4 c.c. saline solution. This diluted antigen solution is used in the Hecht-Gradwohl test.

Sheep Cells

The sheep cells are procured and washed in the manner described under the Wassermann reaction. For use in the Hecht-Gradwohl test, twice the strength of the suspension used in the Wassermann reaction is used.

As previously explained, since no accurate dilution of sheep cells can be made, it is better to rely on a definite color after dilution to standardize the suspension used. However, about a 6 per cent suspension of sheep cells in saline is the correct dilution.

If both Wassermann and Hecht-Gradwohl tests are made on the same bloods, the Hecht-Gradwohl sheep cell suspension can be made, then the Wassermann suspension made by adding 50 c.c. of the Hecht-Gradwohl sheep cells to 50 c.c. saline.

Water-Bath

The water-bath for the Hecht-Gradwohl test is regulated between 37° and 40° C. No inactivator is necessary for carrying out this test.

Technic of the Hecht-Gradwohl Test

All bloods for the Hecht-Gradwohl test should be examined at the same time. After recording the numbers of the bloods on the laboratory sheet, each blood is given a letter which represents its place in the day's work.

Prepare the patient's blood serum as described.

Dilute the sheep cells and the antigen.

Rack up 14 Hecht-Gradwohl test tubes for each blood serum to be tested. A tag with the letter representing the letter of the serum in the day's work is attached to the tube.

Pipette, first the serum, then the saline, then antigen in 11, 12, 13 tubes, then the sheep cells to the first 10 tubes.

If more than one test is made, place the serums in their respective test tubes first. Then add the saline to each blood serum, then the antigen, then the sheep cells.

In placing the saline in the tubes, draw up 1 c.c., and place in Tube 1. Draw up 1 c.c., and place 0.1 c.c. in Tube 10, and the remaining 0.9 c.c. in Tube 2. Draw up another 1 c.c., placing 0.2 c.c. in Tube 9, the remainder being placed in Tube 3. Continue in this manner until all tubes have received the saline.

Add the sheep cells in the same manner in order to hasten the process of pipetting. See Table 201 for quantities of reagents used.

Reading the Index

The last tube in which complete hemolysis of the sheep cells occurs is the index tube. For example, if Tubes 1, 2, 3, 4, 5, and 6 are completely hemolyzed, and the remainder show partial or complete inhibition of hemolysis, Tube 6 is the last tube in which hemolysis occurred, and is, therefore, the index tube. In such case, 0.15 c.c. sheep cells would be added to the last four tubes.

If no tubes show hemolysis, there is no index, and the test cannot be completed. Frequently, another specimen of the same patient's blood, taken at a later date, will give an index.

If all tubes show complete hemolysis, an additional 1 c.c. sheep cells is added to each of the first 10 tubes, and the rack replaced in the water-bath for another thirty minutes. If, at the end of this time, no tubes show complete hemolysis, the index is the 10th tube. or 1.0. In such case, 0.2 c.c. sheep cells should be added to the last four tubes.

If, after the addition of the extra 1.0 c.c. sheep cells to all of the first 10 tubes, and reincubation is completed, Tubes 1 and 2 show complete hemolysis, the index is 1.2, and 0.25 c.c. sheep cells is used in the test.

Reading the Results

Tube 14 should always show complete hemolysis. If it shows partial or complete inhibition of hemolysis, the result of the test is unreliable. If the blood gave a low index, then report the specimen as a ''no index'' blood. If, however, the index was above 4, some mistake has been made, and the last four tubes should be re-run.

If the specimen is negative, complete hemolysis will occur in all of the last four tubes.

A positive result may be any of the following:

Tubes	11	12	13
	+	+	+
	–	+	+
	–	–	+

If Tubes 11 and 12 are clear, and Tube 13 is cloudy, it is best to run Tube 13 over, since some error in pipetting may be responsible for this result. In treated cases of syphilis, it is not unusual to obtain such results.

Report the result of the Hecht-Gradwohl Tests as in Table 202.

TABLE 202.—RESULTS OF TESTS

TUBE 11	TUBE 12	TUBE 13	TUBE 14	REPORTS
+	+	+	–	++++
–	+	+	–	+++
–	±	+	–	++
–	–	+	–	+
–	–	–	–	–

Great care must be taken to mix the contents of the tubes thoroughly before placing in the water-bath. The tubes are narrow, and consequently, unless carefully watched, the various reagents are not thoroughly mixed with each other. If there is not enough serum to make a complete Hecht-Gradwohl test, some of the index tubes may be omitted. At least one tube in each index group should be run; for example, Tube 1, Tube 5 or 6, Tube 9 or 10. Tube 1 must always be run, as occasionally a blood will hemolyze only 0.1 c.c. sheep cells.

It is the practice of some laboratories to report as ''no index'' all bloods which show an index below 0.3 c.c.

THE CARDIOLIPIN TEST OR VDRL SLIDE TEST[1]

Reagents.—

Antigen.—

Antigen for this test is an alcoholic solution containing 0.03% cardiolipin, 0.9% cholesterol, and sufficient purified lecithin to produce standard reactivity (0.21% ± 0.01%). It may be purchased from Sylvana Chemical Company* or the Lederle Laboratories, Inc.† Store it in a refrigerator. Discard any antigen containing a precipitate. (See page 2016.)

Serum.—

Prepare serum in the usual manner. Heat at 56° C. for 30 minutes. Recentrifuge all sera showing particulate debris. If used more than four hours after heating, reheat at 56° C. for 10 minutes before using.

Temperature at the time of use should be 73° to 85° F.

---

*407 South Jefferson St., Orange, N. J.

†30 Rockefeller Plaza, New York 20, N. Y.

[1] Harris, A., Rosenberg, A. A., Ridel, A. L.: J. Ven. Dis. Inform. 27: 169, 1946.

V.D.R.L. Slide Test Venereal Disease Research Laboratory, U.S. Marine Hospital, Staten Island 4, New York, May 1, 1946.

Buffered Saline.—

Formaldehyde, neutral, reagent grade	0.5	c.c.
Dibasic sodium phosphate ($Na_2HPO_4 \cdot 12H_2O$)	0.093	gm.
Monobasic potassium phosphate (KH_2PO_4)	0.170	gm.
Sodium chloride A.C.S.	10.0	gm.
Distilled water	1000.0	c.c.

Store in screw-capped or glass-stoppered bottles. Reaction should be pH 6.0 ± 0.1. Temperature should be 73° to 85° F. (23° to 29° C.).

Slides.—

Slides must be fat-free. Slides to be used are glass slides with paraffin rings, or glass slides with ceramic rings. Certified Blood Donor slides or the Clay-Adams ceramic ring slides are satisfactory, provided the rings are high enough to hold the tests when the slides are rotated at the proper speed.

Antigen Emulsion.—

Pipette 0.4 c.c. buffered saline to the bottom of a 30 c.c. round, glass-stoppered or screw-capped bottle, with a *flat* bottom (on the inside of the bottle). If it is concave or convex, the first quantity of buffered saline will not cover the bottom of the bottle.* Bottles must be rinsed 8 times in tap water and twice in distilled water and then dried in an oven.

Add 0.5 c.c. antigen, drop by drop, from the lower portion of a 1.0 c.c. pipette graduated to the tip, directly onto the saline, while continuously rotating the bottle on a flat surface. Antigen is added rapidly, so that approximately 6 seconds are allowed for each 0.5 c.c. of antigen. Blow out the last drop of antigen without touching it to the saline, and continue rotation for 10 more seconds. Pipette tip should remain in the upper third of the bottle.

Proper speed of rotation is obtained when the outer edge of the bottle describes a 2-inch circle three times in a second.

Add 4.1 c.c. buffered saline, using a 5 c.c. pipette. Replace stopper and shake bottle vigorously for approximately 10 seconds, throwing the liquid from the top to the bottom of the bottle. This amount of antigen is sufficient for 250 tests. It may be used for only one day. Twice this quantity may be made at one time in a 30 c.c. bottle, but no more. Temperature for use should be 73° to 85° F. (23° to 29° C.).

Technic.—

Preliminary Testing of Antigenic Emulsion.—

Add 1 drop of antigen emulsion to 0.05 c.c. of both a reactive and a nonreactive serum, and carry out the qualitative test. Reactions should be typical. The number of antigen particles per microscopic field in the nonreactive serum should be optimum.

Antigen emulsion delivery is made with a syringe with an attached 18 gauge needle with the bevel filed off. Hold the syringe in a vertical position to deliver the proper size drop of antigen, 60 drops per c.c.

Check the needle each day. Drops should be of constant size (about $\frac{1}{60}$ c.c.). Gently shake the bottle of antigen and fill and empty the syringe once before using, to mix the antigen.

(1) VDRL SLIDE QUALITATIVE TEST

Always include reactive, weakly reactive, and nonreactive control sera.

Pipette 0.05 c.c. heated serum to one of the paraffin rings.

Add one drop (approximately $\frac{1}{60}$ c.c.) of antigen emulsion.

Rotate the slide for 4 minutes on a flat surface, describing a 2-inch circle 120 times per minute, or use the Boerner-Lukens rotator.

Read immediately, using the low power objective of the microscope, without the condenser, and the 10× ocular. Antigen particles appear as short rod forms at this magnification. Aggregation of the particles into large or small clumps is interpreted as degrees of reactivity.

---

*Suitable bottles are made by Corning Glass Works, Corning, N. Y. These are No. CA-1, bottle No. 90530, Micro-reagent bottle, 30 ml., with stopper No. 14.

Report.—

Results	Report
No clumping or very slight roughness	Nonreactive (N)
Small clumps	Weakly reactive (W.R.)
Medium and large clumps	Reactive (R)

The *weakly reactive* range includes clumpings similar to those recorded as plus-minus or 1 plus, the *reactive* range, those reported 2 plus, 3 plus, or 4 plus, in other slide tests. This method of reporting is not recommended.

Zonal reactions, due to excess of reactive serum component, appear as irregular clumps, loosely bound. Reactive results show large or small clumps, fairly uniform in size. If zonal reactions are suspected, dilute the serum 1:5 and 1:25, and re-test. The maximum reaction in either dilution, if greater than that with undiluted serum, is the test finding. ✓

(2) VDRL SLIDE QUANTITATIVE TEST A

All sera producing reactive or weakly reactive results in the qualitative VDRL slide test should be tested quantitatively.

Dilute the serum 1:10 by adding 0.1 c.c. of the heated serum to 0.9 c.c. of 0.9% saline, using a 0.2 c.c. pipette graduated in 0.01 c.c. for measuring the serum.

Mix the serum and saline thoroughly, and allow the pipette to stand in the test tube.

Using this same pipette, transfer 0.05, 0.02, and 0.01 c.c. quantities of the 1:10 dilution to the 4th, 5th, and 6th rings, respectively, of the VDRL test slide.

With the same pipette, transfer 0.05, 0.02, and 0.01 c.c. quantities of the undiluted serum into the 1st, 2nd, and 3rd ringed areas.

Add 1 drop (0.03 c.c.) of 0.9% saline to the 2nd and 5th rings of each serum by vertical delivery, from a 15 gauge hypodermic needle fitted to a glass syringe. Needles should be checked for proper drop size.

Add 1 drop (0.04 c.c.) of 0.9% saline to the 3rd and 6th rings by vertical delivery from the syringe fitted with a 13 gauge needle.

The 6 mixtures are equivalent to dilutions of 1:1 or undiluted, 1:2.5, 1:5, 1:10, 1:25, and 1:50.

Rotate the slides gently by hand for 15 seconds to mix the serum and saline.

Add 1 drop ($\frac{1}{60}$ c.c.) of antigen emulsion to each ring, using a syringe and needle as described for the slide qualitative serum test.

Rotate the slides in the manner described on page 2063.

Read the results microscopically. The highest serum dilution giving a reactive result (not weakly reactive) is reported as the reactivity end point; e.g., reactive–1:25 dilution, or reactive–25 dils.

If all the dilutions give reactive results prepare a 1:100 dilution of that serum by adding 0.1 c.c. of the 1:10 serum to 0.9 c.c. of 0.9% saline solution and proceed as above. The serum dilutions are now 1:100, 1:250, and 1:500. Test each dilution and report.

(3) VDRL SLIDE QUANTITATIVE TEST B

Prepare a 1:8 dilution of the serum by adding 0.1 c.c. of heated serum to 0.7 c.c. of 0.9% saline, using a 0.2 c.c. pipette graduated in 0.01 c.c. for measuring the serum.

Mix the serum and saline solution thoroughly and allow the pipette to stand in the test tube.

Using this pipette, transfer 0.04, 0.02, and 0.01 c.c. of the 1:8 serum dilution into the 4th, 5th, and 6th paraffin rings, respectively.

With the same pipette, transfer 0.04, 0.02, and 0.01 c.c. of the undiluted serum into the 1st, 2nd, and 3rd rings.

Add 2 drops (0.01 c.c. in each drop) of 0.9% saline to the 2nd and 5th rings of each serum by vertical delivery from a 23 gauge hypodermic needle fitted to a glass syringe.

Add 3 drops of 0.9% saline to the 3rd and 6th rings of the serum.

Rotate the slides gently by hand for 15 seconds to mix the serum and saline.

Add 1 drop ($\frac{1}{75}$ c.c.) of antigen emulsion to each ring, using a syringe and needle of appropriate size.

Complete tests as described above. Serum dilutions are 1:1, 1:2, 1:4, 1:8, 1:16, and 1:32.

If all dilutions give reactive results continue with the dilutions and tests.

Reading and Reporting VDRL Slide Quantitative Tests

Read microscopically at 100× magnification.

Report results in terms of the greatest serum dilution that produces a reactive (not weakly reactive) result in accordance with Table 203.

TABLE 203

DILUTIONS OF SERUM					REPORT
				Method A	
1:1	1:2.5	1:5	1:10	1:25	
R	WR	N	N	N	Reactive, undiluted only, or 1 dil.
R	R	WR	N	N	Reactive, 1:2.5 dilution, or 2.5 dils.
R	R	R	RR	N	Reactive, 1:5 dilution, or 5 dils.
				Method B	
1:1	1:2	1:4	1:8	1:16	
R	WR	N	N	N	Reactive, undiluted only, or 1 dil.
R	R	WR	N	N	Reactive, 1:2 dilution, or 2 dils.
R	R	R	WR	N	Reactive, 1:4 dilution, or 4 dils.

R—reactive; WR—weakly reactive; N—nonreactive.

NOTE: Under conditions of high temperature and low humidity, antigen emulsions may be stored in a refrigerator but should be restored to room temperature before use. To prevent surface drying under these conditions, tests should be completed and read as rapidly as possible.

THE VDRL TUBE FLOCCULATION TEST

General Equipment.—

Kahn shaking machine, which must be operated at 275 to 285 oscillations per minute.

Reading lamp, fluorescent or gooseneck type.

Reagents.—

Antigen.—

VDRL slide flocculation test antigen (see page 2062).

Saline Solutions.—

Prepare **1% buffered saline** as for the VDRL slide flocculation test (page 2063).

Prepare **unbuffered 1% sodium chloride solution** by adding 1 gm. of dry sodium chloride to each 100 c.c. of distilled water.

Serum.—

Use clear serum obtained by centrifuging whole clotted blood. Heat at 56° C. for 30 minutes or at 60° to 62° C. for 3 minutes before testing. Examine all sera when they are removed from the water-bath. Recentrifuge those which contain particulate debris. Sera to be tested more than 4 hours after being heated should be reheated at 56° C. for 10 minutes just before use.

Antigen Emulsion.—

Prepare antigen emulsion as described for the VDRL slide flocculation test (page 2063).

Add 4 parts of 1% sodium chloride solution to 1 part of VDRL slide test emulsion.

Mix well and allow to stand 5 minutes or more, but no longer than 2 hours, before use. This solution will be referred to as "**diluted antigen emulsion.**"

(1) QUALITATIVE SERUM TEST

Pipette 0.5 c.c. of heated serum into a test tube 12 by 75 mm. outside diameter.

Add 0.5 c.c. diluted antigen emulsion to each serum.

Shake tubes in a Kahn shaker for 5 minutes.

Centrifuge all tubes for 10 minutes at 2,000 r.p.m. in No. 1, or at 1,700 r.p.m. in No. 2, I.E.C. centrifuge (or its equivalent).

Return tubes to the Kahn shaking machine and shake for exactly 1 minute.

Include reactive and nonreactive sera controls.

Reading and Reporting Qualitative Test.—

Read reactions *as soon as secondary shaking period is completed,* by holding the tubes close to the shade of a reading lamp with a black background, at approximately eye level. A shaded fluorescent desk lamp or a gooseneck-type lamp with a blue bulb is a satisfactory reading light source.

Record results as follows:

Reactive—

Visible aggregates in a clear or slightly turbid medium. All borderline reactions, where the observer is in doubt regarding visible clumping, should be reported as negative.

Nonreactive—

No visible clumping or aggregation of antigen particles; appearance slightly turbid or granular; definite silken swirl on gentle shaking.

Note: Cloudy or hemolyzed sera may cause completed tests to be too turbid for macroscopic reading. Fluid from these tubes may be examined microscopically. Reactive reports may be rendered when large antigen-particle masses are detected microscopically if the serum tested is found to be free of particles at the same magnification.

Zonal reactions, due to excess of reactive serum component, may appear to be very weak, or, in rare instances, nonreactive. Whenever a zonal reaction is suspected, another test should be performed using 0.1 c.c. of heated serum and 0.4 c.c. of saline in place of the original 0.5 c.c. of serum. If a reactive result is obtained with the smaller amount of serum, a reactive report should be issued.

(2) QUANTITATIVE SERUM TEST

Pipette 0.5 c.c. of freshly prepared 0.9% saline into each of 5 or more test tubes (12 by 75 mm.).

Add 0.5 c.c. of heated serum to the first tube and mix.

Transfer 0.5 c.c. from the first to the second tube and mix.

Continue transferring 0.5 c.c. from each tube to the next, and mixing, until the last tube is reached.

Discard 0.5 c.c. from the last tube.

Add 0.5 c.c. of diluted antigen emulsion to each tube and proceed as described under "VDRL Slide Qualitative Serum Test," page 2063.

Reading and Reporting Quantitative Test.—

The greatest dilution of serum which produces a definitely positive reaction is the reactivity end point in accordance with the following example:

SERUM DILUTIONS					REPORT
(1:1)	1:2	1:4	1:8	1:16	
R	N	N	N	N	Reactive,undiluted only, or 1 dil.
R	R	R	N	N	Reactive, 1:4 dilution, or 4 dils.
R	R	R	R	N	Reactive, 1:8 dilution, or 8 dils.

THE VDRL TEST ON SPINAL FLUID

Reagents.—

The VDRL slide test antigen and the 1% buffered saline used in this test are the same as for the VDRL slide flocculation test (pages 2062, 2063).

10% Sodium Chloride Solution.—

Dissolve 10 gm. dry sodium chloride (A.C.S.).
in 100 c.c. distilled water.

Filter through filter paper.

Spinal Fluid.—

Centrifuge each spinal fluid and decant the supernatant fluid. Spinal fluids which are visibly contaminated or which contain gross blood are unsatisfactory for this test.

Heat in a water bath at 56° C. for 15 minutes, and cool to room temperature before testing.

Sensitized Antigen Emulsion.—

Prepare antigen emulsion as for the VDRL slide flocculation test, page 2063.

Add 1 part of 10% sodium chloride solution
to 1 part of VDRL slide test emulsion.

Mix well and allow to stand at least 5 minutes but not more than 2 hours before using.

QUALITATIVE SPINAL FLUID TEST

Pipette 1 c.c. heated spinal fluid into a 13 by 100 mm. test tube.

At the same time, prepare similar tubes, but using reactive and nonreactive spinal fluid specimens as controls.

Resuspend the sensitized antigen emulsion immediately before use by inverting the container several times.

Add to each tube in the test and to each control 0.2 c.c. of sensitized antigen emulsion.

Shake the racks of tubes on a Kahn shaking machine for 15 minutes.

Centrifuge for 5 minutes at 1,800 r.p.m. if a No. 1 centrifuge is used, and at 1,600 r.p.m. if a No. 2 is used.

Shake tubes in a Kahn shaking machine for *exactly* 2 minutes.

Read reactions as soon as possible after the second shaking period. Hold tubes close to the shade of a desk lamp with a black background. Each tube may be held motionless or shaken gently during the reading. Excessive agitation should be avoided.

Report as follows:

Reactive: definitely visible aggregates suspended in a water-clear or turbid medium.

Nonreactive: no aggregation, complete dispersion of particles, appearance turbid or slightly granular.

QUANTITATIVE SPINAL FLUID TEST

Prepare dilutions of spinal fluid, 1:2, 1:4, 1:8, 1:16, 1:32, etc., as follows.

Pipette 1.0 c.c. of 0.9% sodium chloride solution into each of 5 or more tubes.

Add 1.0 c.c. of heated spinal fluid to tube 1.

Mix and transfer 1.0 c.c. to tube 2.

Mix and transfer 1.0 c.c. to tube 3.

Continue mixing and transferring 1.0 c.c. to each successive tube. Discard 1.0 c.c. from the last tube.

Test each dilution as for the qualitative spinal fluid test.

Read each tube as for the qualitative spinal fluid test.

Report as follows:

Report test results in terms of the highest dilution of spinal fluid producing a reactive result. The term "dils," which expresses the same dilution reactivity end point, may be applied. Example:

SPINAL FLUID DILUTIONS					REPORT
1:1	1:4	1:8	1:16	1:32	
N	N	N	N	N	Reactive, undiluted only, or 1 dil.*
R	R	R	N	N	Reactive, 1:8 dilution, or 8 dils.
R	R	R	R	N	Reactive, 1:16 dilution, or 16 dils.

*Reactive finding with undiluted spinal fluid in the qualitative test.

THE KAHN PRECIPITATION TEST FOR SYPHILIS

Materials Required for Kahn Test for Syphilis

The material for thirty tests is given.

About 12 antigen vials. These are flat bottom vials, 5.5 cm. in length and 1.5 cm. inside diameter. One gross Kahn test tubes, 7.5 cm. in length and 1 cm. inside dimeter. (These are made of pure white glass.)

6 10 c.c. pipettes, graduated in 0.1 c.c.

3 dozen serologic pipettes, 1 c.c., graduated in 0.01 c.c. to the tip.

2 0.5 c.c. pipettes graduated to 0.025 c.c. and

2 0.25 c.c. pipettes graduated to 0.0125 c.c. These are Kahn antigen suspension pipettes and should be graduated to tip.

2 0.2 c.c. pipettes graduated in 0.001 c.c.

3 Kahn test tube racks. These racks have three 10 hole rows. The holes are 0.5 inch in diameter. The center row of holes is offset 0.5 inch. The rack is 3 inches wide, 11½ inches long and 2¾ inches high.

1 shaking machine, 3 or 6 rack capacity. Speed of 275 to 285 oscillations per minute with a stroke of 1½ in.

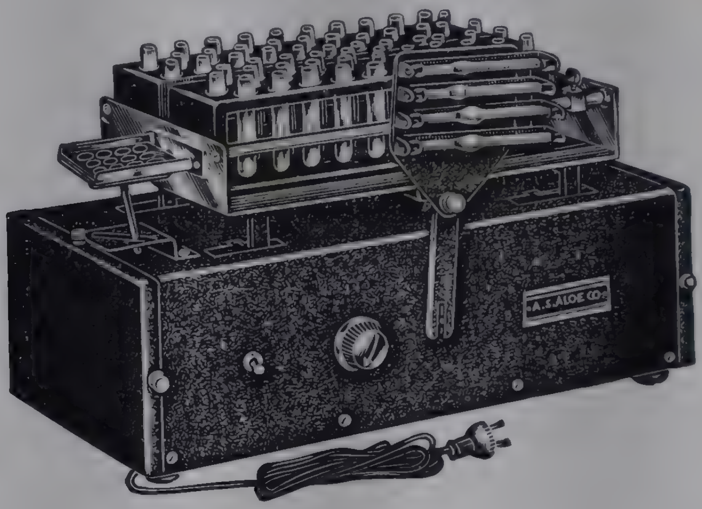

Fig. 604.—Aloe-Feder shaking machine. (Courtesy A. S. Aloe Co., St. Louis, Mo.)

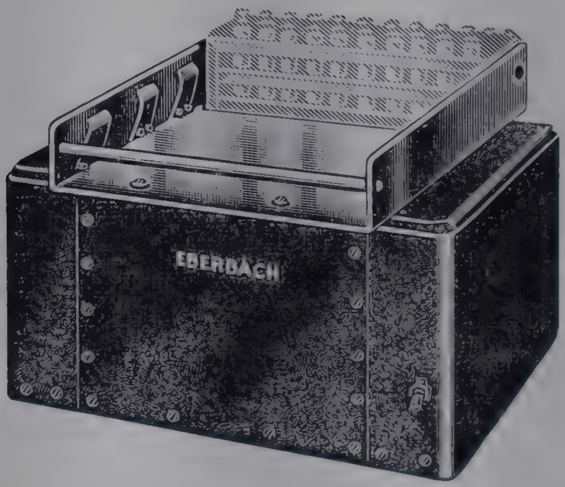

Fig. 605.—Kahn shaking machine. (Courtesy Eberbach Corporation, Ann Arbor, Mich.)

3 1,000 c.c. Pyrex Erlenmeyer flasks for saline solutions.

1 56° C. automatic temperature control water bath. If complement fixation tests are made in the same laboratory, the same bath may be used.

1 centrifuge.

Numerous test tubes for collecting the blood and removing the serum.

1 gooseneck lamp.

1 microscope mirror.

Preparation of Glassware

Rinse the glassware thoroughly in tap water.

Place new glassware in 1% hydrochloric acid solution for two hours, otherwise omit this step.

Rinse thoroughly in tap water.

Rinse thoroughly in distilled water.

Sterilize in the dry heat sterilizer at 170° C. for two hours. (It is not necessary actually to sterilize; glassware needs only to be thoroughly dry.)

This should be done about once a month: The pipettes should be kept overnight in cleaning solution (page 192), then rinsed thoroughly in tap water. Place them in a crock, and wash in running tap water for several hours.

Rinse in distilled water.

Sterilize in the dry heat oven at 170° C. for two hours (not necessary to sterilize, only to dry thoroughly).

The glassware must be neutral and dry.

Saline

The saline is prepared in the same manner as for the Wassermann test except that 0.9% sodium chloride is used. If any traces of foreign matter remain in the solution, they should be removed by filtration even after sterilization. The sterility of the solution is not as important as its chemical purity and its freedom from particles. Saline should be prepared every two weeks.

Patient's Serum

The patient's serum is obtained and prepared in the same manner as for the Wassermann reaction. If sera are held over from day to day, they should be reheated for ten minutes at 56° C. before use. Tests should be made within 5 to 10 minutes after removing serum from the bath. If a sediment develops, it should be removed by centrifuging. Any trace of cells must also be removed. The serum must be clear. Hemolyzed blood may be used for the Kahn test, provided it contains no precipitate.

Antigen

Antigen already titrated and standardized, plain or cardiolipin type, with the titer for serum and spinal fluid, may be purchased from various biological houses. It should be stored at room temperature in the dark.

To make the antigen, purchase powdered beef heart (Digestive Ferments Co.). Place 25 grams of powdered beef heart in a 250 c.c. Pyrex Erlenmeyer flask.

Add 100 c.c. anesthesia ether.

Shake the flask at frequent intervals for ten minutes.

Filter through filter paper in a Buckner funnel fitted to a side-arm filter flask by means of a one-hole rubber stopper.

Transfer the moist beef heart to the original flask.

Add 75 c.c. ether, and again shake for ten minutes at frequent intervals.

Refilter, and again discard the filtrate. Use fresh filter paper.

Transfer the moist heart to the flask, and again add 75 c.c. ether.

Shake for ten minutes, and filter through filter paper.

Repeat this process for the fourth extraction with ether. Use fresh filter paper for each filtration.

Spread the moist heart muscle on a sheet of white paper in the incubator. Allow it to dry. It should be free from the odor of ether before the following procedures are carried out.

Weigh the dry powder. Place in a 250 c.c. Erlenmeyer flask.

Add 5 c.c. 95% alcohol for every gram of powder.

Cover a cork with tin foil and place tightly in the flask.

Shake the flask for 10 minutes.

Allow to remain at room temperature in the dark for 3 days. Do not shake the flask during this period.

Filter through filter paper, shaking the flask for five minutes before filtration. Place the filtrate in a ground glass stoppered bottle in the dark at room temperature.

This is the **stock antigen solution.**

For cholesterolization add to every 1 c.c. stock antigen solution 6 mg. cholesterol.

Place the bottle or flask in a warm bath until all the cholesterol is in solution. Do not keep this solution in the refrigerator, as the cholesterol will not remain in solution.

After the cholesterol is dissolved, filter through filter paper until absolutely clear. The cholesterolized antigen must be titrated before use.

STANDARDIZATION OF KAHN ANTIGEN*

(a) Determination of Titer

The purpose of the titration is to determine the minimum amount of 0.9% saline to be added to 1 c.c. of antigen to produce a suspension of aggregates that completely disperses upon the addition of a designated amount of saline solution, and which reproduces the opalescence of the standard antigen.

Using a 1 c.c. pipette graduated in 0.01 c.c., place 0.9, 1.1, 1.2, 1.3, 1.4, 1.5, 1.7, and 1.9 c.c., respectively, of 0.9% saline in 8 antigen-suspension vials.

Using a 1 c.c. pipette, place 1 c.c. of 0.6% cholesterolized antigen to be titrated in each of 8 similar vials. Set up a standard antigen control at the same time at the titer indicated on the label.

Prepare the different antigen suspensions by mixing the antigen with the varying amounts of saline. Empty the saline into the antigen as rapidly as possible without waiting to drain the tube, and pour the mixture back and forth 12 times. Allow to stand for 30 minutes.

Test for dispersibility in saline of the lipid aggregates in the antigen-saline solution suspension as follows:

1. Set up 9 series of 3 Kahn tubes each.
2. Pipette 0.05, 0.025, and 0.0125 c.c. quantities of each of the 8 antigen suspensions, after thorough agitation, to the bottoms of the tubes, in series, using a 0.25 c.c. antigen pipette. Pipette the same quantities of emulsion, prepared from the standard antigen, into the last 3 tubes.

   Use a different antigen pipette for each suspension.
3. Using a 1 c.c. pipette, add 0.15 c.c. saline solution to each of the 27 tubes.
4. Shake the racks vigorously for 10 seconds by hand and then for 3 minutes on a Kahn shaking machine at a speed of 275 to 285 oscillations per minute.
5. Add 1 c.c. of saline to the tubes containing the 0.05 c.c. amounts of antigen suspension, and 0.5 c.c. to the remaining tubes. Shake the rack by hand to mix and observe whether the mixtures are opalescent or contain aggregates.

A typical titration may show cloudiness in the 3-tube test containing the antigen suspension which was prepared with 0.9 c.c. and with 1.1 c.c. saline. These suspensions contain aggregates which were not completely redispersed in saline solution. Those containing antigen suspension mixed with 1.3 c.c. of saline may appear opalescent, like the antigen control. The other four tests may appear clearer than the control. In this case, the titer of the antigen would be 1 c.c. of antigen plus 1.3 c.c. of saline; that is, 1.3 c.c. is the smallest amount of saline solution, which, when added to 1 c.c. of antigen, produces aggregates capable of complete dispersion upon the further addition of saline solution and which reproduces the opalescence of the standard antigen.

Table 204 illustrates a typical antigen titration. The ''normal'' range of titers for standard antigen may vary from 1 + 1.1 to 1 + 1.5.

TABLE 204.—TYPICAL ANTIGEN TITRATION

ANTIGEN PLUS 0.9% SALINE SOLUTION	APPEARANCE OF MIXTURE
1 + 0.9	Cloudy, nondispersible aggregates
1 + 1.1	Slightly cloudy, fine, nondispersible aggregation
1 + 1.2	Very slightly cloudy
1 + 1.3	Opalescent, standard (titer)
1 + 1.4	Very slightly clearer
1 + 1.5	Slightly clearer
1 + 1.7	Very clear
1 + 1.9	Almost water clear
Standard antigen control: Opalescent, standard	

---

*Serologic Tests for Syphilis, 1955 Manual, U.S. Department of Health, Education, and Welfare, Public Health Services, Publication No. 411.

Antigens made with progressively increasing volumes of saline solution will usually show a correspondingly progressive increase in clarity of mixtures. Rarely, however, an antigen suspension will show a ''titration zone''; that is, cloudiness and nondispersible aggregates may appear again beyond the titer, for example, in tubes containing 1.7 or 1.9 c.c. of saline. This antigen has a short workable range and should not be used.

(b) Determination of Reactivity Level

A series of sera with graded reactivities may be prepared from pooled, Seitz-filtered reactive and nonreactive sera by combining selected proportions of these sera so that the desired number of strongly and weakly reacting specimens is obtained. These may be used for preliminary testing but not for final checking of the reactivity. All sera should be heated before use.

(1) **Preliminary Testing.—**

Prepare antigen suspensions with both antigens according to their respective titers. Allow to stand for 10 minutes.

Carry out tests with at least 10 sera as for the Kahn standard qualitative test with serum. If comparable reactions are obtained with both antigen suspensions, final checking should be made.

(2) **Final Checking of Antigen.—**

Obtain at least 50 sera that show varying degrees of reactivity in the Kahn test, and 50 nonreactive sera.

Perform Kahn standard qualitative tests, using both antigens simultaneously on all the sera.

Each serum should be tested with both antigens in the same rack so as to eliminate the time factor. Two readings should be made in each instance where recordable reactions are observed during the first reading. The two readings are necessary since some antigens that produce standard first readings may allow readable particles to redisperse at a rate different from that of the standard antigen. Thus, the final report on a given specimen could be less or greater than that obtained with standard antigen. If the results produced by the new antigen are comparable with those of the standard antigen, it is considered to have standard reactivity.

(3) **Correction of Antigen.—**

The reactivity level may be greater or less than that of the standard antigen. Correction to standard requirements can usually be accomplished.

TABLE 205.—STANDARDIZATION OF KAHN STANDARD ANTIGEN

ANTIGEN REACTIVITY	METHOD OF ADJUSTMENT
Less reactive than standard	1. Addition of cholesterolized alcohol 2. Addition of sensitizing reagent 3. Addition of sensitizing reagent plus cholesterolized alcohol 4. Addition of overreactive antigen
More reactive than standard	1. Addition of cholesterolized alcohol 2. Addition of a less reactive antigen 3. Lecithin correction solution

Cholesterolized Alcohol:

To 100 c.c. of 95% alcohol in a 250 c.c. glass-stoppered Erlenmeyer flask or bottle, add 600 mg. of cholesterol. Rotate the flask in a warm water bath until all cholesterol is dissolved. Filter when cool.

Sensitizing Reagent:

Refilter the ether filtrate obtained in the preparation of the antigen to remove traces of powdered muscle.

Place in an evaporating dish and evaporate with the aid of an electric fan. A few c.c. of water may condense in the evaporating dish, and appear at the bottom of the dish. Remove with a capillary pipette as it is formed. The lipid residue is brownish, semitransparent, and viscous.

When the volume has been reduced to a point where ether odor is no longer detectable, transfer the residue to a small, previously weighed evaporating dish, and weigh.

Add a volume of absolute alcohol equal to 10 c.c. per gram of residue. Transfer the lipid mixture to a flask.

Extract for 30 minutes at room temperature, with frequent shaking of the flask. Little of the residue is soluble in alcohol, lipid masses being distributed throughout the mixture.

Place in a refrigerator at 4° to 9° C. for 3 hours.

Filter while cold.

Place the flask containing the clear filtrate in an incubator at 37° C. for 24 hours.

Allow the clear filtrate to stand for 3 days at room temperature. If a precipitate forms, the solution should be refiltered.

Cholesterolize the filtrate with 6 mg. of cholesterol per c.c., according to the usual technic.

The cholesterolized extract is known as the sensitizing reagent. Filter. It is now ready for use. Keep in the dark at room temperature.

Correction of Antigens More Reactive Than Standard Antigens:

(1) *Mix the more reactive antigen with a less reactive antigen.*

a. Add equal amounts of the more reactive and less reactive antigens to a small bottle and mix.

b. Titrate, as described on page 2070.

c. Make preliminary comparative tests at the determined titer. Use a standard antigen as control.

d. If results are comparable, perform a final check, page 2071.

e. If antigen reactivity is not comparable, try different proportions of the two antigens.

f. Perform a final check after the entire lot of antigen has been corrected.

(2) *Add lecithin correction solution to the antigen.*

Prepare a **stock lecithin correction solution** from egg lecithin:

a. Add 5 gm. commercial egg lecithin to 100 c.c. of 0.6% cholesterolized absolute alcohol.

b. Extract 1 hour at 56° C. in a water bath.

c. Cool and filter off clear solution.

Method:

a. Add a given amount, such as 0.2 c.c., of the stock lecithin solution to 10 c.c. of the overreactive antigen.

b. Titrate the antigen, page 2070.

c. Test this antigen with 10 sera, most of which are known to give weakly reactive results, using standard antigen as a control.

d. If the modified antigen gives results comparable to those obtained with the standard antigen, adjust the entire amount of the more reactive antigen, and submit to final checking.

(3) *Dilute with cholesterolized alcohol.*

Refer to ''Corrections of antigens less reactive than the standard,'' below.

Corrections of Antigens Less Reactive Than Standard Antigen:

(1) *Dilution of antigen with cholesterolized alcohol.*

a. Add 10 c.c. of the less reactive antigen (0.6% cholesterolized) to a ½-ounce bottle. Add 1 c.c. of the 0.6% cholesterolized alcohol.

To another bottle of the same size, add 10 c.c. of the 0.6% cholesterolized antigen and 2 c.c. of 0.6% cholesterolized alcohol, making 10 and 20% dilutions, respectively.

b. Titrate both according to the method on page 2070.

c. Make comparative tests with weakly reactive sera, using standard antigen simultaneously as a control.

d. If neither 10 nor 20% dilution brings the antigen to standard reactivity, try other dilutions not exceeding 30%.

(2) *Addition of sensitizing reagent.*

Some less reactive antigens can be brought to standard level of reactivity by adding a trace of sensitizing reagent (page 2071), 0.2% to 0.7%. In some cases, sensitizing reagent in addition to dilution with cholesterolized alcohol is necessary.

(3) *Mixing less reactive antigen with one of greater reactivity.*

This is the same as described above for correction of a more reactive antigen by mixing with a less reactive one.

CHARACTERISTICS OF DIFFERENT KAHN STANDARD ANTIGENS AND THEIR IMPORTANCE IN SEROLOGIC RESULTS

Kahn antigens may show ''sloping'' or ''flat'' titers.

Antigens with sloping titrations show titration pictures of increasing clarity with the increase in the amounts of saline solution used in the preparation of the suspensions.

Antigens with flat titrations show titration pictures of similar clarity with the increase in the amounts of saline solution used in the preparation of the suspensions.

Antigens with a sloping titer are the most desirable. Some antigens which show a flat titer before standardization may show a sloping titer after standardization. Antigens which continue to show a flat titer after standardization are safe for use provided they do not begin to show a ''reversed'' sloping titration, namely, increased cloudiness following an increase in the amount of saline solution added to the antigen.

Serologic Tests for Syphilis, 1955 Manual, Public Health Service Publication No. 411 U.S. Department of Health, Education, and Welfare, Public Health Service.

The Standard Kahn Qualitative Precipitation Test of Blood Serum

Kahn racks should be used.

All sera for the Kahn test should be prepared at the same time. After recording, each serum is given a letter which represents its place in the day's work.

Centrifuge the bloods for 10 minutes at 2,000 r.p.m. and remove the serum.

Heat serum for 30 minutes at 56° C. Allow to stand at room temperature at least 10 minutes.

Prepare a *dilution of the antigen* as follows:

Place 1 c.c. antigen in an antigen vial.

Place 1 c.c. (or the quantity indicated by the titer) of saline in another antigen vial.

Mix the two by pouring back and forth twelve times without waiting to drain the tubes, pouring the saline into the antigen first.

Wait at least 10 minutes, and not longer than 30 minutes, before beginning the tests. Protect with waxed paper and shake briskly, to suspend the particles, placing the thumb over the waxed paper.

Use a 1 c.c. pipette graduated in 0.01 c.c. for measuring the 0.05 c.c. quantities of antigen suspension into the first row.

Use a 0.2 c.c. pipette graduated in 0.001 c.c. or Kahn antigen pipette for measuring the other quantities of antigen suspension.

Use the back row of tubes for the 0.0125 c.c. quantities of antigen suspension.

Draw up a pipetteful of antigen suspension. Remove any excess antigen from the outside with a clean cloth. Hold the pipette in a vertical position. Place it into each tube to the bottom of the tube. Place 0.05 c.c. of antigen suspension in the front row, 0.025 c.c. in the middle row, and 0.0125 c.c. in the back row of tubes.

Use a 1 c.c. pipette graduated in 0.01 c.c. for measuring the serum. Use a different pipette for each serum.

Place 0.15 c.c. serum in each of its three tubes.

Be sure to make a test on a known reactive and a known nonreactive serum (controls), and if possible on sera giving varying degrees of reactivity.

After placing the serum in each tube, shake the rack vigorously by hand for 10 seconds. Let stand 3 to 7 minutes at room temperature, and then place in the shaking machine and shake for 3 minutes.

Place 1 c.c. saline in each of the front tubes.

Add 0.5 c.c. saline to each of the tubes in the middle and back rows.

Mix by shaking vigorously. Read the results at once and check them 15 minutes later. Complete the addition of antigen suspension and sera to one rack before adding antigen suspension and sera to another rack. Add saline to one rack and complete reading before adding saline to another rack.

Reading Results

Place a microscope mirror on the laboratory table with the concave side upward.

Adjust a reading lamp above the mirror so that the bulb image is not visible. The Kahn tube is to be held within the cone of light. Adjust light properly.

Place each tube to be read in a nearly horizontal position, with the lower portion of the tube about 1 or 2 inches above the mirror, and note the degree of flocculation by viewing the image of the tube contents in the mirror.

Recording Results.—

Record degree of flocculation as follows:

4+	Relatively large floccules
3+	Medium-sized floccules
2+	Fine floccules easily distinguishable
1+	Very fine floccules
±	Extremely fine floccules, just distinguishable
–	An opalescent medium free from visible floccules

Reporting Results.—

There are two types of reactions possible with the Kahn test, the typical reactions and the zonal reactions. The typical reactions are characterized by greatest degree of flocculation with the smallest amounts of antigen, while the zonal reactions are characterized by having the greatest degree of flocculation with the largest amounts of antigen or equal degree with all three amounts of antigen suspension.

(a) *Typical Reactions.*

Add the pluses, disregarding the ± readings, obtained in the first and second readings. Report results as reactive, weakly reactive, and nonreactive according to Table 206.

TABLE 206.—REPORTING TYPICAL KAHN REACTIONS

SUM OF PLUSES OF FIRST AND SECOND TUBE READINGS	REPORT
22 to 24	Reactive (4+)
16 to 21	Reactive (3+)
10 to 15	Reactive (2+)
5 to 9	Weakly reactive (1+)
4*	Weakly reactive (±)
3 or less†	Nonreactive

*Should be given a nonreactive report when results are – 1 1 and – 1 1 on first and second readings.

†Should be given a weakly reactive report when the results are – – 3 on first reading and – – ± on second reading, or when they are – – 2 on first reading and – – 1 on second reading.

(b) *Zonal Reactions.*

Report zonal reactions according to Tables 207 to 213.

Supplementary Test No. 1

Place 0.05 c.c. antigen suspension in each of two tubes.

Add 0.05 c.c. of previously heated serum to tube 1.

Add 0.1 c.c. of serum to tube 2.

Shake the rack by hand for 10 seconds. Allow to stand 3 to 7 minutes at room temperature.

Shake the rack on a Kahn shaker for 3 minutes.

Add 1 c.c. of saline to each tube.

Shake by hand to mix and read immediately, and again after 15 minutes.

Reactive: 4+ or 3+ reaction in each of the two tubes.

Nonreactive: Less than 3+ reaction in each of the two tubes.

Supplementary Test No. 2

Prepare serum dilutions 1:4, 1:8, and 1:16.

Place 0.6, 0.4, and 0.4 c.c. of saline in tubes numbered 1, 2, and 3, respectively.

Add 0.2 c.c. of serum to tube 1 and mix.

Transfer 0.4 c.c. from tube 1 to tube 2 and mix.

Transfer 0.4 c.c. from tube 2 to tube 3, and mix.

Add 0.0125 c.c. of antigen suspension to the bottom of three Kahn tubes numbered 1, 2, 3, respectively.

Add 0.15 c.c. of the 1:4, 1:8, and 1:16 serum dilutions to tubes 1, 2, and 3, respectively, beginning with the highest serum dilution.

Shake the rack by hand 10 seconds to mix. Allow to stand 3 to 7 minutes.

Shake in a Kahn shaker for 3 minutes.

Add 0.5 c.c. saline to each tube and shake to mix.

Read immediately.

Reactive: 4+ or 3+ reaction in at least the 1:4 dilution.

Nonreactive: 2+ reaction or less in the 1:4 and higher dilutions.

Reporting Results

If the supplementary tests 1 and 2 are reactive, report results of the standard test as reactive, 4+.

If supplementary tests 1 and 2 are nonreactive, report results according to Tables 209 through 213.

If supplementary test 1 is reactive and supplementary test 2 is nonreactive, prepare 1:32, 1:64, and 1:128 dilutions of the serum and test as described under supplementary test 2. If the result is reactive in one or more tubes (4+ or 3+ reaction), report the results of the standard test as reactive 4+. If the result is nonreactive in all tubes, less than 3+ reaction, report the results of the standard test as indicated in Tables 209 through 213.

If supplementary test 1 is nonreactive and supplementary test 2 is reactive, test the undiluted serum in a 1:2 ratio of serum to antigen suspension (0.05 c.c. of antigen plus 0.025 c.c. serum). If the result is reactive (4+ or 3+), report the results of the standard test as reactive 4+. If the result is nonreactive (less than 3+), report the results of the standard test as indicated in Tables 209 through 213.

Control System for Kahn Standard Test

Control sera of graded reactivity and a saline solution control should be tested with each antigen suspension along with the regular tests.

Do not report results on sera or spinal fluids if the prescribed pattern of reactivity is not obtained with the controls. Failure to obtain satisfactory results may be caused by (1) improperly prepared saline solution; (2) substandard antigen; (3) incorrectly prepared antigen suspension; (4) using antigen suspension more than 30 minutes old; (5) performing tests at cold room temperature.

The Quantitative Kahn Test of Blood Serum

The quantitative Kahn test is made only on sera giving 4+ or 3+ reactions with the standard Kahn test. Its purpose is to determine the exact number of reaction units in a positive serum. Thus, a serum may give a 4+ reaction in the routine Kahn test, but if diluted might become negative. Another serum may be able to withstand a dilution of many volumes and still react as a positive serum.

Physiologic salt solution is used as the diluent.

Prepare serum dilutions of 1:2, 1:4, 1:8, 1:16, 1:32, 1:64, and higher if necessary, as follows:

Pipette 0.5 c.c. of 0.9% sodium chloride solution into each of six or more tubes.

Add 0.5 c.c. of inactivated serum to the first tube and mix.

Transfer 0.5 c.c. from the first to the second tube and mix.

Continue transferring and mixing from one tube to the next until all dilutions have been made. Allow the mixing pipette to remain in the last tube (so that further dilutions can be made if necessary).

Note: Serum dilutions should be used in the test soon after they have been prepared.

Prepare antigen suspension as previously described by mixing standard Kahn antigen with 0.9% sodium chloride solution, the quantity of saline according to the titer.

After the antigen suspension has stood at least 10 minutes but not more than 30 minutes, cover the mouth of the mixing vial containing the suspension and shake gently to obtain a smooth suspension of antigen particles.

Pipette 0.0125 c.c. of antigen suspension to the bottom of each of 6 or more numbered Kahn tubes.

Add 0.15 c.c. of the 1:64 dilution of serum to the antigen suspension in tube 6.

Add 0.15 c.c. of the 1:32 dilution of serum to the antigen suspension in tube 5.

Continue adding 0.15 c.c. of decreasing dilutions of serum to tubes 4, 3, 2, and 1, respectively.

Shake the rack by hand for 10 seconds and then allow it to stand for 3 to 7 minutes at room temperature.

Shake in a mechanical shaker for 3 minutes.

Add 0.5 c.c. of 0.9% sodium chloride solution to each tube.

Note: Add the saline to one rack and complete the reading before adding saline to another rack.

Shake the rack by hand a few seconds.

Read each tube within 2 minutes after the addition of the 0.9% saline solution to those in the rack.

Note the titration end point; that is, the highest dilution of serum in which 4+, 3+, or 2+ reactions are observed.

Compute the quantitative titer by applying the formula $S = 4D$ where S is the potency of the serum in terms of Kahn units, and D is the highest dilution demonstrating definite flocculation.

Examples:

(a) Highest dilution demonstrating definite flocculation is 1:64. $S = 4 \times 64$, or 256 Kahn units.

(b) Highest dilution demonstrating definite flocculation is 1:16. $S = 4 \times 16$, or 64 Kahn units.

Report results both in terms of Kahn units and the highest serum dilution in which a 4+, 3+, or 2+ reaction is observed:

(a) 256 Kahn units (1:64 dilution).

(b) 64 Kahn units (1:16 dilution).

Sera giving 3+, 2+, or 1+ reactions in the Kahn qualitative test may be reported as 3, 2, or 1 Kahn units, respectively, in the quantitative test if serum dilutions are nonreactive.

False Precipitate in the Kahn Test

Occasionally there is a false precipitate in the Kahn test. The late J. C. Willette, former Chief of Laboratories, St. Louis Health Division, in a personal communication stated that there were many factors that cause this trouble, among others the following: "It was discovered that we were using an ordinary commercial grade of nonabsorbent cotton to plug all of our glassware—that in the process of hot air sterilization the fat contained in the cotton plugs was vaporized; as the glassware cooled the fat condensed on the surface forming an almost imperceptible fatty film which was readily washed off by aqueous diluents forming the troublesome flocculent precipitate in our Kahn and agglutination tests.

"This difficulty, we found, had been encountered by others, and has resulted in the trade furnishing the laboratory worker with a fat-free nonabsorbent cotton, which satisfactorily disposes of this factor as a cause of false precipitates in flocculation and agglutination tests."

THE SPINAL FLUID KAHN PRECIPITATION TEST

Standard Qualitative Kahn Test of Spinal Fluid

Reagent.—

Saturated Ammonium Sulphate Solution.—

To 500 gm. of ammonium sulphate, c.p., reagent grade, add 500 c.c. doubly distilled water, in a clean 3 liter Pyrex flask.

Boil until solution becomes clear.

Allow to cool to room temperature.

Filter and store in glass-stoppered bottles at room temperature.

Technic.—

Spinal fluid should be clear. Centrifuge to remove cells or foreign matter, and decant the clear supernatant fluid.

Place 1.5 c.c. spinal fluid in a Kahn tube.

Add 1.5 c.c. saturated solution of ammonium sulphate. Mix well.

Place in a water bath at 56° C. for 15 minutes to precipitate the globulin.

Centrifuge at 2,000 r.p.m. for 15 minutes.

Pour off the supernatant fluid by inverting the tube, removing the last drop by means of filter paper. Drain 10 minutes on the filter paper.

Add to the residue in the centrifuge tube 0.15 c.c. saline, placing the pipette to the bottom of the tube just above the precipitate, and mix.

The spinal fluid is now ready for the test.

Dilute the antigen according to its titer. Allow to stand 10 minutes.

Place 0.01 c.c. antigen suspension in the bottom of a Kahn tube.

Add 0.15 c.c. concentrated spinal fluid.

Shake the rack by hand for 10 seconds, then in the Kahn shaker for 4 minutes.

Add 0.5 c.c. saline to each tube, shake by hand, and read.

Reading Results.—

Use Table 214 for reporting results.

TABLE 214.—REPORTING KAHN STANDARD QUALITATIVE TESTS WITH SPINAL FLUID

READING	REPORT
4+	Reactive, 4+
3+	Reactive, 3+
2+	Reactive, 2+
1+	Weakly reactive, 1+
±	Nonreactive
–	Nonreactive

Kahn Standard Quantitative Test With Spinal Fluid

Perform quantitative tests on spinal fluids which give reactive results in the qualitative test.

Whole spinal fluid is considered 1:10 dilution, since the qualitative test is made on spinal fluid globulin concentrated 10 times.

DILUTION	SALINE (C.C.)	SPINAL FLUID (C.C.)
1:10	None	
1:15	0.1	0.2
1:20	0.2	0.2
1:30	0.2	0.1
1:40	0.3	0.1

Place 0.01 c.c. antigen directly in the bottom of a Kahn tube. Use 1 tube for each dilution of spinal fluid being tested.

Add 0.15 c.c. diluted spinal to its respective tube, beginning with the highest dilution.

Shake the rack by hand for 10 seconds and then in a Kahn shaker for 4 minutes.

Add 0.5 c.c. saline to each tube, mix, and read immediately.

Note the highest dilution of spinal fluid producing a reactive result, 4+, 3+, or 2+.

Calculate the Kahn units according to the formula S = 4D,

where *S* is the potency of the spinal fluid in terms of Kahn units,

and *D* is the highest dilution in which a 4+, 3+, or 2+ reaction is observed.

Example:

(a) Spinal fluid reactive at 1:10 dilution (designated) = 10 × 4 = 40 Kahn units.

(b) Spinal fluid reactive at 1:40 dilution (designated) = 40 × 4 = 160 Kahn units.

Retest spinal fluids that produce only nonreactive results in the designated dilutions in the following manner:

Prepare a spinal fluid globulin concentrate, page 2078.

Add sufficient saline to make a 1:5 dilution, 0.15 c.c. of globulin solution plus 0.6 c.c. saline.

Perform a 1-tube test as described for testing spinal fluid dilutions.

If this gives a reactive result, the quantitative titer is 20 Kahn units; if it gives a nonreactive result, the titer is equivalent to the reading obtained with the undiluted globulin concentrate.

KLINE MICROSCOPIC SLIDE PRECIPITATION TESTS FOR THE DIAGNOSIS OF SYPHILIS

Patient's Serum

Prepare sera as for the Wassermann test. Sera must contain no red blood cells and no foreign particles. Heat the sera at 56° C. in an inactivator for 30 minutes.

Instrument for Making Paraffin Rings

This is essentially the instrument proposed by Green. Wind a piece of soft wire (No. 28) twice tightly about a 15 mm. diameter test tube, forming a double loop and leaving a double shaft about an inch in length. Twist the two shafts together to within a quarter of an inch of the free end. Remove the looped wire from the test tube. Use No. 12 linen thread to wind the wire. Begin at the free end of the shaft after fastening the thread there by a single twist of the free ends. Make three long turns to reach the loop, then wind tightly with the thread. Continue the winding up the shaft to the free end, and fasten it there between the two ends of the wire by twisting them. Bend the loop at right angles to the shaft. Reshape by working against the bottom of the test tube. Insert the shaft into the handle of a teasing needle or into straight hemostatic forceps. This loop is used to make the proper size rings for diagnostic and exclusion heated serum tests, diagnostic unheated serum, and finger blood tests.

To make paraffin rings, dip the instrument into smoking paraffin, at about 120° C., drain quickly at one point, and transfer the remainder to a glass slide.

Glassware

Slides are the standard Kline slides, 2 × 3 inches. These must be clean and grease-free.

Mount 12 paraffin rings, each with an inside diameter of 14 mm.

For spinal fluid tests, prepare double slides.

Pipettes are 0.2 c.c. graduated in 0.01 c.c. to the tip.

Centrifuge tubes, round-bottomed, 3 × 1 inch.

Bottles, round, glass-stoppered, 30 c.c. capacity.

Syringe, glass, hypodermic, 1 or 2 c.c. capacity.

Reagents

Antigen.—

Antigen for the Kline standard tests may be procured from LaMotte Chemical Products Co., Towson 4, Md. It is composed of cardiolipin, 0.2%, and purified lecithin, 1.6 to 2.6%, in absolute alcohol. It must be standardized by comparison with an antigen of standard reactivity. Store in a refrigerator at 6° to 10° C.

Cholesterol Solution.—

Dissolve 1 gm. of cholesterol (Pfanstiehl, ash-free, precipitated from alcohol) in 100 c.c. of absolute alcohol.

Store in a glass-stoppered bottle at room temperature.

Distilled water.—

This should have a reaction of pH 6.0, with a minimum number of positive ions or other electrolytes.

Saline.—

This is an 0.85% solution of sodium chloride in distilled water. It should preferably be made on the day of use, but may be satisfactory for as long as a week if kept in a clean glass-stoppered bottle.

Preparation of Antigen Emulsion.—

Pipette 0.85 c.c. of distilled water to the bottom of a 30 c.c. glass-stoppered bottle.

Add 1 c.c. of 1% cholesterol solution by allowing the cholesterol to drop slowly from a pipette while the bottle, held at an angle, is vigorously and continuously rotated on a flat surface.

Rotate for an additional 20 seconds.

Add 0.1 c.c. of antigen against the side of the neck of the bottle from a 0.2 c.c. pipette, avoiding the ground glass area.

Place the stopper in the bottle and shake vigorously for 1 minute, throwing the fluid from the bottom to the stopper and back.

Add 2.45 c.c. of 0.85% saline rapidly to the bottle and shake less vigorously for 30 seconds.

The emulsion is ready for use. If refrigerated it may be used for 48 hours. Double quantities of the antigen emulsion may be prepared in 30 c.c. bottles.

Preliminary Kline Test With Serum

Check the delivery of the hypodermic needle and make adjustments so that approximately 125 drops are obtained from each c.c. of antigen emulsion (0.008 c.c. per drop).

Complete tests with control sera of graded reactivity.

Reactions with control sera should reproduce the reactivity pattern. The nonreactive serum should show complete dispersion of antigen particles and the optimum number of particles per microscopic field.

Kline Standard Qualitative Test With Serum

Place 0.05 c.c. of heated serum in a paraffin ring on a glass slide.

Add 1 drop (0.008 c.c.) of antigen emulsion to each serum.

Rotate slides on a rotating machine at 180 r.p.m. for 4 minutes.

If tests are made in a hot, dry climate, cover with a box lid containing a moistened blotter, during rotation, to prevent excess evaporation.

Examine microscopically, using 100× magnification.

Report as follows:

(a) *Typical Reactions.—*

Nonreactive	Antigen particles dispersed, no clumping
Weakly reactive (± or 1+)	Antigen particles in small but definite clumps
Reactive (2+, 3+, or 4+)	Antigen particles in medium-sized or large clumps

(b) *Atypical Reactions.—*

Atypical reactions are characterized by irregular feathery clumping in which smaller clumps predominate. Atypical reacting sera should be retested in dilutions of 1:2 to 1:64. A reactive report is given if a reactive result is obtained with 1 or more serum dilutions.

Kline Standard Quantitative Test With Serum

Add 0.5 c.c. of saline to each of 6 or more tubes.

Add 0.5 c.c. of heated serum to the first tube and mix.

Transfer 0.5 c.c. from the first to the second tube and mix.

Continue in this manner until the last tube contains 1.0 c.c.

Pipette 0.05 c.c. of undiluted serum and of each serum dilution into separate paraffin rings on a glass slide.

Add 1 drop of antigen emulsion (0.008 c.c.) to each serum dilution.

Rotate slide at 180 r.p.m. for 4 minutes.

Read and record reactions as above.

Report results in terms of the highest dilution which produces a reactive result (4+, 3+, or 2+).

Example:

UNDILUTED SERUM	SERUM DILUTIONS						
1:1	1:2	1:4	1:8	1:16	1:32	1:64	
4	4	3	1	–	–	–	Reactive, 1:4 dilution or 4 dils
4	4	4	4	2	–	–	Reactive, 1:16 dilution or 16 dils
4	4	4	4	4	2	–	Reactive, 1:32 dilution or 32 dils

Kline Tests With Spinal Fluid

Preparation of Spinal Fluid.—

Spinal fluids turbid with exudate, blood, or bacteria, or containing injected substances including horse serum, are unsatisfactory for testing. Centrifuge spinal fluids with slight turbidity or few particles at 2,000 r.p.m. for 5 minutes and withdraw or decant the clear fluid.

Place the required number of test tubes, 6 × ⅝ inch, each containing 5 c.c. of Benedict's solution (1926), in a beaker (Pyrex). Add water halfway to the top. Heat. Keep the tubes in vigorously boiling water for 5 minutes.

Place the tubes in a rack. After making certain no copper reduction has occurred in any of the tubes, add to each tube, properly numbered, 0.5 c.c. of spinal fluid. Shake tubes individually vigorously for ten seconds.

Replace the tubes in the beaker. Add water halfway to the top. Heat. Keep the tubes in vigorously boiling water for 5 minutes.

Replace the tubes in the rack, inspecting each immediately after removal from the beaker for precipitate indicating presence of sugar.

Spinal fluids giving a negative reaction for sugar in the above test are unsatisfactory for testing for syphilis. These are fluids that have been acted upon by bacteria either inside or outside of the body. In the former case of the various bacterial meningitides in which organisms and ferments of the exudate have acted upon the sugar, the fluids may contain substances giving positive or unsatisfactory reactions in various tests for syphilis. Bacterial contamination subsequent to withdrawal of spinal fluids from cases of syphilis causes a steady loss both of sugar and of the specific reacting substance if the fluids are kept at room temperature.

On the other hand, if spinal fluids containing sugar when withdrawn from the body are kept at low temperature (8° to 10° C.) they continue to give a positive reaction for sugar with the test described above for several weeks, and syphilitic spinal fluids under these conditions show no appreciable loss of specific reacting substance for at least a week.

Preparation of Double-Ring Slides.—

Use clean Kline slides, 3 × 2 inches.

Place steel mold* and two center disks on slide.

Fill spaces between disks and outer mold with hot paraffin mixture, containing 1 part of paraffin and 2 parts of petroleum jelly.

Remove mold and disks from slide after paraffin has cooled.

Preparation of Antigen Emulsion for Spinal Fluid.—

Pipette 0.6 c.c. of 1% cholesterol solution to the bottom of a 3 × 1 inch, round-bottomed test tube.

Add 0.4 c.c. of distilled water rapidly by removing the finger from the pipette and blowing in the last drop while vigorously rotating the tube on a flat surface.

Continue rotation of the tube for another 10 seconds.

Add 0.1 c.c. of antigen and rotate the tube vigorously for 1 minute.

Add 1.4 c.c. of saline and rotate the tube on a flat surface for 30 seconds.

Centrifuge at 1,100 r.p.m. for 5 minutes. This time and speed may vary. The sediment should be in such an amount that when resuspended in 0.6 c.c. of saline, 1 drop, or 0.008 c.c., of the emulsion in 0.3 c.c. of spinal fluid will contain the optimum number of antigen particles per microscopic field.

Decant the turbid supernatant fluid.

Add 0.6 c.c. of saline to the sediment and rotate the tube vigorously for 30 seconds to resuspend the particles uniformly.

Transfer the emulsion to a stoppered 13 × 100 mm. tube. If stored in a refrigerator, the emulsion may be used for 48 hours.

Preliminary Kline Tests With Spinal Fluid

Check the delivery of the hypodermic needle and adjust so that approximately 125 drops are obtained from each c.c. of antigen emulsion. Each drop is 0.008 c.c.

Complete tests with reactive spinal fluid and nonreactive spinal fluid controls as described under Kline standard qualitative test with spinal fluid.

Clumping of antigen particles will be observed in the reactive spinal fluid. The nonreactive spinal fluid should show complete dispersion of antigen particles and the optimum number of particles per microscopic field.

Kline Standard Qualitative Test With Spinal Fluid

Place the required number of double-ring slides in a holder.

Heat the spinal fluid at 56° C. for 5 minutes as previously directed.

Pipette 0.3 c.c. of warm spinal fluid into a ringed chamber. Include reactive and nonreactive controls.

Add 1 drop (0.008 c.c.) of antigen emulsion to the spinal fluid in each chamber.

Rotate the slides on a flat surface with moderate vigor for 30 seconds to distribute the antigen emulsion.

Move the slide holder back and forth rapidly, about 3 complete movements a second, a linear distance of one-fourth to one-half inch, for 8 minutes.

Examine reactions microscopically at 100× magnification and report observed results as follows:

Nonreactive------------------Antigen particles dispersed, no clumping
Weakly reactive (± or 1+)------Antigen particles in small but definite clumps
Reactive (4+, 3+, or 2+)--------Antigen particles in medium-sized or large clumps

---

*This mold can be procured from LaMotte Chemical Products Co., Towson 4, Md.

Kline Standard Quantitative Test With Spinal Fluid

Prepare spinal fluid dilutions of 1:2, 1:4, 1:8, 1:16, etc., using nonreactive spinal fluid or 0.9% saline as the diluent.

Test undiluted spinal fluid and each spinal fluid dilution in the usual manner as for the qualitative test.

Report results in terms of the highest dilution which produces a reactive (4+, 3+, or 2+) result in the manner described for the quantitative test with serum.

THE MAZZINI MICROSCOPIC FLOCCULATION TEST FOR SYPHILIS[1]

Equipment.—

Rotating machine, adjustable to 100 to 180 r.p.m., circumscribing a circle ¾ inch in diameter on a horizontal plane.

Slide holder to accommodate 1 to 4 slides, 2 × 3 inches.

13 and 21 gauge hypodermic needles with bevels removed.

Kline slides, 2 × 3 inches, with 10 concavities, 16 mm. in diameter by 3 mm. in depth.*

Kline slides with 3 concavities, one, 38 mm. in diameter, and two, 20 mm., for spinal fluid tests.*

Round bottles, glass-stoppered or screw-capped, 30 c.c. capacity.

Luer syringe, 1 or 2 c.c. capacity, or an observation tube No. 420 LST.*

Reagents.—

Antigen.—

Antigen for this test is an alcoholic solution containing 0.025% cardiolipin, approximately 0.2% lecithin, and 0.75% to 0.9% cholesterol, previously serologically standardized against an antigen of known reactivity.

Buffered Saline Solution.—

This solution must have a pH of 6.3 to 6.4 and a salt concentration of 10 gm. per liter.

Sodium chloride, c.p.	8.1 gm.
Primary potassium phosphate (KH_2PO_4)	0.2 gm.
Secondary sodium phosphate ($Na_2HPO_4 \cdot 12H_2O$)	1.7 gm.
Doubly distilled water	1,000.0 c.c.
N/1 hydrochloric acid	3.2 c.c.
Formaldehyde, Merck reagent grade	1.0 c.c.

Dissolve and filter. Check the hydrogen ion concentration. The colorimetric method is sufficiently accurate. Keep in a glass-stoppered Pyrex bottle. This will remain unchanged indefinitely. If the solution should become contaminated with particles of dirt, cotton fibers, or other debris, filter the solution so that particles may not be transferred to the suspension and be misinterpreted as a positive reaction.

Serum.—

Prepare sera as for the Wassermann, Kahn, Kolmer tests, etc. (page 2031). Inactivate at 55 to 56° C. for 30 minutes.

Visible precipitates after heating must be removed by centrifugalization and decantation, so as not to interfere with serologic reactions.

Specimens containing an excessive amount of fat must be reported as unsatisfactory.

Retest weakly reacting sera which have been heated and thereafter kept at room temperature or in a refrigerator for several hours by withdrawing a new portion of the sera from the clots.

Hemolyzed sera may be tested unless they are excessively viscous after heating.

---

*Procurable from Serological Reagents Co., Indianapolis, Ind.

[1] Mazzini, L. Y.: Ven. Dis. Inform. 23: 123, 1942; 1955 Manual, Serologic Tests for Syphilis, U. S. Department of Health, Education, and Welfare.

Preparation of Antigen Emulsion

Pipette 0.4 c.c. buffered saline to the bottom of a 30 c.c. bottle.

Measure 0.4 c.c. of cholesterolized antigen, reading from the bottom of the pipette, with a 1 c.c. pipette graduated to the tip.

Hold the bottle in the left hand and impart a rapid rotating motion to it as the antigen is being blown directly and at once into the saline from the pipette held in the right hand.

Mix by drawing the suspension into the pipette and blowing out exactly 6 times, returning all of the emulsion left in the pipette into the last mixture.

Add 2.6 c.c. of buffered saline, cap the bottle, and shake from the bottom to the top and back *50 times in 15 seconds.*

Preliminary Testing of Antigen Emulsion

Check the delivery of the syringe or observation tube, fitted with a 21 gauge needle. When this is held in a vertical position, 0.01 c.c. of antigen suspension per drop should be delivered.

Test control sera of graded reactivity and buffered saline in the usual manner for the qualitative test. The results should reproduce the reactivity pattern previously established for these sera, and should show complete dispersion of the antigen particles in both nonreactive serum and buffered saline.

Mazzini Qualitative Test With Serum

Pipette 0.03 c.c. of each serum into a separate concavity.

Add 1 drop of antigen emulsion (0.01 c.c.) to each.

Rotate slides on the rotating machine for 4 minutes. The speed should be 160 to 180 rotations per minute. If rotating by hand, circumscribe a 2 inch circle 120 times per minute.

Read each reaction microscopically using a low power objective (16 mm.) and a 6× ocular. Record and report all sera that are nonreactive (no clumping) and all that are reactive (4+).

Add 1 drop, about 0.05 c.c., of 0.9% saline from a syringe with a 13 gauge needle with cut-off bevel, to each test which gives a 1+, 2+, 3+, or atypical reaction.

Rotate for a second 4-minute period on a rotating machine at 100 to 120 r.p.m. or by hand.

Examine microscopically. Report as follows:

DESCRIPTION	READING	REPORT
No clumping or coarse reactions	–	Nonreactive
Very small clumps	1+	Weakly reactive
Small clumps	2+	Weakly reactive
Medium-sized clumps	3+	Reactive
Large clumps	4+	Reactive

Atypical Reactions:

Atypical reactions are characterized by irregular particle aggregates of various sizes in which the small clumps and free antigen particles predominate. Atypically reacting sera must be retested as for the quantitative test.

Mazzini Quantitative Test With Serum

Procedure for quantitative test with serum is the same as for the qualitative test except that each serum is tested in serial dilutions.

Place 6 test tubes in a rack. Place 0.5 c.c. buffered saline solution in each tube. Place 0.5 c.c. heated serum in tube 1. Mix contents thoroughly, and transfer 0.5 c.c. to tube 2, mix and transfer 0.5 c.c. to tube 3, and continue the process throughout the 6 tubes. Carry out tests on each dilution of serum, using 0.05 c.c. of each serum dilution and 1 drop of antigen suspension (used for the qualitative Mazzini test with serum) in each wax ring. Rotate for 4 minutes at 180 r.p.m.

Report results in terms of the highest dilution of serum giving a reactive result (4+ or 3+).

Example:

SERUM DILUTIONS						REPORT
1:2	1:4	1:8	1:16	1:32	1:64	
4	4	4	2	–	–	Reactive, 1:8 dilution or 8 dils.
4	3	1	–	–	–	Reactive, 1:4 dilution or 4 dils.
4	4	4	4	1	–	Reactive, 1:16 dilution or 16 dils.

Mazzini Qualitative Test With Spinal Fluid

Test spinal fluid as soon as possible after withdrawal. Do not use grossly contaminated fluids. The spinal fluid should not contain blood. Do not heat the spinal fluid.

Centrifuge the fresh spinal fluid at 2,000 r.p.m. for 5 minutes. Pour off the clear supernatant fluid into a clean tube.

Pipette 0.05 c.c. and 0.2 c.c. of spinal fluid, respectively, into each of the two 20 mm. chambers, and 0.5 c.c. of spinal fluid into the 38 mm. chamber of the special glass slide.

Include known reactive and nonreactive spinal fluids as controls.

Add 1 drop (0.01 c.c.) of antigen emulsion to each chamber.

Rotate slides on a mechanical rotator for 10 minutes at 100 to 120 r.p.m.

Add 2 drops of 0.9% saline, immediately, from a syringe using a 13 gauge needle with cut-off bevel, to the chamber containing 0.05 c.c. of spinal fluid.

Rotate for another 20 minutes at 80 to 100 r.p.m.

Record results as for the serum tests. Report the results of the strongest reactions regardless of which of the three quantities it might be.

Example:

SPINAL FLUID QUANTITY			REPORT
0.05 c.c.	0.2 c.c.	0.5 c.c.	
1+	2+	4+	Reactive
–	1+	3+	Reactive
4+	2+	2+	Reactive
2+	4+	3+	Reactive
–	1+	2+	Weakly reactive
–	–	1+	Weakly reactive

Mazzini Quantitative Test With Spinal Fluid

Prepare serial dilutions of spinal fluid, which has been shown to be strongly reactive, in buffered saline: 1:2, 1:4, 1:8, 1:16, etc.

Pipette 0.5 c.c. of each dilution into respective 38 mm. chambers.

Add 1 drop (0.01 c.c.) of antigen emulsion to each chamber containing spinal fluid.

Rotate the slides on a mechanical rotator for 10 minutes at 100 to 120 r.p.m.

Rerotate for 20 minutes longer, at 80 to 100 r.p.m.

Record results of each dilution.

Report in terms of the highest dilution giving a reactive result in the manner described for quantitative test with serum.

THE TREPONEMAL IMMOBILIZATION TEST IN THE DIAGNOSIS OF SYPHILIS*

Nelson and Mayer[1] succeeded in maintaining *Treponema pallidum* alive, motile, and virulent until 5 to 10 days on artificial medium largely free of tissue components. When suspensions of motile treponemes in this medium were added to normal sera along with complement, the treponemes remained alive and virulent up to 15 to 18 hours. In mixtures of syphilitic human and rabbit serum with complement, however, they became immobilized and were killed. This test is now known as the "*Treponema pallidum* immobilization (TPI) test." This immobilizing antibody has been found separate and distinct from the Wassermann antibody or reagin.

---

*Antigen for this test is now available from Sylvana Chemical Company, 407 S. Jefferson St., Orange, N. J.

[1] J. Exper. Med. 89: 309, 1949.

Later information on this test is given by Miller and Slatkin.[1] This immobilizing antibody develops only in response to the treponematoses: syphilis, yaws, pinta, and bejel. This test is highly specific for the treponematoses. Certain limitations of the test are present: If treatment is given in the primary stage or early in the secondary stage of syphilis, the test may become negative with the passage of time. It is thought that the test remains positive for life if the patient is not treated until the latent phase of syphilis.

Miller's studies were directed toward five phases of the subject: (1) the place the treponemal immobilizing test should occupy as a guide to treatment; (2) the significance of the reactive or weakly reactive serologic test for syphilis; (3) the significance of the results of the treponemal immobilizing test on spinal fluid; (4) the significance of the reactive serologic test in a group of patients admitted to the hospital for other diseases; (5) the evidence for passive transfer of the immobilizing antibody from mother to baby and the length of persistence of the antibody in the baby.

Their conclusions were that (1) the treponemal immobilization test is a practical means of differentiating biologically false positive reactions from the true positive reactions indicative of syphilis; (2) the concept of significance of weakly reactive and reactive serologic tests in the absence of signs or history of signs of syphilis must be revised in the light of evidence gained from the results of the treponemal immobilizing test; (3) the treponemal immobilizing test and the spinal fluid are of value in the diagnosis of neurosyphilis in patients in whom the spinal fluid serologic test has become negative as a result of the passage of time or treatment; (4) in acute disseminated lupus erythematosus positive serologic test represents biologically false positive reactions in a high percentage of cases; (5) little evidence for the recurrence of biologically false positive reactions was found in sarcoidosis; (6) passive transfer of the immobilizing antibody across the placenta occurs in nonsyphilitic babies born of syphilitic mothers; (7) in passive transfer the immobilizing antibody persists up to six months, whereas reagin disappears before three months.

According to Public Health Service Publication No. 327, in a booklet entitled *Management of Venereal Disease,* in cases with doubtful diagnoses (of syphilis), "it is anticipated that there will be seen an increasingly large number of patients who have a positive or doubtful standard test for syphilis as the sole referring complaint. In this group, a *Treponema pallidum* immobilization test may be found helpful when considered in the light of a complete study of the patient."

Method*

The treponemal immobilization test in the diagnosis of syphilis, introduced by Nelson and Mayer in 1949,[2] is the first successful in vitro measurement of specific treponemal antibody in syphilis. This antibody has been shown to be distinct from syphilitic reagin. It is now believed that the mechanism of the reaction is based on the specific combination of antigen and antibody. Combination will take place in the absence of complement, but immobilization will not ensue until complement has been added. Loss of motility of the organism in the presence of syphilitic serum and complement is believed to indicate death of the organism.

---

*Compiled chiefly from Chorpenning, Frank W., U. S. Armed Forces M. J. 4: 807, 1953.

[1] J. A. M. A. 154: 1241, 1954.

[2] J. Exper. Med. 89: 309, 1949.

The amount of complement fixed appears to be small. The reaction depends on the temperature and the concentrations of antigen, antibody, and complement.

The test is of particular value when dealing with a serum from a clinically negative patient, whose serum gives a positive serologic test with standard tests for syphilis. This might be due to biologically false positive reactions, or it may be from a latent syphilitic patient.

Medium.—

1. **Bovine Plasma, Fraction V:**

Dissolve 20 gm. of the Armour Co. powder
in 350 c.c. of 0.85% sodium chloride solution.

Add sufficient M/1 sodium hydroxide (about 4.5 c.c.) to adjust the reaction to pH 7.0.

Dilute to 400 c.c. with 0.85% sodium chloride solution.

Sterilize by Seitz filtration and store at 5° C. Renew every second week.

2. **Phosphate Buffer, pH 7.1:**

(a) Dissolve 7.1 gm. of disodium phosphate
in 500 c.c. of distilled water.

(b) Dissolve 10.21 gm. of monopotassium phosphate
in 500 c.c. of distilled water.

(c) Mix 120 c.c. of (a) with 30 c.c. of (b) and sterilize by Seitz filtration. Store at 5° C. Renew biweekly.

3. **Sodium Bicarbonate, 1.25% Solution:**

Dissolve 1.25 gm. of sodium bicarbonate in distilled water and dilute to 100 c.c. with distilled water.

Sterilize by filtration through a glass-sintered filter and store at 5° C. Renew biweekly.

4. **Sodium Chloride, 0.85% Solution:**

Dissolve 8.5 gm. sodium chloride in 1,000 c.c. distilled water. Sterilize and store as directed in No. 3.

5. **Sodium Thioglycollate, 1.5% Solution:**

Dissolve 1.5 gm. of thioglycollate (order freshly made powder from Baltimore Biological Laboratory) in enough distilled water to make 100 c.c. solution.

Sterilize by filtration through a glass-sintered filter.

Plug, close tube with paraffin, and store at –20° C. Renew biweekly.

6. **Cysteine Hydrochloride, 0.63% Solution:**

Dissolve 0.63 gm. of cysteine hydrochloride, Matheron†
in 100 c.c. of 0.85% sodium chloride solution.

Sterilize and store as in No. 5.

7. **Glutathione, 1.23% Solution:**

Dissolve 1.23 gm. of glutathione, Matheron†
in 100 c.c. of 0.85% sodium chloride solution.

Sterilize and store as in No. 5.

8. **Sodium Pyruvate, 1% Solution:**

Dissolve 1 gm. of sodium pyruvate, Nutritional Biochemicals,‡
in 100 c.c. of 0.85% sodium chloride solution.

Sterilize and store as in No. 5.

---

†East Rutherford, N. J.

‡Cleveland 28, Ohio.

9. **Ultrafiltrate of Bovine Serum:**

Procure a batch of ultrafiltrate of bovine serum without indicator from the Microbiological Associates, P.O. Box 5970, Washington 14, D. C.

10. **Composition of the Medium:**

Mix under sterile precautions.

Bovine plasma solution	50 c.c.
0.85% sodium chloride solution	11.6 c.c.
Phosphate buffer	15.65 c.c.
Sodium bicarbonate solution	5.65 c.c.
Glutathione solution	3.15 c.c.
Cysteine solution	3.15 c.c.
Thioglycollate solution	3.0 c.c.
Pyruvate solution	1.55 c.c.
Bovine serum filtrate	6.25 c.c.

Keep in a deep freezing unit.

Treponemal Suspension.*—

Treponema pallidum (Nichols strain) is used.

Inoculate intratesticularly male rabbits of about 2.5 kilograms weight.

Maintain in a new group of rabbits by passage immediately after onset of a definite orchitis. After preliminary passages, the average incubation period can be made to approximate 8 days.

After the early orchitis (1 or 2 days after onset) has been diagnosed by palpation, sacrifice the rabbit by injecting air into the marginal ear vein, aseptically remove the testicular syphiloma from the scrotal sac, and slice the testicle by making eight transverse and one longitudinal sections.

Wash once in about 20 c.c. of chilled, sterile 0.85% saline solution.

Place the slices in a flask containing 30 c.c. of medium for each testicle under an atmosphere of 95% nitrogen and 5% carbon dioxide.

Gently agitate, mechanically, at 40 to 45 oscillations per minute, for 1 or 2 hours at a temperature of 35° C.

Obtain counts of the number of treponemas per c.c. in the suspension by dark-field examination after 1 hour, and again after 2 hours, if the first count is unsatisfactory.

Between 3 and 5 organisms per high dry field (or 5,000,000 per c.c.) is optimal. If more are obtained, dilute with medium.

Pour off the treponemal suspension.

Centrifuge for 10 minutes at 1,000 G to remove the gross debris.

Use the supernatant fluid for the test.

Chorpenning and associates[2] recommend the use of frozen syphilomatous testicles. This method would allow the setting up of a center from which branch or subordinate laboratories could be supplied.

The test proper must be set up under sterile precautions. Some authors recommend loose plugging of all tubes. Sera and complement must be cold before use. All examinations of the end results must be carried out within one hour after the tubes have been taken out of the nitrogen-carbon dioxide jars, to prevent death of the organisms under aerobic conditions.

Technic of the Test.—

Carry out the test in Kahn tubes.

Place 0.05 c.c. of inactivated (56° C., 30 min.) serum of the patient in a Kahn tube.

Add 0.05 c.c. of undiluted guinea pig serum (complement).

Add 0.4 c.c. of treponemal suspension.

---

*Antigen for the TPI test is now available as TPCF and TPIA antigen from Sylvana Chemical Company,, 407 S. Jefferson St., Orange, N. J.

[2] Am. J. Syph. 36: 401, 1952.

The complement is best prepared by bleeding 10 to 12 guinea pigs and pooling their sera. It will keep for use in this test for about 1 month, if kept frozen in a freezer unit.

Controls.—

(1) Place in a Kahn tube
0.05 c.c. of serum to be tested
0.05 c.c. of inactivated guinea pig serum (heated in a water bath at 56° C. for 30 minutes)
0.4 c.c. of treponemal suspension

(2) 0.1 c.c. saline
0.4 c.c. treponemal suspension

(3) 0.05 c.c. of ultrafiltrate of bovine serum or nonsyphilitic human serum
0.05 c.c. of pooled guinea pig serum
0.4 c.c. of treponemal suspension

(4) 0.05 c.c. of ultrafiltrate of bovine serum or nonsyphilitic human serum
0.05 c.c. of inactivated pooled guinea pig serum (heated in a water bath at 56° C. for 30 minutes)
0.4 c.c. of treponemal suspension

Incubate the test and all controls in a 95% N and 5% CO_2 atmosphere at 35° C. for 18 hours.

Remove a portion of the test suspension by means of a platinum loop and prepare a wet mount for dark-field examination.

Determine the number of motile organisms in the control tube (1) and figure the per cent of motile organisms present.

Determine the per cent of motile organisms in the test.

Subtract the per cent of motile organisms in the test from the per cent of motile organisms in the control.

Multiply this by 100 and divide by the per cent of motile organisms in the control tube. This gives the per cent of treponemas specifically immobilized.

50% and more immobilization is considered a positive test.

20 to 49% is considered a doubtful reaction.

Below 20% is considered negative.

A check for the utilization of the complement is carried out by adding 0.1 c.c. of sensitized 5% sheep cells to each test tube after the reactions have been read and the results recorded. The sensitized sheep blood cells are prepared as in the Kolmer qualitative test, using 2 units of hemolysin.

Incubate the tubes at 37° C. for 30 minutes. The presence of at least 2 plus hemolysis signifies an adequate surplus of complement which prevents false negative reactions.

If quantitative results are desired, the per cent of organisms specifically immobilized with the various serum dilutions (at least 3) can be recorded on semilogarithmic graph paper, plotting the reciprocal of the dilution logarithmically and the per cent of organisms specifically immobilized linearly. The reciprocal of the dilution at which specific immobilization of 50% of the treponemas occurs (IT_{50}) is read as the titer after method of Nelson and Diesendruck.[3]

Precautions.—

All sera to be tested should be sterile and free from preservatives, including penicillin. Penicillinase may be used to neutralize the presence of penicillin.

If the orchitides have progressed too far in the animal hosts, the treponemas are partially or completely immobilized by complement alone. This can be prevented if diagnosis of an early orchitis is made, by carefully examining the inoculated animals daily, to prevent the possibility of sensitization of the organisms to antibodies produced by the animals.

Interpretation.—

Patients with late syphilis consistently give positive results.

A few negative and doubtful tests occur in the early stages of syphilis. A period of antibody formation is necessary before serologic tests become positive. The titer follows a rising curve during this period.

---

[3] J. Immunol. **66**: 667, 1951.

This test is at least 99% specific. It gives few, if any, positive results with non-syphilitic sera.

The test is positive in only about 57% of primary syphilitic cases.

In secondary syphilis, greater than 90% of the patients give positive reactions.

The greatest value of the TPI test lies in the latent, late symptomatic stages of syphilis, or with patients whose sera give biologic false positive reactions with the standard tests for syphilis.

The titer of the TPI test is not necessarily a direct measure of the patient's immunity.

There is a significant cross-reactivity between *Treponema pallidum, T. pertenue,* and *T. cuniculi,* although the degree of reactivity using *T. pallidum* and *T. pertenue* antisera against *T. cuniculi* and vice versa was consistently lower than with homologous antiserum or in cross-reactions between *T. pallidum* and *T. pertenue.*

The TPI test must be performed carefully. Difficulties lie in the need for fresh syphilomatous rabbit testes as a source of motile treponemas, which may be surmounted by preservation of the testicular syphiloma by freezing; the need for air-conditioned rabbit rooms; constant danger of obtaining partially sensitized treponemas from testicular lesions; the degree of reproducibility of quantitative results. Development of antibody in the rabbit may be inhibited or delayed by pre-treating the animals with nitrogen mustard or by x-radiation just prior to infection.

At the time of writing this text, the author was privileged to witness the entire performance of this test under the direction of Dr. John F. Kent, Chief of Serology, Army Medical Service Graduate School, Walter Reed Army Medical Center, Washington, D. C., to whom he wishes to express his heartfelt thanks for the courtesies extended to him by Dr. Kent and his assistants, Miss Barbara Rosenau and Mr. Robert W. Sanders.

In a form used by the Army, it is directed that 10 c.c. of sterile serum or cerebrospinal fluid be forwarded to the laboratory performing the test. In this same pamphlet the following criteria for submission of treponemal immobilization tests are set forth:

The TPI test *is not* indicated, and *should not* be requested under the following conditions:

1. Where the diagnosis of syphilis has been definitely established on the basis of unequivocal clinical and anamnestic evidence. This requirement would be fulfilled under the following conditions:

   a. Where *Treponema pallidum* has been identified by dark-field examination of primary or secondary lesions.

   b. Where a diagnosis of secondary syphilis made on clinical evidence (rash, etc.) has been corroborated by repeated positive reactions in the standard cardiolipin microflocculation (CM) and cardiolipin complement fixation (CCF) tests of the Army and Air Force.

   c. Where a patient, repeatedly seropositive in one or both of the standard cardiolipin tests (CM and/or CCF), has been shown to have evidence of visceral syphilis, especially involvement of the cardiovascular or central nervous systems. Cases of inactive syphilis of the central nervous system (Dattner-Thomas type, i.e., CCF and colloidal gold-positive, cell count and total protein within normal limits) will fall in this category.

2. Where a patient is an infant born of a mother with positive serology, in which case the positive serum reaction may be due to passively transmitted antibody.

The TPI test is indicated, and a request should be initiated under the following conditions:

1. Where the patient has been *repeatedly* seropositive in one or both of standard STS* and there is neither clinical nor anamnestic evidence of a syphilitic infection. There should be no evidence of visceral involvement, i.e., cardiovascular disease or CNS syphilis. Seropositivity should have persisted for three months *without significant reduction in titer* as determined by repeated (three) cardiolipin microflocculation tests (STS). (During this period no antisyphilitic chemotherapy should have been administered. The TPI test should be requested after the last standard serologic test for syphilis.†)

2. In the occasional instances where the patient has been repeatedly seronegative in both of the standard cardiolipin tests (STS confirmed over a three-month period), but shows evidence of visceral syphilis, e.g., cardiovascular involvement.

The result of the initial TPI test should be confirmed one week later by submitting a second specimen (10 c.c.) of sterile serum.

Frozen Syphilomatous Rabbit Testes as a Source of Treponema Pallidum for the Immobilization Test for Syphilis

Anderson, Kent, and Sanders[1] detail a schedule for utilizing frozen rabbit testes containing *T. pallidum.* This study gives results obtained with an additional 185 testes, many frozen for periods considerably exceeding those obtained at the time of the publication of the preliminary report.[2] In other words, this report shows that frozen material may be used for carrying out this test instead of having to depend on freshly procured material.

Rabbits were young males of mixed breeds, ranging in weight from 3.5 to 4.5 kilograms. They were caged in a room maintained at 18° to 20° C. by air-conditioning. Each animal was inoculated with 5-7 × 10^7 treponemes of the Nichols strain. Inoculum was contained in 1.0 c.c. of a 1:10 dilution of normal rabbit serum in 0.85% sodium chloride solution and was administered intratesticularly, 0.25 c.c. aliquots being introduced at two sites on each testis. Acute orchitis developed, on the average, eleven days thereafter, whereupon the animal was sacrificed by air embolism, and the syphilomatous testes were enucleated aseptically.

The technique of preservation was essentially that given in the preliminary report.[2] The testis was incised with a special instrument similar to that described by Chorpenning and associates, then washed with 2 to 3 c.c. of sterile 0.85% sodium chloride solution, and transferred aseptically to a sterile 25 by 150 mm. Pyrex test tube. The tube was plugged with gauze-wrapped cotton, and the cotton plug surmounted with a sterile rubber stopper. Finally, the testis was frozen quickly in a slush of methyl cellosolve and solid carbon dioxide (–78° C.), and the tube placed immediately in a cabinet refrigerated with solid carbon dioxide; storage temperature varied within the range –55° to –45° C.

When selected for tests, a syphilomatous testis was thawed by partially immersing the tube for 5 to 10 minutes in a water bath at 35° C.; the rubber stopper was removed as a safety measure during this operation. The thawed testis was transferred aseptically to a flask containing the prescribed survival medium, the treponemes were eluted, and the resulting suspension evaluated according to standard procedure for the immobilization test.

---

*Serologic tests for syphilis.

†Attention in this connection is invited to TB Med. **230**: 8, 1952.

[1] Am. J. Syph. **38**: 527, 1954.

[2] Chorpenning, F. W., Sanders, R. W., and Kent, J. F.: Am. J. Syph., Gonorr. & Ven. Dis. **36**: 401, 1952.

Requests for the Nichols strain treponeme are filled by air-mailing frozen syphilomatous rabbit testis in a special container* refrigerated with solid carbon dioxide. Shipments have been made by these workers in this manner to facilities in Germany, Cuba, California, Michigan, and New York, where inocula from the frozen material were used successfully to initiate the treponemal infection in rabbits.

In this manner, actively motile *T. pallidum,* suitable for use in the treponemal immobilization test for syphilis, may be obtained from syphilomatous rabbit testes stored in the frozen state for periods varying from one day to one and one-half years.

At the date of this text writing, the author believes that this TPI test of Nelson and Mayer is a useful complement fixation test, using the immobilization of the *T. pallidum* as the indicator. He wishes to express his opinion that it is quite a difficult test to perform and expensive to operate. He believes that with a proper set-up with experienced workers the test is a valuable one, especially in pointing out biologic false positive reactions. It is not yet applicable to the ordinary hospital clinical pathological laboratory.

THE WASSERMANN AND HECHT-GRADWOHL COMPLEMENT FIXATION TESTS FOR GONORRHEA AND TUBERCULOSIS

We advise the purchase of the gonococcus and tubercle bacillus antigens for these tests from a reliable biological house. The titer and dilution of the antigen for use in complement fixation tests will be marked on the container.

Dilute the antigen according to the dilution given on the label.

The reagents used in these tests are the same as are used in the tests for syphilis with the exception of the antigen.

The technic for each test is the same as the test for syphilis. The only difference is the substitution for syphilis antigen of gonococcus antigen in the test for gonorrhea, and tubercle bacillus antigen in the test for tuberculosis.

The antigen for the Hecht-Gradwohl test is half the strength of the Wassermann antigen.

The results are reported as either positive or negative, dependent on whether there is inhibition of hemolysis or complete hemolysis of the sheep cells.

THE WELTMANN SEROCOAGULATION REACTION FOR TUBERCULOSIS[1, 2]

Studies in the field of tuberculosis have been made along the lines of both specific and nonspecific reactions. The complement fixation test in tuberculosis is an example of the specific reaction; the sedimentation test and the Weltmann serum coagulation reaction are examples of the nonspecific reactions.

The Weltmann test was introduced in 1930,[3] at which time it was claimed that this test would indicate either an exudative or a fibrotic process.

---

*Virus Shipping Container, Model VSC-2C, Hollinger Corporation, Arlington, Va.

[1] J. Lab. & Clin. Med. 23: 994, 1938.

[2] Sedlacek, B., Miller, Ed. G., and Medical Staff, Navajo Medical Center, Fort Defiance, Ariz.: Lab. Digest 6: 3, Aug., 1942.

[3] Weltmann, O.: Med. Klin. 26: 240, 1930.

Levinson and Klein,[4] in 1938, reported on the Weltmann serum coagulation test. In general, acute inflammatory and exudative conditions give a shortened coagulation band or a "shift to the left." In chronic diseases, characterized by fibrotic changes, in the healing stage of acute infection, and in parenchymal liver damage, the coagulation band tends to be lengthened, or results in the "shift to the right." The coagulation band does not always parallel the sedimentation rate.[5] In tuberculosis the Weltmann coagulation test is of importance because it can be used as a guide in the course of and in the prognosis of the disease. It reflects tissue changes that occur in the body. Exudative changes in tuberculosis are manifested by a shortening of the coagulation band, while fibrotic changes are accompanied by a prolonged coagulation band. When exudative and fibrotic changes occur in the lung at the same time, as happens frequently in tuberculosis, the Weltmann reaction may not be of great assistance. The two divergent processes occurring at the same time result in the coagulation band's striking the normal zone. In miliary tuberculosis, peritoneal tuberculosis, and in meningeal tuberculosis, the Weltmann reaction gives a shortening of the coagulation band in the exudative zone. Isolated bone tuberculosis is accompanied by The Weltmann test has been applied not only to tuberculosis in the minimal, moderately advanced, and far advanced stages, but also to the complications that occur in pulmonary disease. It has also been employed and compared with the sedimentation rate in several examples of various types of tuberculosis over a prolonged period of time. The results are given in the text. Although unable at the present to explain the mechanism of the Weltmann serum coagulation reaction, it is believed that this test is of importance in the diagnosis and prognosis of disease, particularly in tuberculosis.

In normal pregnancy, the sedimentation rate is accelerated, while the Weltmann test gives a normal band.

The sedimentation rate varies according to the temperature of the room, and in normal individuals it may fluctuate within a 24-hour period, while the Weltmann test is unaffected by atmospheric conditions.

In patients receiving artificially induced fever, the coagulation band is normal, but it shows a shift to the left in febrile conditions. This indicates inflammatory changes such as exudation occurring in pulmonary tuberculosis, pleural effusion, or suppurative processes. If a normal band or a shift to the right is obtained in these cases, exudative processes must be ruled out. In the absence of inflammatory or exudative processes, the Weltmann test shows no deviation,[6] and therefore it is a means of determining quantitatively the degree of pathologic changes.

In artificial pneumothorax or bilateral pneumothorax, the coagulation band shows a shift to the right, paralleling clinical improvement of the patient.

Hartwell[7] used the Weltmann reaction in the management of patients with myocardial infarction. Long after the temperature, white count, and sedimentation rate had returned to normal, the Weltmann reaction gave incontrovertible proof that the area of infarcted muscle was not yet healed and that the patient should remain quiet for a while longer.

---

[4] Am. Rev. Tuberc. 37: 200, 1938.

[5] Loc. cit.

[6] Sedlacek, B., and Miller, E. G.: Lab. Digest 6: 3, 1942.

[7] Hartwell, Alfred S.: Hawaii M. J. 4: 136, 1945.

The reaction is not affected by plasma proteins, hydrogen ion concentration, electrolytes, and bilirubin. Blood calcium level does affect the band slightly.

Technic:

From a stock solution of 10 per cent calcium chloride ($CaCl_2.6H_2O$), ten dilutions consisting of 0.1 per cent, 0.09 per cent, 0.08 per cent, 0.07 per cent, 0.06 per cent, 0.05 per cent, 0.04 per cent, 0.03 per cent, 0.02 per cent, and 0.01 per cent are made. These dilutions are numbered from one to ten, beginning with the strongest concentration. Ten small test tubes, such as are used in the Wassermann reaction, are placed in a metal rack and numbered in order from 1 to 10. Into each tube is pipetted 5 c.c. of the similarly numbered calcium chloride solution and 0.1 c.c. of unhemolyzed serum. The tubes are then shaken so that the contents are well mixed and placed in a boiling water-bath for fifteen minutes. They are then removed and the reaction can be immediately determined. The contents of the tubes may be clear, faintly opalescent, turbid, or there may be a flocculation. There is usually a sharp and easily noted difference between flocculation and turbidity.

The number of tubes in which coagulation occurs is designated by Weltmann as the coagulation band (C.B. of that particular serum). If there is a very slight or doubtful flocculation in one tube the reaction is interpreted as being intermediate between that tube and the one before it. In normal serum the first 6 tubes usually show flocculation. Sometimes there is a slight or doubtful flocculation in the seventh tube. The normal coagulation band is, therefore, 6 to 6½, and is remarkably constant. This means that normal human serum diluted 50 times with calcium chloride solution and heated in a boiling water bath for fifteen minutes will not coagulate nor flocculate if the concentration of the calcium chloride is less than 0.04 per cent. If the coagulation band is less than 6, Weltmann speaks of the reaction as showing a shift to the left, whereas, if the coagulation band is 7, or greater, the reaction indicates a shift to the right.

A **numerical system** of reporting by figures instead of by a graph has been worked out by McCune.[2]

Key for Interpretation of Weltmann Reaction (McCune)

Complete flocculation—100%; partial flocculation—75%; turbid but no flocculation—50%; opalescent—25%; clear—0. The coagulation number is the sum of the individual tubes expressed in terms of percentage.

Below 650 to 0..........Exudative
700 to 650..............Slightly exudative
From 700 to 775.........Normal
From 775 to 825.........Slightly fibrotic
Above 825...............Fibrotic

For example, the first two tubes show complete flocculation.	2 × 100 = 200
The third and fourth tubes show partial flocculation.	2 × 75 = 150
The fifth and sixth tubes show turbidity.	2 × 50 = 100
The seventh and eighth tubes are opalescent.	2 × 25 = 50
The ninth and tenth tubes remain clear.	2 × 0 = 0
Coagulation number	500,

which indicates an *exudative* process.

---

[2] Loc. cit.

An example of a *fibrotic* process is:

The first seven tubes show complete flocculation.	7 × 100 = 700
The eighth tube is only partially flocculated.	1 × 75 = 75
The ninth tube is turbid.	1 × 50 = 50
The tenth tube is opalescent.	1 × 25 = 25
Coagulation number	850

Exudative Conditions or Shift to the Left With a Total Coagulation Number Below 700.—Lobar pneumonia shows extreme shift to the left, almost to zero, during the stage of consolidation, or a total of about 450. In acute rheumatic fever and peritoneal tuberculosis, the total is not over 550. Nephrotic syndrome, exudative pulmonary tuberculosis, meningitis, miliary tuberculosis, peritoneal tuberculosis, appendiceal abscess, and exudative lobar pneumonia may give a total as low as zero. Pulmonary tuberculosis gives a total of about 500 or lower after the patient has received artificial pneumothorax or bilateral pneumothorax for some time where x-ray of the lung shows improvement; this may be accompanied by complication in the pleural cavity. Pyelitis gives a total of about 525.

Fibrotic Conditions or a Shift to the Right With a Total Coagulation Number Over 775.—Cirrhosis of the liver, fibrotic tuberculosis, septic states, endocarditis lenta, peritoneal carcinoma will give an extreme right shift. Pulmonary tuberculosis, when the shift is to the right or over 775, is paralleled by clinical improvement of the patient. Tuberculosis of the bone, chronic diseases characterized by fibrotic changes, acute infections, parenchymal liver damage in the healing stage, and trachoma will give a right shift.

Complement Fixation Test for Amebiasis is discussed on pages 1831 and 1835.

Complement Fixation Tests for Viruses and Rickettsial Diseases are discussed on page 1742.

The **Cold Hemagglutination Test in the Diagnosis of Primary Atypical Pneumonia** is discussed on page 1757.

The **Hemagglutinin Inhibition Test** is described on page 1754.

CHAPTER XIV

TISSUE CUTTING AND STAINING

Preparation of Tissues

There are two methods commonly used in the preparation of tissues: (1) the frozen section; and (2) the embedding method either in paraffin or celloidin.

Tissue Fixation

The term "tissue fixation" means the preservation of the normal structure of a tissue as closely as possible to its condition during life. It is necessary, therefore, to place tissues intended for microscopic examination in a fixative solution as soon as possible after they are removed from the body and cut off from the normal circulation. The ideal fixative would be one that preserves tissue exactly as it appeared during life but this is next to impossible to accomplish. The most commonly used fixative is a solution of formaldehyde. Formaldehyde is a gas, soluble in water to the extent of 40 per cent by weight. It has the advantages of penetration and fixation with great speed, thus enabling one to cut and stain frozen sections as well as paraffin sections. Its best strength is a 10 per cent solution, which is prepared by taking one volume of commercial or 40 per cent formeldahyde to nine volumes of tap water or saline. In order to prevent formaldehyde from developing formic acid, which is injurious to the tissue, the stock solution of formaldehyde should be neutralized by addition of 5 gm. of calcium carbonate to a gallon of fluid. When specimens are to be kept for a long time in this solution, place a few marble chips in the container.

Other fixatives are used, depending upon the type of pathologic lesion which is to be studied. Zenker's solution is one of the most reliable types of fixative since it preserves nuclear structure, bacteria, and fibrils of all kinds. Formula for this solution is found on page 2115. Make a stock solution of Zenker's fluid but do not add the acetic acid until immediately before using. Tissues are fixed from 12 to 16 hours in this solution, then washed overnight under tap water to remove all excess potassium bichromate, and transferred to 70 per cent alcohol.

Stowell[1] has made a distinct contribution to the effect on tissue volume of fixation, dehydration, and embedding. He found that all fixatives showed specific differences. Susa and Bouin fixatives gave the best general results, and neutral Formalin mixtures, especially pyridine-Formalin, the poorest. Isotonic saline was found superior to distilled water as a Formalin diluent, reducing tissue swelling during Formalin fixation. Reagents producing marked decreases in tissue volume render such tissues less susceptible to shrinkage during subsequent procedures. Shrinkage of tissue during dehydration and infiltration with hot paraffin may exceed that produced by fixation alone. Excessive heat causes tissue distortion and shrinkage. Infiltration with hot paraffin causes considerable shrinkage, with hot nitrocellulose less, and with cold nitrocellulose the least shrinkage.

---

[1] Stain Technology 16: 2, 1941.

Alcohol is also useful as a fixative because it hardens and dehydrates tissue at the same time. Tissues kept in alcohol, however, cannot be immediately used for frozen section work. There is also a tendency on the part of alcohol to produce too great hardness in tissue, rendering it difficult for sectioning purposes. It does not penetrate as well as formaldehyde so the tissues must be cut in very small pieces.

In general, all tissue for fixation must be of a size sufficient for penetration. The volume of the fixative solution must be at least twenty-five times the volume of the tissue. It is therefore obvious that the smaller the tissue, the smaller the receptacle need be to get this 25:1 ratio.

Microtomes

The instrument used for cutting thin sections of tissue or other material for preparation for microscopic examination is called a *microtome*. These instruments are designed to cut material extremely thin, from 1 to 60 microns, and may or may not be provided with mechanical feeding mechanism. There are various types of microtomes:

Frozen sections are made with a microtome specially designed for this purpose known as an automatic microtome with a swinging carriage. The peculiar motion of the knife makes this microtome especially desirable for cutting **celloidin sections**, when equipped with freezing attachment. It is not adapted for paraffin work. The extreme ends of the knife rest in the carrier, and, as the lever handle moves the swinging arms, the knife describes a flattened curve, corresponding to the double movement of free-hand sectioning. By this manner of holding the knife by arms which are not parallel, the entire length of its cutting edge is utilized, insuring uniform wear and permitting the cutting of very large sections. With this microtome use a knife about 110 mm. long. The automatic feed mechanism consists of an accurately cut ratchet wheel, keyed to the vertical feed screw, in the teeth of which a hardened steel pawl engages. By means of a lever extending to the graduated scale on the front of the main frame base, this pawl may be thrown out of action or it may be set to cut sections of any desired thickness. Each division of the graduated scale marks 5 microns. Better results are obtained in making frozen sections if the automatic feeding mechanism is detached and the microtome operated by hand (see page 2103).

Possibly the best type of microtome for **paraffin work** is known as the Minot simplified rotary microtome, with universal ball and socket specimen clamp, designed in accordance with the wishes of the late Dr. Charles S. Minot, of Harvard University, to provide an instrument having the efficiency of the more elaborate rotary microtomes, but of simpler construction. The feeding apparatus operates automatically and may be adjusted to cut any thickness from 2 to 26 microns at intervals of 2 microns. The object holder consists of a disk 25 mm. in diameter which can be oriented to any angle and which moves on a vertical slide actuated by a crank operated by a heavy balance drive wheel. The latter is grooved for belt drive. The knife block consists of a heavy iron casting which is attached to the base and holds the knife in a fixed position, adjustable to and from the object and from side to side to permit the use of nearly the entire cutting edge. It may also be tilted in its support to set the angle of the cutting edge as desired. With this microtome use a plain knife 125 mm. long.

Another microtome which is intended for more accurate and more careful work is the Spencer precision rotary microtome. An inclined plane feed, which is independent of the up-and-down movement on the perpendicular support, overcomes the inaccuracies inherent in other rotary microtomes. The provision of an accurate and reliable feed mechanism, combined with the utmost rigidity of parts, makes this instrument very precise and accurate for laboratory or research work. Sections may be cut of any definite thickness, each section having the same thickness.

The feed mechanism is composed of a rigid bearing, on which the feed block is moved by an accurate screw, cut with two threads to the millimeter; it is revolved by a ratchet feed wheel with 250 teeth; each tooth represents, therefore, a movement forward of the object of one micron. The feed is so arranged that it can be set for sections of any thickness, from 1 micron to 60 microns, by turning the knurled button at the back of the case until the number representing the desired thickness appears opposite the indicator at the small opening in the side of the case near the balance wheel. The total excursion of the feed is 37 mm., allowing a sufficient range for cutting a complete series of a very large object without the necessity of a break due to resetting the knife and feed mechanism.

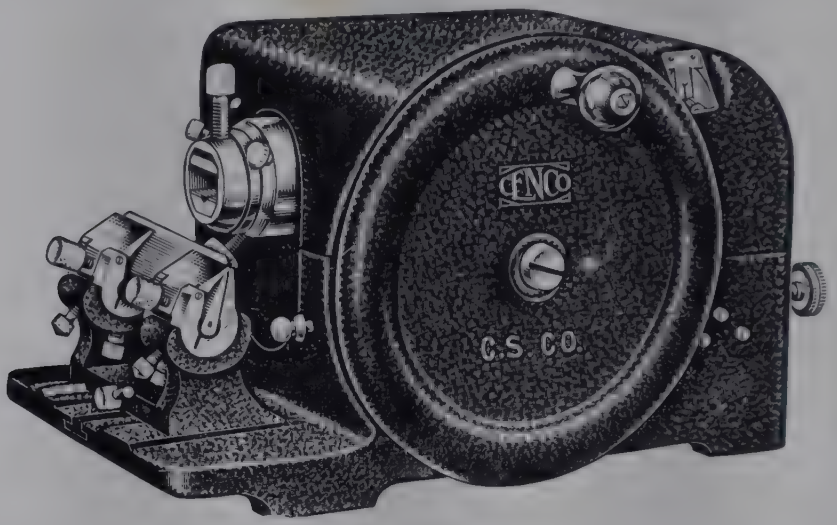

Fig. 606.—Minot simplified rotary microtome. (Courtesy Central Scientific Co.)

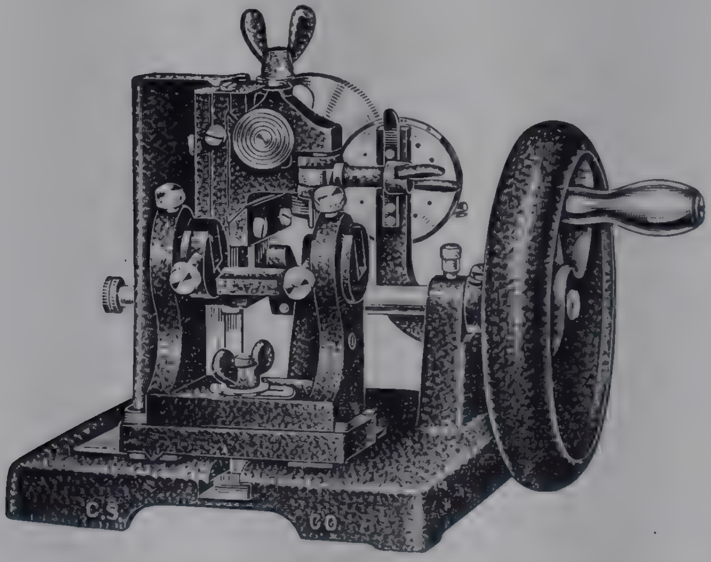

Fig. 607.—Spencer precision rotary microtome. (Courtesy Central Scientific Co.)

The up-and-down stroke of the object clamp is 50 mm. which permits the cutting of very large sections and gives sufficient stroke for celloidin cutting. The clamp may be held at its upper limit for orienting or trimming the block by pushing in a pin. The object may be rotated easily.

The knife is fastened by two clamps, each of which clamps the knife at the back and along 1¼ inches of the edge as well. It may be turned to any desired angle, and the clamps may also be moved toward one another to bring them as near to the ribbon as desired to gain additional rigidity. When the clamps are thus drawn together, the knife may be moved so that practically all of the cutting edge can be used before the necessity of resharpening. The adjustment screws provide for knives of different widths. The whole knife support is adjustable to and from the object, and is very easily and conveniently clamped in any location by a lever connected with an excentric cam.

The whole of the feeding mechanism is covered, protecting the wearing parts from dust. The top of the case is hinged to the lower part, permitting it to be easily opened. The balance wheel is grooved, so that the instrument may be run by a motor.

When desired, the microtome is provided with an adjustable knife support which is especially adapted to celloidin sections. The knife holder of this support is adjustable from a horizontal position through 55° upward.

Another type of microtome, which is very essential for celloidin embedded specimens, is a sliding microtome. This microtome is operated in much the same manner as the paraffin microtomes already described. The essential difference in this type of instrument is the fact that the knife moves against the object. The angle of the knife to the instrument is also different. In addition to this, in using this instrument, the object and the knife must be constantly wetted down with alcohol.

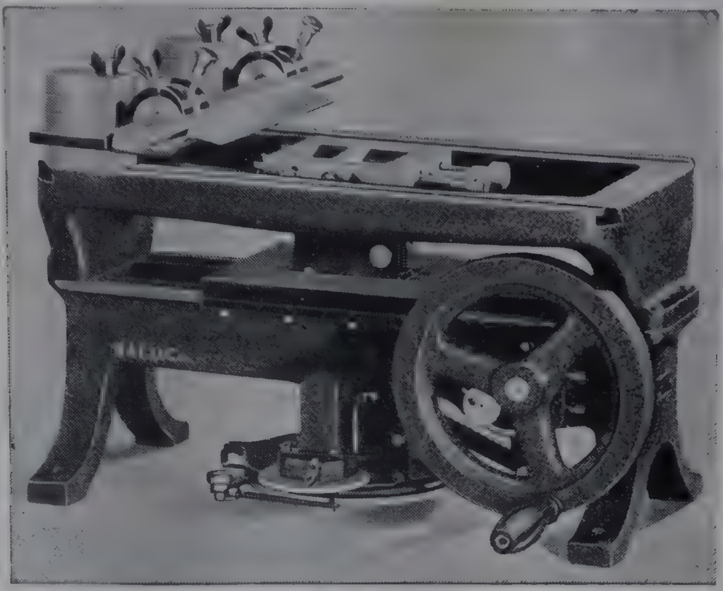

Fig. 608.—Sliding microtome. Can be used for both paraffin and frozen section technics. (Courtesy Bausch & Lomb Optical Co., Rochester, N. Y.)

To Sharpen a Microtome Blade.[1, 2]—

Prepare the microtome knife for honing by screwing the handle into the threads provided at one end of the knife, then slide the sharpening back onto the knife. This sharpening back raises the knife and establishes the correct angle of the cutting facets. Take care to put the proper back onto the knife. Each knife has its own sharpening back; these backs should not be interchanged between knives.

---

[1] The Micro Sharp Company, Box 363, Niagara Falls, New York, and Box 456, Toronto, Ontario, Canada, does excellent work in sharpening microtome blades. The author recommends this company to those who do not sharpen their own blades.

[2] For much of the material on the care and use of micotome we are indebted to Dr. O. W. Richards, Research Biologists, of American Optical Co., Scientific Instrument Division; this material is contained in a pamphlet by Dr. Richards, "The Effective Use and Proper Care of the Microtome," published by Spencer Lens Company, Buffalo, N. Y.

Look at the cutting edge of the blade under the low-power objective of the microscope to examine for nicks. If the edge is appreciably nicked or not straight and even, it may be straightened by rubbing gently on a smooth stone, holding the knife at right angles to the stone. This will establish a straight flat surface along the cutting edge. Now hold the knife so that a strong nearby light reflects from the cutting edge. There will be a broad line of reflected light. Honing will remove small amounts of the metal first from one side of the edge and then from the other until nothing is left but the sharp cutting edge.

Use a fine hone or a piece of plate glass with appropriate abrasive. Lubricate the hone with a solution of neutral soap. Pass the knife over the stone, the cutting edge forward. In other words, proceed forward with the cutting edge of the blade, turn the knife over *across its back,* not over its edge, and bring it back, maintaining sufficient pressure to hold the edge evenly against the hone. If no pressure is used, the hone does not take hold well. If too much pressure is used, the edge is rounded. Gauge the amount of pressure in accordance with the hardness of the knife and the fineness of the hone. By watching the reflection of light from the edge of the knife, the progress of honing may be ascertained. When the reflection is very slight, examine the knife under the microscope to make sure that the edge is smooth and well sharpened.

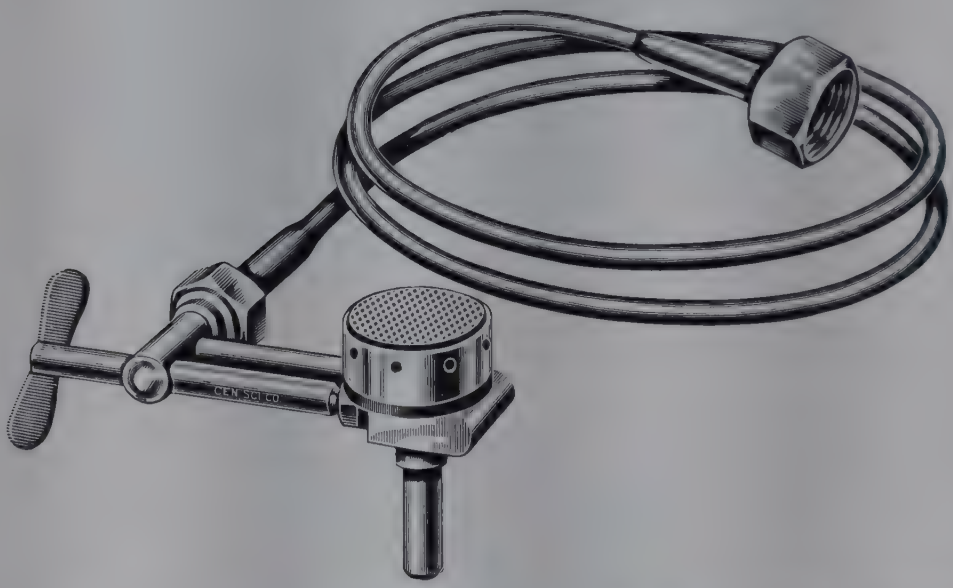

Fig. 610.—Spencer freezing microtome table. (Courtesy Central Scientific Co.)

The glass plate should be at least 3/6 inch thick or preferably thicker. Use plate glass 12 to 14 inches long and at least an inch wider than the length of the knife. The abrasive may be purchased graded to size; or it may be prepared by making a suspension in water and settling it in a tall cylinder. The heavy particles fall rapidly to the bottom; the lighter particles fall more slowly. The time of standing must be gauged by experience. Use the middle portion containing particles of proper size. For grinding, use an average size of 20μ, with none larger than 40μ. For final polishing of the facet, particles averaging 4μ and less than 8μ may be used. Suspend the particles in a solution of neutral soap (about 1 per cent). Gradation of abrasives is accomplished by pouring the supernatant liquid of the abrasive preparation serially from one container to another. The final supernatant liquid contains the finest particles.

To smooth the edge when nicks must be removed, No. 303 or 304 Corundum may be used. Levigated alumina or No. 305 Corundum is suitable for ordinary sharpening and after the above grinding compounds. Diamantine or similar material should be used for the final polishing of the cutting facets.*

To polish.—The knife is prepared as for honing. Use the finer abrasive. Very little is required. Proportions are soon learned by experience. Avoid too much abrasive. Wash the plate free from abrasive occasionally to rid it of large particles and any bits of steel freed from the edge of the blade. Hold the edge evenly against the glass; do not force

---

*Dr. A. Klein, Norton Co., has suggested that a good polishing compound similar to Diamantine may be made by calcining pure ammonia alum in an *unglazed* clay or fused silica crucible for one-half hour at 2300° F. The crucible should be only one-quarter full as the alum swells during heating. The yield is about one-eighth of the original weight.

against it, or the edge will become round rather than sharp. If the facets are irregular, the grinding or polishing is uneven. Use fresh abrasives from time to time during the polishing operation. Toward the end use more dilute abrasives than at the beginning. Examine under the microscope. If the edge shows that the knife is well honed, stropping is unnecessary.

Stropping.—Do not strop too much, or the edge may become curved. Strop the knife from heel to toe. Clean the strop and free it from any abrasive larger than about 2 microns. The strop should be mounted on a board or held against some other surface so that it will not give as the knife is pulled over it. If the strop gives, or if the knife is pressed against the strop, the edge will be rounded and spoiled. Hold the knife firmly against the strop, with light pressure. After a few strokes, first on one side, then on the other, examine the edge under the microscope. Discontinue stropping just as soon as an edge appears smooth. It is unnecessary to test the knife with the fingernail, hairs, or other material; this only tends to dull the knife. The test of the knife is whether or not it cuts effectively.

If a knife needs touching up, but does not need a thorough honing, use a strop with one side embedded with diamond dust or other coarse abrasives. Then strop on the smooth side.

After the knife has been used, it must be cleaned and wiped dry, then put away in its proper place. If the atmosphere is corrosive, it may be necessary to oil the knife to prevent corrosion. Use only a good grade of light neutral oil.

If the knife is in such poor condition that it must be ground, it must be sent back to the manufacturing house which supplied it*; grinding should be done only by experts.

Krajian's Method of Sharpening a Microtome Blade.—

If the knife is dull, but free from nicks, it may be sharpened by stropping. Frequent stropping of the blade usually keeps it in good condition. If, however, the knife is used for a great many blocks, stropping alone will not keep it sharp enough, and one must resort to honing. If the knife must be ground, it should be sent back to the supply house where it was purchased;* grinding should be done only by experts.

For honing, use a number 108 carborundum stone. Before honing, cover the surface of the stone with fine machine oil. Be sure the back is in place on the knife, and that the handle is firmly screwed into the blade. Place the knife at one end of the hone, then, without any pressure except that caused by the actual weight of the knife, gently push it to the other end, so that the sharp edge is proceeding forward. Turn the knife over (against the back, not across the cutting edge) and push it back on its other side to the other end of the hone. Continue until the nicks are gone, or until it feels sharp to the thumb. This honing can be accomplished in about 5 to 10 minutes if properly carried out. If there are deep nicks in the knife, then exert firm pressure while honing.

Use a strop with both rough and smooth sides. When stropping, turn the knife over at the end of every stroke so that both sides are stropped in turn. Usually it requires about one dozen strokes on the rough side and about two dozen strokes on the smooth surface to obtain the proper cutting edge. Strokes should be gentle. Do not exert pressure. The weight of the blade is sufficient when stropping.

General Facts About Care of the Microtome

The microtome should be kept free from dust. Always cover it when not in use.

Be sure that all sliding parts are clean. Oil these parts occasionally with a good grade light machine oil. Be careful not to over-oil or to add the lubrication to dirty mechanisms. Place oil on the main bearing block through the oil inlet provided. Occasionally oil the feed screw.

Like all other precision instruments, the microtome requires gentle handling. Do not put undue pressure on the fly-wheel or other portions of the apparatus which are handled frequently. If the alignment of the microtome is interfered with by constant pressure at certain points, the instrument will have to be sent back to the manufacturer for repairs. To tighten connections, use a smooth wrench, not a pair of pliers. We have seen instruments literally "chewed up" with the erroneous use of pliers on the soft metal.

---

*See footnote[1] on p. 2099.

After considerable use,[1] the microtome may cut sections irregularly due to wear. Turn the handle of the feed mechanism. A distinct drag or tension should be felt. When it turns freely it should be tightened. This usually stops the irregularity of the cutting. Tighten the friction screws on the friction bracket one full turn at a time until the friction is regained. If the feed pawl drags over the teeth of the ratchet wheel, adjust the friction block in the pawl lever by turning the two screws to be found back of the ratchet wheel. Turn these screws one at a time until the pawl lifts out, clear of the teeth of the ratchet wheel on the down stroke.

Do not disturb the feed screw mechanism. Exercise great care in returning the feed screw to its initial position after it has reached the end of its excursion and stopped advancing the specimen. Avoid use of force when handling the feed screw.

THE FROZEN SECTION METHOD OF TISSUE DIAGNOSIS[2]

It is essential to eliminate as completely as possible all lost time and lost motion from laboratory methods. The specialty is already so overcrowded with procedures that any saving of time, especially with promise of increased exactitude, should be welcomed by the practicing clinical pathologist and laboratory technician. The handling and examination of pathologic tissues have constituted for many years most important steps in the development of the hospital laboratory. Every piece of tissue removed at the operating table must be submitted to a pathologic investigation, both macroscopic and microscopic. In various places, one of three methods is used: the paraffin, the celloidin, or the frozen section. The celloidin method is used, so far as we know, in only a few places. The most common method in use is the paraffin method. The frozen section is used in some places as routine and in other places only as an emergency method.

The advantages of the frozen section method are as follows: (1) ease of manipulation; (2) saving of reagents; (3) lack of change in the normal structure of tissues, whereas in the process of paraffin embedding, it is impossible to prevent some shrinkage; (4) definite saving of time, which allows for more rapid diagnosis and permits the technician more time for other procedures; and (5) less expense in preparation. Slides are permanent.

Routine Frozen Section Method for Preparation of Permanent Slides (Krajian)

Technic of Freezing, Cutting, and Affixing Section to Slide.—

Fixation.—Ten per cent Formalin is used. Dilute 10 c.c. of commercial Formalin (40% formaldehyde) to 100 c.c. with tap water or saline. Neutrality of formaldehyde is important to preserve the staining qualities of the nuclei of the tissue. It is often necessary to add 5 grams of calcium carbonate or sodium bicarbonate to a gallon of the stock commercial formalin.

Immediate fixation is essential. Place the tissues in formaldehyde as soon as possible after removal from the body. At least 25 times as much fluid as bulk of tissues must be utilized. Pieces of tissue should not be too thick. Use a 15 per cent neutral commercial formaldehyde for 24 hours. **For rapid fixation** in cases where one is making a biopsy at the operating table, drop the tissue in boiling 10% Formalin for 30 seconds, then in dioxane for 30 seconds, and freeze immediately. For rapid fixation of autopsy material, use formaldehyde that has been brought to the bubbling point in a test tube, then pour it on the tissue in a bottle, which reduces the temperature of the formaldehyde to about 65° C. Allow it to remain in an oven at 56° C. for from 20 to 30 minutes. Shrinkage will be not more than 5%.

---

[1] O. W. Richards: Loc. cit.

[2] Revised from the Pamphlet The Frozen Section Method of Tissue Diagnosis, compiled by R. B. H. Gradwohl, St. Louis, Mo., and A. A. Krajian, Los Angeles, Calif.

After 24 hours' *fixation* (with the slower method), the block should be cut in pieces about 1 to 2 cm. square, and from 3 to 5 mm. thick, and placed in 10% neutral commercial Formalin.

Washing.—Have handy a beaker or glass dish about 6 inches in diameter and about 3 inches high. Fill with tap water. Place the tissue blocks in the water for a short period only. This removes the formaldehyde which is detrimental to the skin of the operator and which would prevent the block from adhering to the holder.

The Microtome.—The Bausch and Lomb Optical Company freezing microtome is preferred. The knife should be honed and stropped in such a way that the edge has a shorter bevel on one side than on the other and should be used with the shorter bevel downward. The block holder should have deep grooves. Place the block on the holder after a drop of water has been placed on the holder. An angle of the block rather than a straight edge should face the knife. If the tissue is covered by a capsule, such as skin or a mucous membrane, this capsule surface must face the knife edge at an angle, and should never be placed on the side away from the knife.

To Freeze.—Place the index finger on the block and turn on the CO_2 gas slightly for temporary holding. Press down firmly but not tightly all around for fixing to the holder, and release more gas gently until the freezing level has passed upward through about one-half of the entire block. Excess water may be removed with a towel while freezing. Take care that there are no holes in the section, since the unfrozen portion will break; hence the importance of pressing the block to the holder firmly and releasing the gas slowly.

Cutting the Section.—Cut off the upper one-third, that is, the unfrozen portion, and drop it back into the specimen bottle. Then shave down to establish a smooth, level surface. If the surface to be cut is frozen too firmly, it is hard and white and the sections will be fragmentary. If the surface is too soft, the section will show holes. The ideal to be reached is a hard, pliable surface so that a section cut therefrom will show no tendency to break as it piles up over the cutting edge of the knife. If holes appear in the block while cutting, touch all parts of the cut surface gently with the fingers to warm it and melt it slightly, then refreeze. In this way, the holes in the unfrozen parts will become filled, and there will be no fragmentary parts of the tissue.

To Operate the Microtome.—Do not use a microtome where constant rotation of the wheel automatically lifts the holder. This faulty method, largely due to the manufacturer's wrong idea of making things look easy, is responsible for poor frozen sections. The author suggests that the automatic lift of the microtome be disconnected for frozen section work. *The hand must be used on the rim of the fly wheel* and the wheel must be turned slowly. Rapid use of the wheel, as is ordinarily carried out in laboratories, does not allow sufficient time to adjust the tissue surface to the proper temperature and consistency. The method recommended by Gradwohl and Krajian, i.e., slow turning by hand, permits warming of the cut surface of the block, giving a pliable section free from undulations.

Turn the notched wheel below the microtome table three (or two if desired) notches with the left hand, using the right hand to turn the fly-wheel. This will give a section about 8 to 10 microns thick. Uneven sections are usually the result of freezing the block too hard, applying too much speed and unnecessary force in cutting the sections, especially with firmer tissues.

Remove the Section From the Knife as follows: Wet the tip of the little or ring finger with water, and with this carefully remove the section from the edge of the knife (with a downward movement at about a 45 degree angle to the knife blade), and place in water. The tissue will float out on top of the water. Keep the knife edge dry. Water left on the edge thaws the tissue with which it comes in contact, causing a hole in succeeding sections. Place the sections in a large dish of water, about 3 inches deep, on a black background.

To Transfer Sections to the Glass Slide.—Clean the slide by dipping in acid alcohol and wipe dry. The dish in which the sections are floated should be at least 7 cm. deep and 15 cm. in diameter. The operator should be seated so as to prevent any direct reflection from the slide to the eyes. A glass rod, pointed or slightly bent, should be used to transfer the sections of delicate internal tissues to the slide. Teasing needles may be used for sections of firm tissues, but not when one is staining for iron or using silver solutions for staining. See Fig. 611.

Anchor the section to the slide at about a 45° angle, with three-fourths of it under the water in such a way that the edge of the water basin will afford support to either the slide or the fingers, thereby aiding in steadying the slide. Put the section, by means of a glass rod, on the middle of the slide, bringing it to the surface of the water immediately above the center of the slide. Now, manipulate the slide so as to straighten out most of the folds. Keep one edge of the tissue above the water. After the folds have been removed, tilt the slide against a staining dish, face down to keep off dust particles, at a 45° angle, so that the water may partially drain. *Do not permit it to become completely dry.* Fifteen seconds to a minute is usually sufficient.

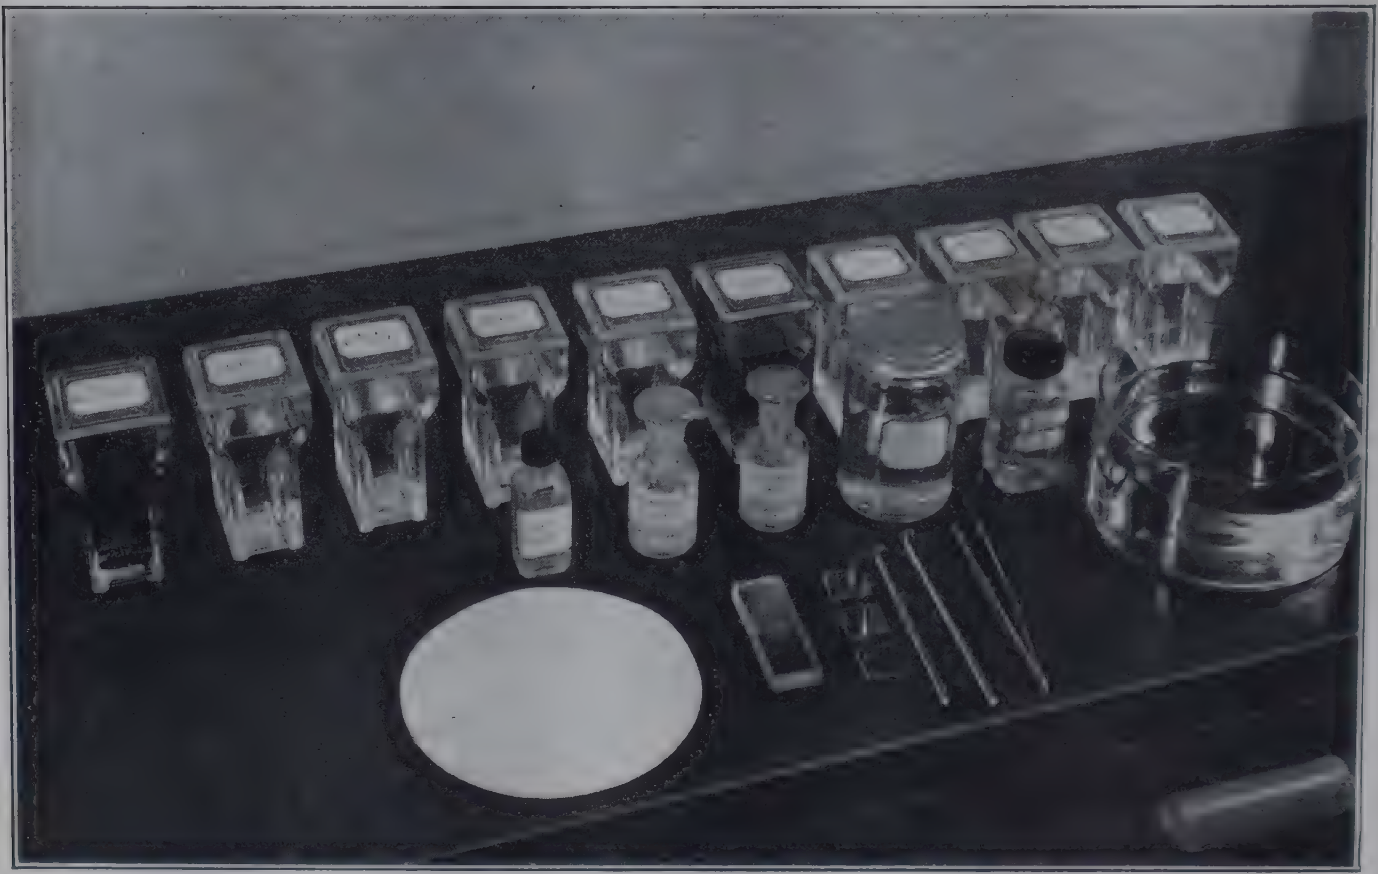

Fig. 611.—Equipment and reagents for staining frozen sections, method of A. A. Krajian.

To Dehydrate the Tissue.—Drop, at short range to prevent breaking the section, two drops of *anhydrous* isopropanol* or absolute alcohol on the section, holding the slide at a slight angle. Blow the breath over the section until the isopropanol or alcohol appears to have evaporated. Flood the slide with isopropanol or absolute alcohol for dehydration, for one minute or more. Pour off the dehydrating agent, taking care not to disturb the section. (In fatty tissues, fat is dissolved by the alcohol and the section may tend to slip away from the slide. Under these circumstances, blow over the surface of the section gently and remove the remaining alcohol by evaporation to keep the section on the slide.) Blot twice with several thicknesses of Whatman No. 1 filter paper, then dip twice (in and out rapidly but carefully, taking care not to change the position of the slide) into a jar of thin celloidin. (See below for technic of making.) Blow gently over the surface, taking care not to change the position of the slide *until the celloidin is dry.* When thoroughly dry, place immediately into the staining solution. Mayer albumin fixative is not recommened. Celloidin is that furnished by DuPont or Schering, or Parlodion, made by Mallinckrodt Chemical Works, St. Louis, Mo.

---

*Isopropanol may be obtained from the Carbide and Carbon Chemicals Corp., St. Louis, Mo.

Thin Celloidin.—Make a *thick celloidin* (stock) by dissolving 30 grams of dry celloidin in 200 c.c. of a mixture of equal parts of ether and absolute alcohol. Shake the container several times a day for a week or longer, and stir the sediment with a heavy glass rod at least once a day until solution is complete. Then add about 7 to 8 c.c. of this thick celloidin to a mixture of 45 c.c. of ether, 45 c.c. of absolute alcohol, and 10 c.c. of acetone. When thoroughly dissolved, add 1 c.c. of saturated alcoholic solution of gum mastic to strengthen the adhesive qualities, make the sections smooth, and to prevent rapid deterioration (Krajian).

Staining Frozen Sections, Method of Krajian.—

Reagents for Staining.—

Harris Hematoxylin.—This hematoxylin formula is recommended as a nuclear stain. It is easily and quickly made.

Hematoxylin crystals	1 gm.
95% alcohol	10 c.c.
Ammonium or potassium alum	20 gm.
Distilled water	200 c.c.

Dissolve the hematoxylin in the alcohol. Dissolve the alum in the water by use of heat, and add the hematoxylin solution. Bring to a boil as quickly as possible, then add 0.5 gm. of mercuric oxide. The solution at once assumes a dark purple color. When this occurs, remove the vessel containing the solution from the flame and cool as rapidly as possible in a bath of running, or frquently changed, cold water. When cool, the solution is ready for use. Addition of 3 c.c. of glacial acetic acid to 95 c.c. of solution at the time of use will increase its nuclear staining properties.

Acid Alcohol.—Add 1 c.c. of concentrated hydrochloric acid, c.p., to 100 c.c. of 70% ethyl alcohol.

Ammonia-Isopropanol.—Add 5 c.c. ammonium hydroxide, c.p., to 100 c.c. of anhydrous isopropanol.

Eosinol.—See page 2133.

Carbol-Xylol.—To one part of melted carbolic acid crystals, add 3 parts of xylol. Be sure all glassware used in making the solution is dry.

Staining Technic.—

Solutions are placed in staining jars in proper order. Have on hand a drop bottle containing anhydrous isopropanol.

Put slide (section mounted under celloidin) in Harris hematoxylin for 3 to 10 minutes, or for rapid work, dip in and out carefully about fifty times or until the section is the proper color.

Place in tap water until blue (4 minutes).

Decolorize in acid alcohol by dipping the slide in and out of the jar, turning for even decolorization, until no more salmon pink solution runs off the tissue. Be sure to decolorize thoroughly, but do not over-decolorize.

Dip in tap water to stop decolorizing.

Place slide in ammonia-isopropanol until every part of the tissue is a good blue color. If desired, examine under the low power of the microscope to see if the nuclei are a good blue. Do not rush this step.

Pour anhydrous isopropanol over the slide (allowing it to flow into the ammonia-isopropanol jar to save it) to dehydrate the tissue. Several drops are sufficient, if repeated twice.

Dip in and out of eosinol several times, turning the slide for even staining, and watching the staining in the air over a white background until the section is stained evenly red. This requires 10 to 30 seconds or more, depending on the strength of the solution.

Place in carbol-xylol for 3 to 4 minutes, or dip in and out of carbol-xylol until clear (about 30 seconds).

Drain and place for 1 or 2 minutes in the first xylol, or dip in and out of the xylol for several seconds.

Place in the second xylol for 2 minutes, then into the third xylol to clear.

Mount in neutral gum damar. Do not allow xylol to dry before mounting.

Gum Damar.—

Gum damar is recommended instead of Canada balsam as a mounting medium because it presents several points of superiority: (1) It dries more quickly; (2) slides stay dry and can be stacked without sticking together; (3) it does not become yellow with age; and (4) it does not produce fading of the section.

Gum damar is a saturated solution of the gum in neutral xylol. Place in an incubator and shake it several times a day until it is of heavy syrupy consistency. Then filter through four layers of gauze and store in a brown bottle. If time permits, allow it to sediment thoroughly and decant the supernatant liquid instead of filtering. If the solution is too thin for mounting purposes, place the unstoppered bottle in an incubator until it is of proper consistency. If too thick, add more xylol.

Special Facts About This Method

In all cases where sections are transferred from one solution to another, be sure to drain off as much of the solution as possible, especially with carbol-xylol. Carrying of carbolic acid into xylols will cause fading of nuclear stains.

If the sections occasionally fall off from swelling, flood them with isopropanol for 2 to 5 minutes, pour off, blow section dry, blot, and dip twice in celloidin, and resume the process from that point on.

If sections do not clear properly, either the isopropanol is not anhydrous, or the carbol-xylol has been used too long, or the tissue has not been properly dehydrated. Try new solutions.

If the sections are cut unevenly, the microtome may be at fault, or the section was frozen too hard.

If a section has been re-celloidined, it must be dehydrated with isopropanol before placing in xylol.

When gum mastic is old or in solution, it deteriorates. It is necessary in such cases to use more gum mastic than the method calls for.

If the celloidin covering the section takes the stain during the staining process, the stain may be removed by dipping the slide back into thin celloidin until clear again.

Always be sure the celloidin has been blown dry before staining to prevent artefacts. The celloidin must completely penetrate the tissue before stain is applied otherwise the cells will not take the stain.

Air bubbles in the section form either because the section is too thick, there is not sufficient gum damar, or the gum is too thin, or the cover slip may not be properly laid down.

The celloidin manufactured by Mallinckrodt is fortified by the addition of gum mastic.

Hard tissues such as uterus and others of fibrous structure may be softened by the application of several drops of dioxane at the time of cutting. Then re-freeze. If the block is still too hard, the dioxane may be applied twice again. Never apply dioxane more than three times.

Soft tissues such as gelatinous carcinoma of lung tissue, if soaked in dioxane 15 to 30 minutes before cutting, give good consistency.

Striated muscle fibers are best shown with the spirochete stain.

If sections show shrinkage, it is usually caused by drying of the sections before they are dehydrated and celloidined. Watch every section very carefully during the draining process, and if any one is even slightly dried, dip that portion back in water and begin the dehydration immediately.

If the outside walls of appendices turn over, it may be due to the drying of the specimen before it reached the technician, and nothing can be done about it.

If the hematoxylin-eosinol stain is satisfactory, the nuclei will be clear under high power, the blues will be *blue* and not *purple* or *lavender*, while the eosin will be *pink* or *red*, but not *lavender* or *purple*. If the blues have a purple cast, the section was not properly decolorized in acid alcohol, nor the blue brought out properly in ammonia-isopropanol.

It is necessary occasionally to add more ammonium hydroxide to the ammonia-isopropanol to replace that lost by volatilization.

If the hematoxylin develops a sediment, pour off the supernatant liquid and continue to use it. A scum may be dissolved with a little glacial acetic acid.

If the celloidin peels off the slide or falls away from the tissue, this may be caused by using celloidin which is too old, or which is contaminated with extraneous material. Make new celloidin. Or it may be due to the fact that some of the solvent has evaporated, resulting in a thickening of the celloidin. Either thin the celloidin with a mixture of alcohol, acetone, and ether in proper proportion, or, better, make fresh thin celloidin.

Do not allow the section to dry at any step. If the section becomes dry, dip it back into the solution from which it has just been taken.

Frozen Sections of Loose Texture Tissues—Serumizing Technic (Krajian)

One of the principal objections to the use of frozen section methods has been the impossibility of securing satisfactory sections of fragmentary and loose-textured tissues, such as curettings, brain abscesses, and body fluids. Krajian[1] has overcome this objection by applying his serumizing method, as follows:

Fix in 10% Formalin (page 2102) in the usual manner for 24 hours, or longer if necessary. Trim the blocks. Wash several times in tap water to remove the formaldehyde. Place the tissue in a small Stender dish or specimen bottle containing uncontaminated human or animal serum. Fresh serum obtained from the day's serologic specimens is ideal for this purpose. The serum should completely cover the tissue. Cover the dish or bottle tightly and put in a warm place overnight. The top of the paraffin oven is a good place for it. Cover any floating tissues such as lung or fatty material with absorbent cotton in order to keep all parts submerged in the serum.

The following morning, decant the excess serum. Without washing, add sufficient dioxane to cover the blocks. Allow it to stand for 3 to 5 hours, or until the serum is completely coagulated. Immediately freeze on the freezing microtome with carbon dioxide gas, and cut, stain, and mount sections in the usual manner.

Since dioxane will eventually shrink the tissues, they cannot be kept in this solution indefinitely. After cutting the sections, place the blocks in 10% formaldehyde for permanent storage.

For emergency examination use very thin blocks of formaldehyde-fixed tissues. Place in serum in a paraffin oven at 56° C. for 1 to 2 hours, then coagulate in dioxane for one hour. Then freeze, cut, stain, and mount.[2]

This method has been used in our laboratories frequently. It causes very little shrinkage and no curling or shriveling of sections, such as other embedding processes intended for frozen sections. This serumizing process makes hard tissues, such as bone and uterus, soft and pliable, giving better sections.

Store the serum in small bottles and preserve by the addition of 2 c.c. of commercial 40% formaldehyde to 50 c.c. of the fluid. This keeps well at room temperature indefinitely without contamination.

Frozen Sections at the Operating Table—Permanent Mounts (Krajian)

In most textbooks and in many hospitals, we see advocated a few different methods of frozen section for rapid biopsy work. The following method has proved very efficient at the Los Angeles County General Hospital and in our laboratory at the Christian Hospital at St. Louis:

Boil in 10% Formalin (page 2102) for ½ minute.

Drop in dioxane ½ minute.

Freeze and cut sections as directed on page 2103.

Place on slides.

Add a few drops of isopropanol (anhydrous) from a drop bottle, and blow dry. Repeat and let evaporate.

Cover the slide with isopropanol for about 30 seconds, drain off excess and blot between several layers of Whatman No. 1 filter paper.

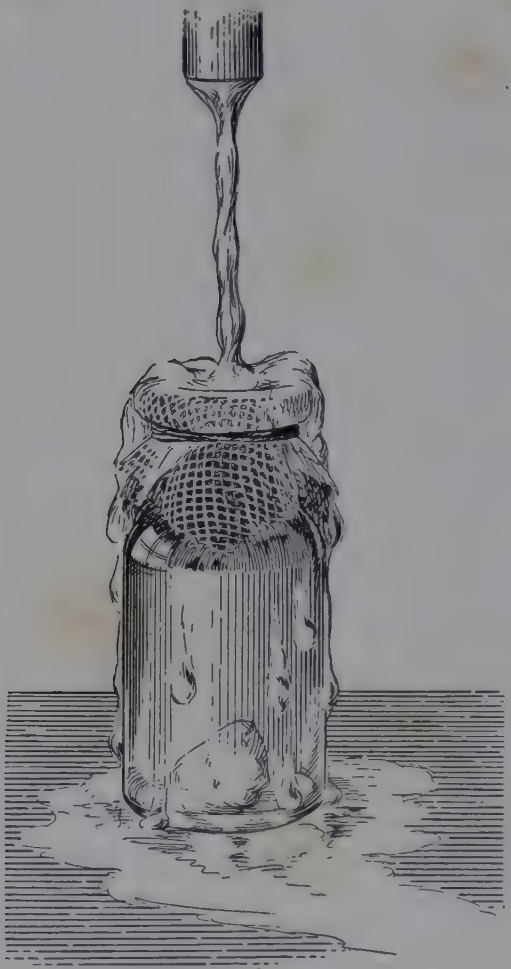

Fig. 612.—Washing tissues.

Dip into thin celloidin (page 2105) twice. Wipe the back of the slide dry. Blow the breath over the surface of the slide to dry the celloidin. *Do not change the direction in which the slide is held during the celloidining process until the celloidin is dry.*

Have all reagents in staining jars. See page 2105 for these reagents.

Dip in and out of Harris hematoxylin about fifty times.

Wash in tap water for a few seconds.

Decolorize in 1% acid alcohol as in the routine method.

Dip in tap water to stop decolorizing, and place immediately in the ammonia-isopropanol mixture until blue (5 c.c. ammonium hydroxide to 100 c.c. of anhydrous isopropanol).

Drop a few drops of isopropanol over the surface of the slide to dehydrate it, catching the isopropanol in the jar of ammonia-isopropanol mixture.

Dip in and out of eosinol several times until the tissue is a good pink color. This requires only a few seconds.

Dip in and out of carbol-xylol to clarify. About twenty or thirty dips usually suffice.

Dip in xylol for a few seconds, about thirty to fifty times.

Repeat in two more changes of xylol.

Remove excess celloidin from around the tissue, and mount in gum damar.

If the specimen becomes elevated on the slide at any time, dip in celloidin again, then back into xylol, and proceed.

AUTOTECHNICON METHOD FOR PARAFFIN SECTIONS*

The Autotechnicon is a special automatic apparatus especially designed for automatic fixation, dehydration, infiltration, decalcification, and staining of tissues. It can be adapted to any technic or method, and once it has been set, assures undeviating adherence to that technic.

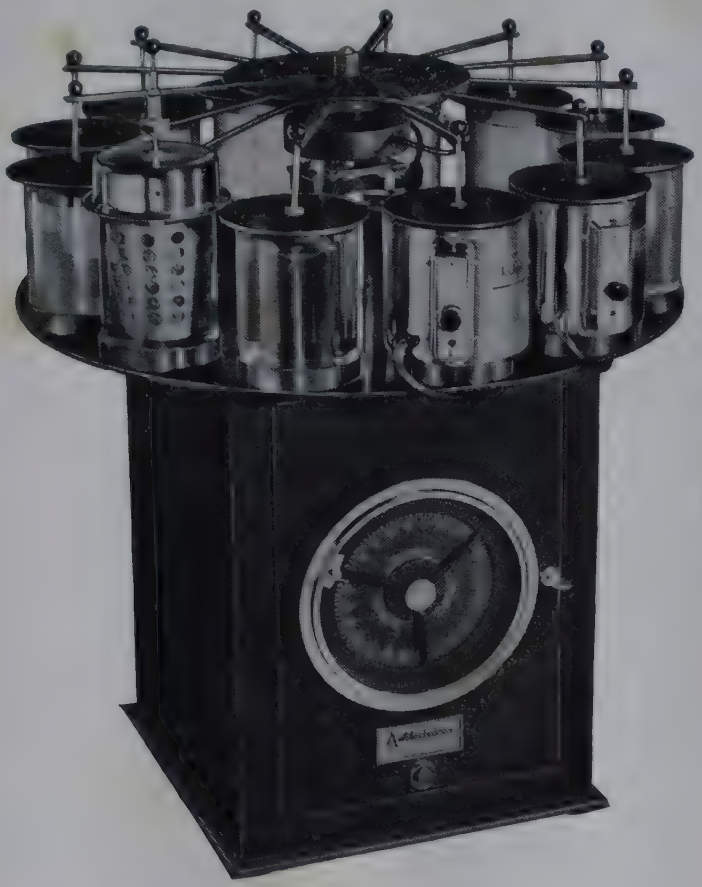

Fig. 613.—The Autotechnicon. (Courtesy Technicon Company, New York.)

The instrument consists of a timing clock, reagent beakers of polyethylene and Pyrex glass, beaker platform, mastershift carriage, beaker covers, displacer rotor, receptacle basket, receptacles, washer, and paraffin bath (Fig. 613). It is especially recommended for overnight tissue routine and for weekend tissue routine.

Suggested Daily Routine Technic, Using the Autotechnicon.—

Collect the tissues in the Technicon Tissue Caddy (Fig. 614) which can be wheeled to any location where it can be plugged into an electrical outlet, outside an operating room, in the morgue, etc.

Immediately upon excision, place the tissues in the refrigerated compartment. This prevents drying or general deterioration. The temperature within the Caddy is maintained at a point just below freezing so that tissues, while properly preserved, will still be easy to cut and trim on removal.

---

*This section has been compiled from information furnished by The Technicon Company and Technicon Chemical Company, 215 E. 149th St., New York 51, N. Y.

When ready to process the tissues, roll the unit into the pathology laboratory, plug it into an electrical outlet, and store the tissues until they are ready for processing.

At a convenient time, the pathologist removes the tissues which have been collected during the day. As he prepares and examines each specimen, he describes its gross aspect, dictating his observations into a recording apparatus. It is convenient to have a permanent microphone set up at the cutting board, with a foot switch to start and stop the recorder, so that both hands are free for dissecting. While dictating the gross description, the pathologist cuts pieces of tissue to proper size for processing. These pieces should be cut no thicker than 4 mm., regardless of other dimensions.

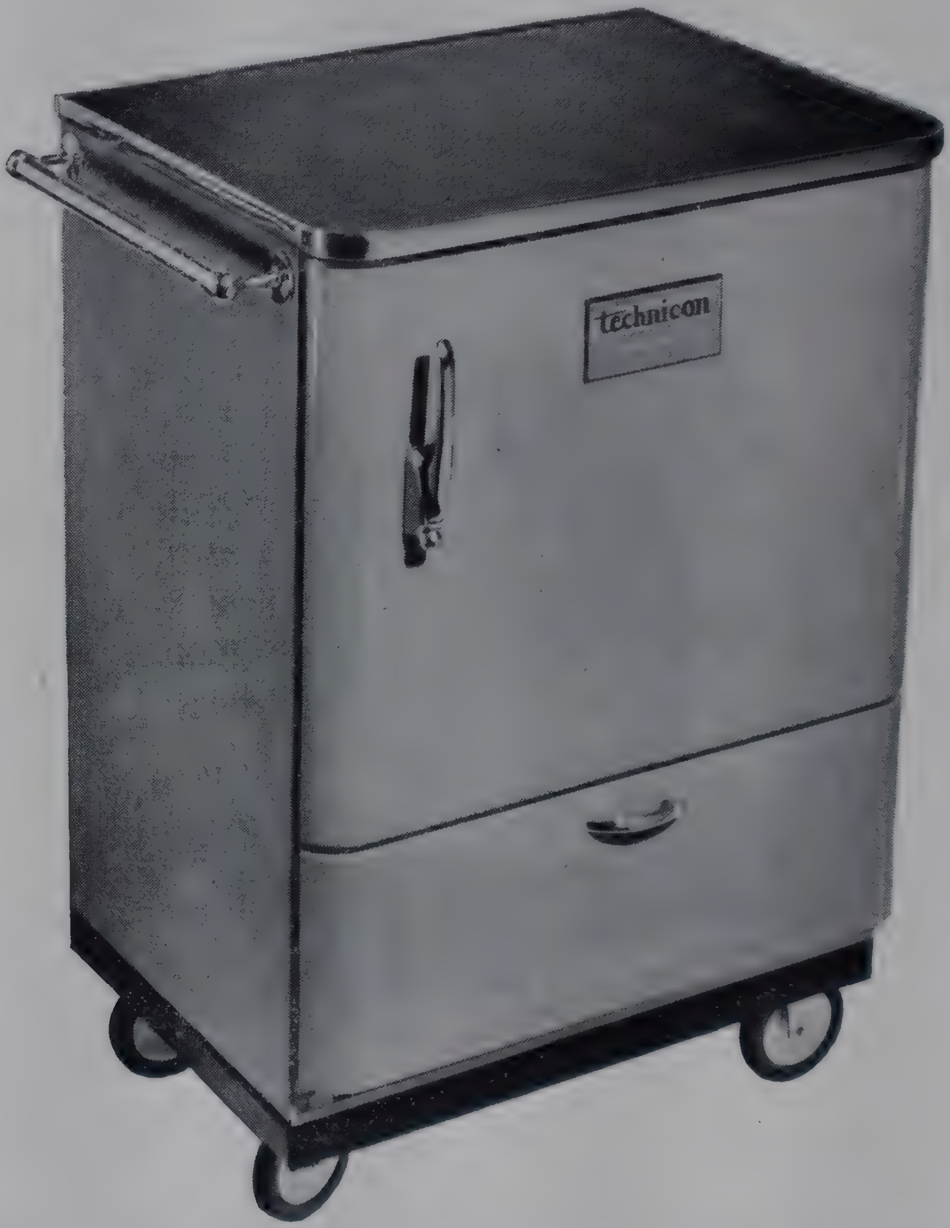

Fig. 614.—Tissue Caddy. (Courtesy Technicon Company, New York.)

As the pieces are cut, place them into a tissue receptacle fitted with proper dividers so that it can hold several specimens for simultaneous processing. During this procedure, store receptacle bottoms on one tray, dividers on another, and tops on a third. The pathologist can then select the tissue, pick the proper dividers, place them in a receptacle, and finally snap on the cover in a continuous operation.

If the pieces are small, the receptacle may hold three; if larger, two; while very large ones may require the entire receptacle. Place a paper identification slip, or slips, in the receptacle along with the tissue. Slips should be no larger than 3 by 10 mm. so as not to impede penetration of the fluid. Notations made with an ordinary graphite pencil will stand up under all the reagents used, and will still be quite legible when finally they come out of paraffin.

As each receptacle basket is filled, attach the displacer rotor to it, and mount the entire assembly, including the beaker of fixative in which it has been lying, on the Autotechnicon.

Check to see that no paraffin adheres to any of the beaker covers. This might solidify, and cause the beaker to tip and spill when the carriage rises.

Start the machine. Since precise time periods for each step have been cut into the timing dial, the process is now completely automatic. (See directions supplied with the apparatus.)

In a typical routine, the tissues will remain in the fixative for 4½ hours. The fixative which is recommended is Technicon fixative. It has all the advantages of Zenker fluid but none of its disadvantages, and is stable. Although it is a potassium dichromate formula, tissues fixed in it do not have to be washed since it produces no appreciable precipitate. It does not harden tissues. Tissues may remain in it for prolonged periods without harmful effects. In order to wash off the excess fixative and to avoid contamination of the reagents that follow, subsequent immersion in a beaker of water, or the tissue washer, for 30 minutes is recommended.

The next step is dehydration, with tissues remaining in each change for 1 hour each. Use the Technicon dehydrant, which is neither hygroscopic nor highly volatile. It does not cause tissue shrinkage, nor does it harden the tissue. Tissues may be left for prolonged immersion without damage.

Next, the tissues must be cleared through two stages, 1 hour each. The Technicon clearing agent is an excellent medium. It has the same qualities as the dehydrant, being neither volatile, hygroscopic, nor markedly inflammable, and having no shrinking, distorting, or hardening action on the tissues. It removes all the dehydrant, and conditions the tissues so that they will cut easily. It is highly soluble in paraffin. It renders the tissues translucent.

The tissues next go for 1 hour into the first paraffin bath, then for 2 hours in a second paraffin immersion. Two paraffin baths must always be used. The first becomes contaminated, but the second remains free from contaminants. The paraffin should have a melting point of 54° to 58° C.

If this process was begun at 5:00 P.M., the tissues will be ready for embedding at 9:00 A.M.

Lift the paraffin bath with its load of tissues in the receptacle basket and carry it to the embedding bench. Plug the bath into a convenient electric outlet to maintain the paraffin at the desired fluidity.

Remove the tissue receptacles one by one from the paraffin.

Lay a receptacle on the table, bottom down. With the forceps handle, strike the top lightly, causing the clamping lugs to spring open with a snap that breaks loose any adhering paraffin.

For embedding, use paraffin with a melting point of 60° to 62° C. Keep it fluid by heating over a Bunsen burner.

Use a flat pan for embedding. Coat lightly with glycerin before pouring in the paraffin so that the final paraffin slab can be easily removed after embedding. Pour in the melted paraffin.

Remove the tissues with a pair of forceps, transferring the tissue and its label to the pan of paraffin with the side to be cut facing down. Place the tissues in straight rows so that neatly squared blocks can be cut when the paraffin slab is divided for sectioning.

Set the pan on a fairly high stand and rub ice along the bottom so that the paraffin solidifies locally, anchoring the tissues firmly in place. The pan should contain about half an inch of paraffin.

To prevent crystalline formations, cool the slab slowly, by allowing it to stand at room temperature until solidified.

Place in cooled water for hardening. Do not use too low a temperature, as this causes the paraffin to form crystals.

Free the hardened slab from the pan and cut into individual blocks, each containing a piece of tissue with its label. Use the Technicon paraffin knife. The hot edge scores the slab deeply so that it is easily broken into individual blocks. (See Fig. 615.) Use the hot knife for final trimming of the blocks. Place the side of the knife against the side of the paraffin block, and as the paraffin begins to melt it can be easily made into a square block.

Mount the tissue block on the microtome object disk in the usual manner after removing the label with the heated paraffin knife. Keep the label with the tissue for identification.

Cut in the usual manner. The microtome blade is adjusted so that there is a 5 degree angle between the side of the paraffin block and the bevel of the microtome knife. A convenient method of determining this angle is to put the sharpening back on the knife, then hold a straight edge between the back and the edge of the knife to determine the exact angle.

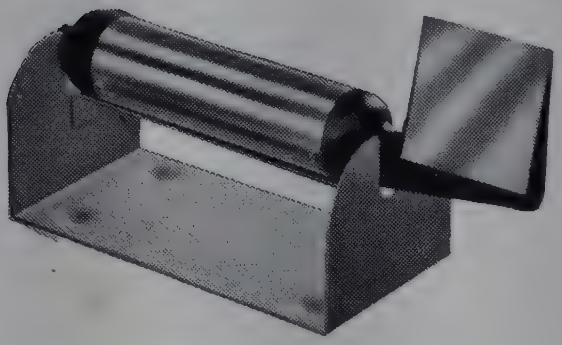

Fig. 615.

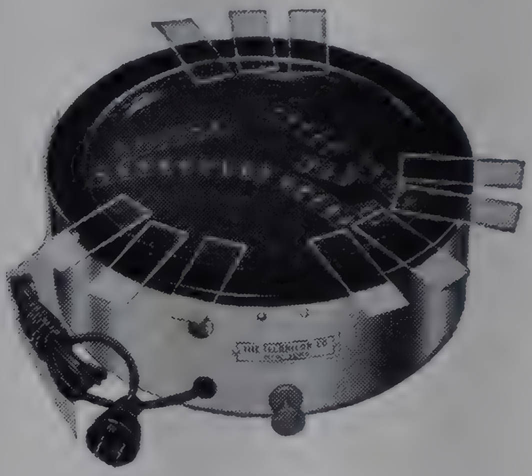

Fig. 616.

Fig. 615.—Technicon paraffin knife. (Courtesy Technicon Company, New York.)
Fig. 616.—Technicon water bath. (Courtesy Technicon Company, New York.)

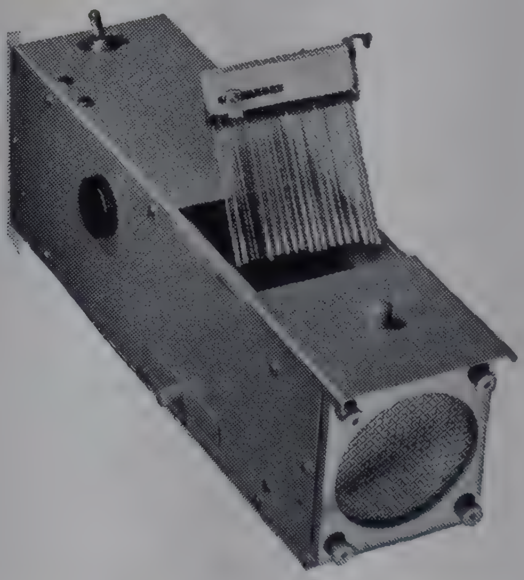

Fig. 617.—Technicon microslide dryer. (Courtesy Technicon Company, New York.)

Do not take preliminary thick trimming cuts. These rapidly dull the knife edge.

Always put the narrower side of the tissue block nearest the knife when inserting the block into the microtome.

As the cut tissues are lifted from the microtome, spread them face up on a Technicon constant temperature water bath (Fig. 616). Before placing a cut tissue section on a slide, identify the specimen by scratching the number into the slide, using a diamond point pencil.

Keep the water bath at 45° C. by adjusting the thermostat. Keep the water level near the top. Remove unwanted tissues by dropping a paper towel flat on the surface. When it is lifted, the paraffin ribbons will come away with it.

Mount the tissues in egg albumin fixative in the usual manner. If desired, dip the mounted slide in a container of very hot water, quickly, to flatten the tissue section. Use a temperature of 95° C., but be sure not to leave the slide in the water, or the paraffin will melt.

As the slides are mounted, insert in the staining rack, and place it in a Technicon microslide dryer. A current of warm (56° C.), filtered air passes over them, completely drying the slides in about 7 minutes (see Fig. 617).

To use the Autotechnicon for staining, plug in a one-hour staining clock, at the same time replacing the processing fluid beakers with others containing those staining fluids required by the prescribed technic.

Keeping the dried slides in the rack, take from the drier, and mount the rack on the Autotechnicon for staining. Operation from this point is completely automatic.

The tissues move first into a beaker containing xylol to remove the paraffin. This immersion is for 2 minutes. They then go into 0.25% iodine dissolved in the dehydrant, to remove any mercuric chloride crystals remaining in the tissue. This requires 2 minutes.

Next, a bath of Technicon dehydrant removes excess iodine, 2 minutes. Then distilled water 2 minutes, hematoxylin for 10 minutes (or longer if desired), a rinse of distilled water for 4 minutes, lithium carbonate to render the hematoxylin alkaline, turning the dye blue, 2 minutes. They then move into distilled water for 2 minutes, then eosin 5 minutes, distilled water to remove excess eosin, dehydrant for two baths of 5 minutes.

Remove the rack after dehydration, and place upside down in a beaker of xylol.

Remove the slides from the rack singly, clean, and mount under a cover glass.

Although any desired stains may be used, it is recommended that the Technicon standardized hematoxylin and eosin be used for the staining process. Technicon tablets of lithium carbonate are also convenient; dissolve 1 tablet in a liter of distilled water to obtain a 0.01 N solution.

The Technicon standardized hematoxylin and eosin will last approximately six months, after which their staining efficiency sinks to zero as the balance is destroyed. No subsequent decolorization is required when Technicon eosin is used.

Technicon mounting medium, Canada balsam, gum damar, etc., can be used as mounting media.

Other staining methods may be used by preparing another clock, according to directions furnished with the apparatus, and substituting other staining solutions.

PARAFFIN SECTIONING

Paraffin sectioning differs from the making of frozen sections in that, with this method, the water is replaced in the section by paraffin, then thin sections cut. In order to remove the water and entirely replace it with paraffin, the tissue, after proper fixation, must first be dehydrated. This is accomplished by carrying it through increasing strengths of alcohol, or isopropanol, beginning usually with 50 per cent strength. Thus the water in the tissue is gradually replaced with the dehydrating agent, until all water is removed, and 100 per cent alcohol or anhydrous isopropanol is present in its place. The alcohol is then replaced by xylol (which clarifies the tissue); the xylol permits the penetration of the tissue by paraffin, which then replaces the xylol. This entire process of dehydrating, clarifying, and embedding requires several days, at the end of which time the tissue is embedded in pure paraffin, then cut into sections of appropriate thickness, and stained.

Before the sections can be stained, they must first be affixed to the slide. Various methods of fixing sections are given below. Next, the paraffin must be removed from the section. This is accomplished by the use of xylol. Water must gradually replace the xylol now in the tissue. This is accomplished by passing the tissue through gradually decreasing strengths of alcohol or isopropanol until eventually the original water content of the tissue is restored. The section is now ready to be stained.

Staining processes are quite similar to each other. The tissue is first submitted to hematoxylin (an excellent nuclear stain), decolorized to remove hematoxylin from all portions of the tissue except the nuclei, the blue color brought back with an alkali, then the tissue counterstained with a contrasting color (red, of the eosin); the nuclei remain blue; other portions take the eosin dye.

The tissue must again be dehydrated, since it is to be clarified and mounted in a material which is immiscible with water. This is accomplished by employing increasing strengths of alcohol, or isopropanol, and finally xylol.

Details of the methods follow.

Formulas for Fixatives (or Tissue Hardeners)

It has been found by Stowell[1] that isotonic saline is superior to distilled water as a Formalin diluent, reducing tissue swelling during Formalin fixation. Reagents producing marked decreases in tissue volume render such tissues less susceptible to shrinkage during subsequent procedures.

Alcohol, 96% or 100%.—

When alcohol is used as a fixative, use very small tissues and keep in alcohol at least two days, changing the alcohol frequently.

Formalin.—

We ordinarily use a 5% or 10% solution (made from the 40% gaseous solution), 5 or 10 c.c. of 40% formaldehyde to each 100 c.c. of solution.

Formol-Alcohol.—

Alcohol, 80% to 100%	2 parts
Formalin	1 part

Susa Fixative.—(See page 2170.)

Orth Mixture.—

Formalin	1 part
Mueller solution	9 parts

(Mueller solution is made up as follows: Bichromate of potassium 2.5; sodium sulphate 1; water 100.)

Acetic Acid Fixative.—

(a) 1 part acetic acid
3 parts absolute alcohol
(b) 1 part acetic acid
6 parts absolute alcohol
3 parts chloroform.

Solution (b) is good for lymph and glandular tissues. The chloroform helps penetration. Tissue is fixed more rapidly. When using alcohol-containing fixatives, omit all steps preceding the solution of the strength of alcohol used.

Wash out the acid-alcohol with 95% alcohol.

If tissue is submitted in alcohol, put it in 95% alcohol or the acid-alcohol solution above, as the exact strength of the alcohol fixative must be known.

Bouin's Fixative.—

Saturated aqueous solution of picric acid	75 c.c.
40% formaldehyde	25 c.c.
Glacial acetic acid	5 c.c.

---

[1] Stain Technology 16: No. 2, April, 1941.

This has good penetration powers. Picric acid present in the fluid, which stains the tissue, is extracted in the process of dehydration.

Zenker's Fluid.—

STOCK Zenker's fluid (fixative)

Potassium bichromate	2.5 gm.
Mercuric chloride ($HgCl_2$)	5 to 8 gm.
Distilled water	100 c.c.

Dissolve by heat.

Zenker's for use.

Glacial acetic acid	5 c.c.
Stock Zenker's	100 c.c.

Mix when ready to use.

Technic when using Zenker's fluid.—

Fix twelve to twenty-four hours, dependent upon the size of the tissue.

Wash in running water twelve to twenty-four hours.

35% alcohol	20 minutes.
50% alcohol	20 minutes.

70% alcohol with enough iodine to give it a good port-wine color. (The iodine removes the mercury.)

Keep in this solution until all the color of the iodine disappears.

Renew the iodine after it disappears and leave the tissue in the solution.

Continue the renewal of the iodine until the tissue no longer decolorizes it. At this point all mercury has been removed from the tissue. This step is very important, as the ensuing processes cannot be carried out successfully if any mercury remains in the tissue.

70% or 80% alcohol until all color (iodine) comes out of the tissue.

Proceed from this step as in the long tissue work.

Fleming Solution.—

Chromic acid 1%	15 parts
Osmic acid 2%	4 parts
Acetic acid	1 part

Use very thin pieces of tissue. Fix several days. Wash twenty-four hours in running tap water.

Regaud's Fixative.—(See page 1407.)

Solutions for Mounting

1. **Canada Balsam.** A good grade of Canada balsam for mounting slides may be purchased from any reliable chemical supply house.

2. **Gum Damar.** Dissolve gum damar in xylol until thin enough for use. (See page 2106.)

3. **Euparol** may be used. It is either colorless or green. Use the green for hematoxylin-eosin stains only. It intensifies the microscopic picture. Very often poorly stained sections mounted in euparol (green) are intensified after mounting. When mounting in euparol, take the tissues directly from the 95% alcohol, omitting the absolute alcohol and xylol steps.

Methods of Fixing Paraffin Sections to Slide

Mayer's Albumin Fixation:

This method was first described by Von Henniguy. It was later modified by P. Mayer, and still later by Von Reinke.

Beat the white of an egg until stiff and dry. Let stand until clear.

Filter through filter paper.

Add an equal volume of glycerine.

A crystal of thymol may be added as a preservative if desired.

To use this fixative, the solution is rubbed briskly over the surface of a slide, but not allowed to dry. The paraffin section is teased onto the slide in a drop of water. The excess water is removed by gentle blotting, and the section is placed in an incubator at 37° C. overnight, or gently warmed in the flame.

Preferred Method:

Use equal parts of egg white and glycerine. Beat thoroughly with a glass rod and filter through several thicknesses of gauze. Add crystal of thymol as a preservative.

Alternate Method:

Equal parts of blood serum and glycerine are mixed with 10% Formalin. To use, a faint trace of the mixture is placed on a slide.

Warm gently in a Bunsen burner, keeping the heat at about 70° C.

Pour distilled water over the slide.

Next the section is placed in the distilled water, and straightened.

The excess water is removed with filter paper.

Place the slide in the incubator at 37° C. for three or four hours,

or

Have the section in slightly warm distilled water.

Float a cover glass on the section to pick it up.

Heat the preparation to 70° C., and continue as described below.

Two Time-Saving Methods of Fixing Sections to Slides:

Two very important improvements in laboratory technic have been reported by Schneidau.[1] These methods possess distinct advantages over Mayer's albumin fixation method commonly used in laboratories for fastening microscopic sections to slides.

The first method described is as follows:

Albumin Solution.—

Egg white	one
Glycerin	50 c.c.
Sodium salicylate	1 gm.
Distilled water	1500 c.c.

Mix thoroughly and filter. Place the solution in a narrow-mouth jar equipped with a two-hole rubber stopper. Through one hole fit a bent-glass siphon to which has been attached a rubber hose containing a small pipette at the end, and a spring clamp. Place the apparatus on a shelf several feet higher than the laboratory table, start the siphon, then shut off the flow with the spring clamp. To use, assemble slides, squeeze the clamp, and allow just enough fluid to run onto each slide to float the section. Float sections by means of a section lifter, spread out by heating, and blot up excess fluid. Set aside to dry. With this method the danger of using too much or too little fixative is practically eliminated. The sections do not entirely dry, due to the glycerin present, but may be left on the slides for months before mounting without danger of drying or cracking.

A second method consists in floating the sections onto the surface of slightly warmed water to spread them out and then placing them on the slides and drying, without the use of albumin at all. Specifically, the procedure is carried out as follows: Use a pan of approximately 15″ × 10″ × 3″. Fill the pan with water and heat until it feels fairly warm to the hand (about 40° C.). While the water is being heated, cut the ribbon into squares of one section each. Take the sections up one at a time on a section lifter and drop them onto the surface of the water. Be sure that one section does not fall on top of another, as they cannot be separated once they are in the water. When all the sections that are to be affixed have been dropped on the water (no more than 100 should be worked at one time in a pan of the dimensions stated above), dip a slide into the water at an angle of about 50° until the water level is about ½ cm. above the midline of the slide. Take a straight probe or needle and, catching any of the sections by one edge, pull it over and hold it against the slide with the needle and pull both slide and needle out of the water together. The water will run out from under the section and leave it in about the center of the slide (depending, of course, upon how close to the center the section was held with the needle). This procedure is repeated until all of the sections have been placed on slides. The slides are then placed in a drying oven overnight to dry. If no drying oven or incubator is available, then the slides must be left alone for three days to insure complete evaporation of the water. Contrary to the belief of many, the sections will not wash off the slides provided they have completely dried and do not receive rough handling in the staining and mounting processes. One precaution to be observed is to see that there are no bubbles on the surface of the water that is used, as a bubble under a section will cause it to crack when dry or to wash off of the slide. This method is essentially a time-saving method, but is not as reliable as the first method described. However, if done carefully it should not cause any trouble.

---

[1] Tr. Am. Microscopical Soc. 56: 258, 1937.

General Considerations of the Formalin-Alcohol-Paraffin Method

This method can be used on all tissues.

Formalin is used because it kills, fixes, and hardens the tissue. This must be done so that the tissue remains intact, undergoing no further change. Use 10% Formalin. Formalin fixes quickly, does not shrink the tissue, nor expand it. Few tissue changes occur. It penetrates all parts equally well, including fat. It properly prepares tissue for subsequent processes.

The second step is washing in water. Use running water, or put the tissue in a bottle, changing the water frequently. All Formalin must be removed. Osmosis is the underlying principle by which penetration is accomplished by the various solutions; therefore, the steps must not be taken too rapidly.

In the dehydrating process, low-grade alcohols or weak isopropanol solutions are used first. Water is removed because paraffin is to be substituted later. Alcohol (or isopropanol) is the best dehydrating medium.

Increasing strengths of alcohol (or isopropanol) are used until the tissue is in absolute alcohol (or anhydrous isopropanol).

When the tissue is in absolute alcohol, it is too opaque for examination. It is clarified in xylol. The xylol displaces the alcohol readily and aids in the penetration of paraffin into tissue. If there is any water left in the tissue, the xylol becomes turbid; replace tissue in the absolute alcohol and transfer back to xylol again if this occurs.

Xylol and paraffin mixture is used to begin the penetration of paraffin.

Paraffin is used to complete the penetration.

The eighth step is embedding in paraffin preliminary to cutting the section.

Cut, place on the slide, and stain.

Mount and label.

Embedding Methods

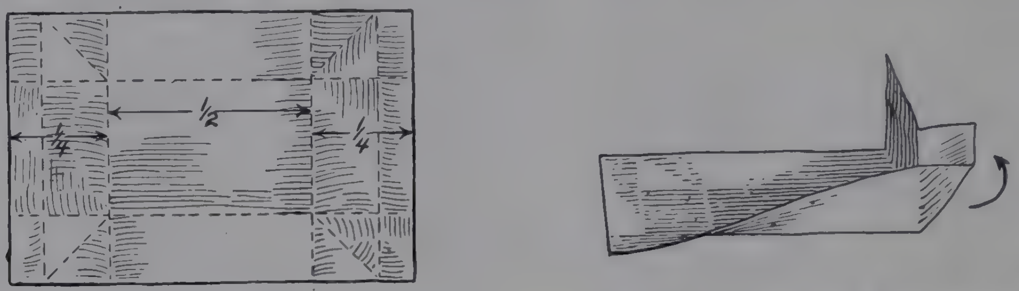
There are various embedding methods useful in histopathologic procedures. Of these, paraffin embedding is most widely used. It is particularly useful when very thin sections are desired. Tissue blocks with this material should be small, not more than 2 to 3 mm. thick. Tissues are placed in paraffin, after being dehydrated either with graded alcohols or isopropanol, and after being placed in a mixture of chloroform, xylol, or benzine. The advantages in the use of chloroform as compared with xylol are that it enables the paraffin in the mixture to partially infiltrate the tissue, and then it rapidly evaporates from the pure paraffin bath. Pure paraffin of a definite melting point is used in these procedures; the so-called ''Fisher Tissuemat''* has been used with great success. This is an embedding compound superior to the paraffin usually employed in that it will not crumble or crack; it adheres to the specimen and enables a thinner section to be cut. It is ideal for making ribbon sections. It is supplied at various melting points. Our own preference has been that with a melting point of between 56° and 58° C. Another excellent paraffin product is Histowax.† If either Tissuemat or Histowax is used for embedding, it is substituted throughout the entire procedure.

---

*Manufactured by Fisher Scientific Company, Pittsburgh, Pa.

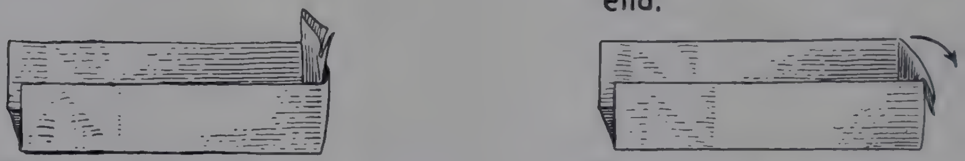
General Facts About Embedding Paraffin.—

Special paraffin is manufactured for embedding purposes. Different samples of paraffin have different melting points, and also different "plastic points."[1] Paraffin is a mixture of hydrocarbons which solidifies into characteristic types of crystals, varying to some degree with the proportion of harder and softer hydrocarbons present. The peripheral crystals are oriented with respect to the cooling surface while the center of the mass forms a meshwork (Dempster, 1941). The "plastic point" is the lowest temperature at which permanent deformation may be made without fracture. A paraffin with low plastic point appears more translucent, is less brittle, but compresses more in sectioning. The hardness of paraffin depends on its plastic point which lies a few, but variable number of, degrees below the melting point. Consequently, the plastic point or, more roughly, the melting point of the paraffin has to be adapted to the temperature of the room in which the sectioning is being done.[2] In warm rooms, higher melting point paraffins must be used than in colder laboratories. The alternative is to condition the paraffin by the addition of various materials. Bayberry wax, rubber, and other waxes may be added to paraffin to improve its plasticity and cutting qualities.



① Crease on dotted lines

② Fold up one end and one side. Fold projecting flap against the end.



③ Repeat with adjoining corner.

④ Fold over and crease the projecting end-flap to lock the corner joints.

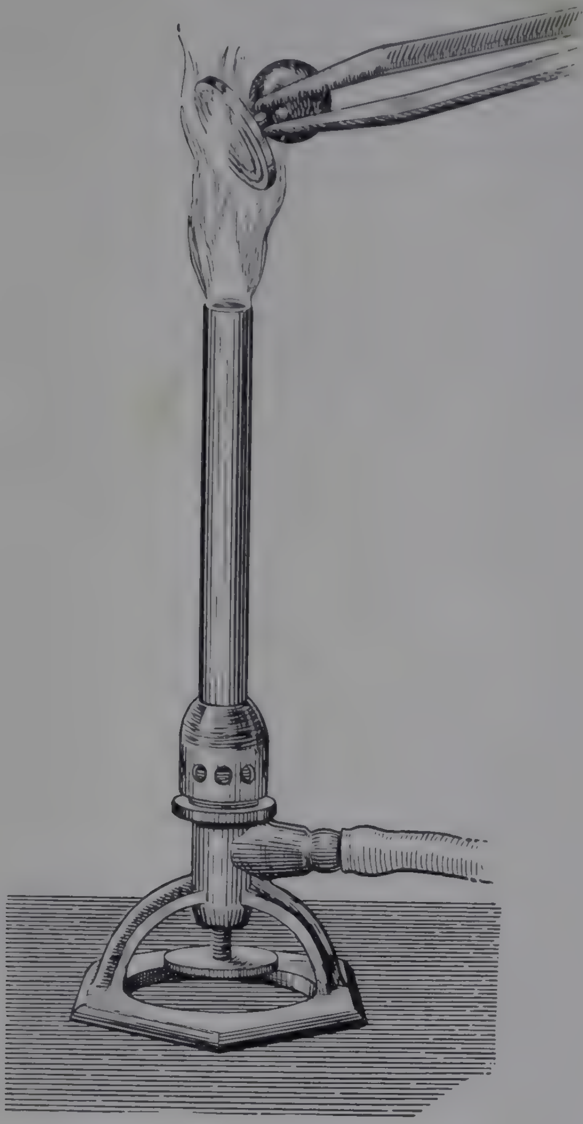

Fig. 620.—Heating the paraffin microtome pivot.

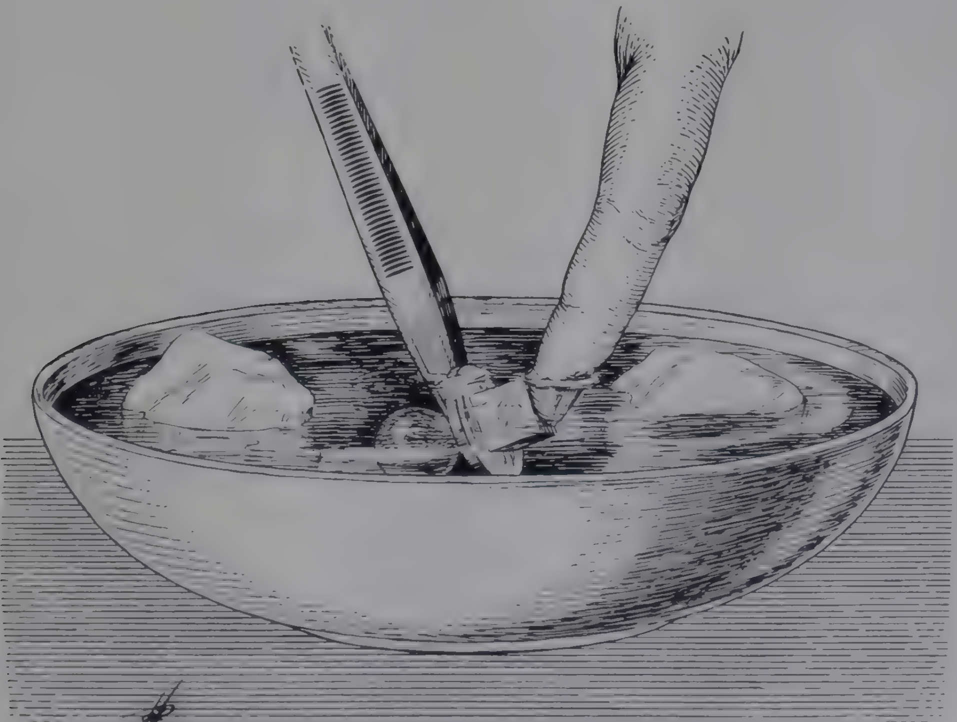

Fig. 621.—Cooling the paraffin block after mounting it on the pivot.

In addition to matching the hardness of the paraffin to the temperature at which it is to be sectioned, it is necessary to match the hardness of the paraffin to the hardness of the tissue. The hardness of the tissue depends upon the preparatory treatment and its structure. The actual process of sectioning leads to distortion so that the sections will be slightly thicker and a little shorter than the block itself. This distortion results from the nature of the paraffin, the tissue, and the action of the knife. Large crystals are sectioned or pushed apart by the wedging of the knife, especially when the paraffin is brittle and has a high plastic point. This upsetting of crystals gives the velvety appearance to the topside of the section.

When the crystals are not of proper size to fit closely to the tissue, they cannot support the tissue adequately, and local deformation will occur, giving a section which cannot be completely flattened out. Small folds show when the thin parts are smaller than the size of the paraffin crystals and compress less than the paraffin. The crystals show clearly in polarized light. All microtomists should examine a section from each batch of paraffin with a polarizing microscope. A finer crystalline paraffin gives adequate support.

Warm paraffin shrinks as it cools and compresses the tissue in the block. Tissue that is harder than the paraffin withstands this pressure, but soft or spongy tissue may be under considerable strain. When sectioned, the tissue tends to expand to the shape and size it had before compression, and if confined by the paraffin around it, pleating or wrinkling results. Stowell[3] reported that Parowax shrinks in volume 14.3 per cent on cooling from 59° to 20° C.

Unless the hardness of the paraffin is adapted to the temperature at which the cutting is done and the nature of the tissue, good sections may not be expected, regardless of the excellence of the microtome and sectioning knife. When the material has been properly dehydrated, it is possible to re-embed it in another paraffin should the first not prove satisfactory. Poorly prepared tissue can rarely be salvaged. Several changes of the melted paraffin should be used to wash out the former paraffin.

TECHNIC OF EMBEDDING AND CUTTING PARAFFIN SECTIONS

Alcohol Dehydration Method for Paraffin Embedding

Reagents.—

10% Formalin.—See page 2102.

50% Alcohol.—Dilute 50 c.c. of 95% alcohol to 95 c.c. with distilled water.

70% Alcohol.—Dilute 70 c.c. of 95% alcohol to 95 c.c. with distilled water.

80% Alcohol.—Dilute 80 c.c. of 95% alcohol to 95 c.c. with distilled water.

100% Alcohol.—Absolute alcohol can be kept at 100% concentration by mixing it with pulverized copper sulphate which has been previously dehydrated. The copper sulphate falls to the bottom of the bottle, the 100% alcohol remaining above.

Xylol.—Purchase chemically pure or U.S.P. xylol (xylene water- and acid-free).

Xylol-Paraffin Mixture.—Mix 1 ounce of pure xylol with 1 ounce of special paraffin, and keep in a warm (not hot) place.

Pure Paraffin.—We suggest the use of pure paraffin, melting point 56° to 58° C., made by Arthur H. Thomas Co. or Matheson Coleman & Bell Inc., or Fisher Scientific Company.

---

[3] Stain Tech. **16**: 67, 1941.

Fisher Tissuemat.—This is an embedding compound manufactured by Fisher Scientific Company, Pittsburgh, Pa. It is superior to paraffin because it will neither crumble nor crack when being cut on the microtome. It is well adapted for ribbon sections since it coheres during slicing and facilitates the cutting of very thin slices. This material is also more convenient to use than paraffin cakes because it is supplied in granular form. It melts rapidly and obviates the necessity of cutting large cakes. The granules are protected by an inner container of cellophane.

"Tissuemat" is available in five melting point ranges.

Histowax.—Histowax is an embedding compound manufactured by Matheson-Coleman & Bell Division, The Matheson Company, Inc., E. Rutherford, N. J. It is an excellent substitute for paraffin, will not crumble or crack during the cutting process, and is well adapted for making ribbon sections.

Mayer's Albumin Fixative.—See page 2115.

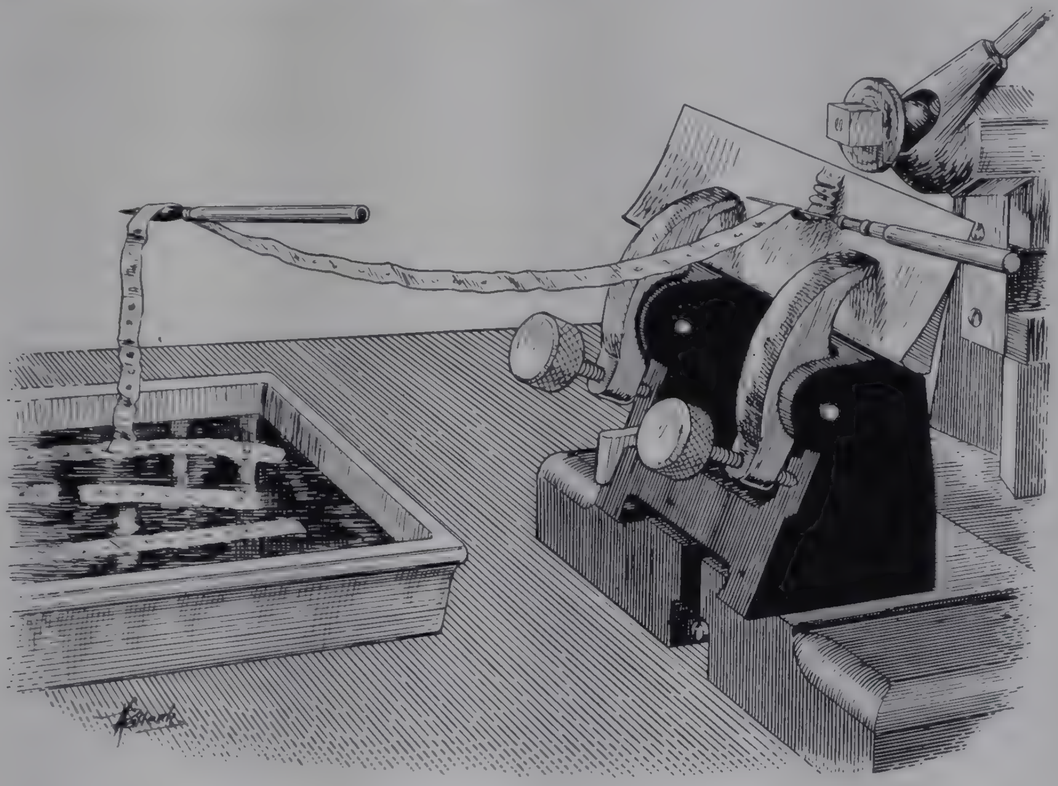

Fig. 622.—Cutting paraffin sections and floating the ribbons on warm water.

Technic.—

1. The pathologist removes the portions of tissue for examination. These should preferably be not thicker than ¼ inch. Keep in Formalin (10%) *at least* two hours. After a month in Formalin, it is difficult to treat the section.

2. Wash one hour in tap water, or a shorter time in running water to remove the Formalin. The tissue may be kept in the same bottle throughout the dehydrating and clarifying processes.

3. 50% alcohol[1]	1 hr. (longer, if necessary. Stopping point is one hour)
70% alcohol	1 hr. (longer, if necessary. Stopping point is one hour)
80% alcohol	1 hr. (longer, if necessary. Stopping point is one hour)
95% alcohol	1 hr. (longer, if necessary. Stopping point is one hour)
100% alcohol	not more than 1 hour.

These solutions may be used repeatedly until a sediment appears.

4. Xylol one hour to clear. If not clear, immerse for a longer period. It is opaque until placed in xylol, when the edges become clear. If there are milky or chalky spots in the tissue, put it back in 95% alcohol, then absolute alcohol, then xylol.

5. Xylol-paraffin (equal parts)—all night with just enough heat to keep liquid. DO NOT PUT IN THE PARAFFIN OVEN.

---

[1] Isopropanol of appropriate strength may be substituted for alcohol in all dehydrating processes, but *not* in the staining solution formulas.

6. Next morning. Pure paraffin two to two and one-half hours at 58° to 60° C.

7. Pure paraffin again. Tissues can be left here a day if necessary. (Four to five hours is all that is necessary.) The oven must not be hotter than 58° to 60° C.

8. Embed or orient. Use paper box or "boat." This may be made of a piece of paper or piece of tin foil about 0.1 mm. thick. This is easily done by folding the tin foil around a small block of wood with rectangular surface or by following directions illustrated in Figs. 618 and 619. Fill this container almost full with paraffin. Transfer the object into it with the aid of a warm spatula. Arrange it in the center of the container and have the whole float in a bowl of cold water. The paraffin congeals rapidly. After the first skin of paraffin appears on the surface, the "boat" may be dipped into the water. In a few minutes' time the paraffin is rigid and the tin foil may be removed. The paraffin block with the enclosed object may be kept for any length of time.

Place the section in paraffin with the side to be cut facing the bottom of the box. Float in cold water until a firm scum appears on the top of the paraffin. Submerge in the water and hold there until the paraffin has hardened. Cut out blocks containing the tissue, leaving an edge of paraffin about 1 cm. wide around the tissue. Opposite sides should be cut parallel. The block should be square or rectangular. Edges parallel to the knife must be parallel to each other.

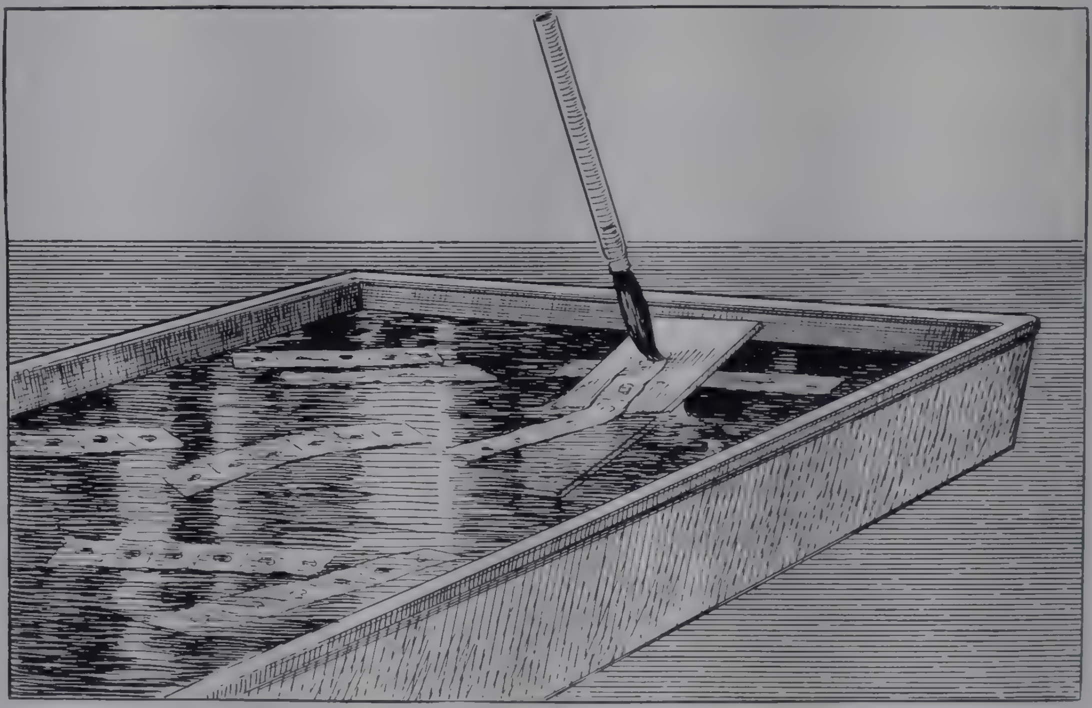

Fig. 623.—Placing paraffin sections on a glass slide.

9. Place on wooden block or pivot. Label back of block or pivot and retain the label throughout the process.

10. Cut tissue (see below). Cut it at right angles and parallel to the surface of the organ. The knife must be sharp. Cut the tissue 6 to 10 microns thick, or thinner if possible.

11. Rub Mayer's albumin fixative on the surfaces of glass slides. Sections are floated in warm water. Place tissue on slide.

12. Allow to stand in an upright position several hours to dry.

13. Stain, mount, and label.

Preferred Methods for Routine Paraffin Embedding

A. Rapid Method (Krajian).[1]—

Fix thin blocks of tissue in 10 per cent formaldehyde for 16 to 24 hours. In emergency cases, fix for one-half hour in paraffin oven at 56° C.

Place in acetone for 1 hour, using at least 20 times as much acetone as tissue.

---

[1] Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, ed. 2, pp. 91 and 92. The C. V. Mosby Co., 1952.

Place in a second acetone for 1 hour, using the same quantity of acetone.

Place in benzine for 30 minutes.

Place in second benzine for 30 minutes.

Place in paraffin No. 1 in the paraffin oven for 1 hour.

Place in paraffin No. 2 in the paraffin oven for 1 hour.

Embed in the usual manner.

B. Slower Method (Krajian).—

Fix tissues as usual in 10 per cent formaldehyde.

Dehydrate in 70 per cent alcohol for 2 to 3 hours.

Dehydrate in 80 per cent alcohol for 2 to 3 hours.

Dehydrate in 95 per cent alcohol for 2 to 3 hours.

Dehydrate in a second 95 per cent alcohol for 2 to 3 hours.

Dehydrate in absolute alcohol for 2 to 3 hours.

Place in chloroform for 2 hours.

Place in the paraffin oven at 55° C. in a mixture of equal parts of chloroform and melted paraffin for 2 to 3 hours.

Place in pure paraffin in the paraffin oven at 55° C. for 2 to 3 hours.

Embed in the usual manner.

Krajian suggests that the acetone-benzine method be used for surgical tissues, while the longer method be reserved for sectioning tissues removed at autopsy.

C. A Benzine Method has been advocated by Krajian as follows:

1. Dehydrate tissues in 70 per cent alcohol 2-3 hours.
2. Dehydrate tissues in 80 per cent alcohol 2-3 hours.
3. Dehydrate tissues in 95 per cent alcohol 2-3 hours.
4. Dehydrate tissues in 95 per cent alcohol 2-3 hours.
5. Dehydrate tissues in absolute alcohol for 2-3 hours.
6. Benzine for 2-3 hours.
7. Benzine and melted paraffin, equal parts, in the paraffin oven at 55° C. for 2-3 hours (for the evaporation of benzine, leave the corks out of the bottle, otherwise the fumes may cause an explosion).
8. Pure melted paraffin in the paraffin oven at 55° C. for 2-3 hours.
9. Second paraffin bath in paraffin oven at 55° C. for 2-3 hours.

The Use of Dioxane or Isopropanol in the Process of Embedding

Dioxane.—The use of a series of graded alcohols, xylol, etc., described above in the preparation of animal tissues requires time and necessitates the constant attention of the worker. One of the bugbears in paraffin work is over-hardening of the object, making it difficult or impossible to section without tearing or cracking the microscopic sections.

For this purpose, an agent called ''dioxane'' (diethyl-dioxide) has been suggested and has proved remarkably efficient. It is miscible in all proportions with water and gives up water and methyl or ethyl alcohol to anhydrous calcium chloride; it is also miscible with melted paraffin. When one puts a piece of tissue into an alcoholic solution containing calcium chloride, the water is removed and the tissue is permeated with dioxane. Upon transfer of such a specimen to molten paraffin the dioxane is removed and the tissue infiltrated with paraffin ready for sectioning when cooled.

Technic.—

Use a vessel with the bottom covered with calcium chloride over which there is placed a fine wire net, on which the objects are placed.

Cover the vessel to prevent evaporation of the dioxane and absorption of water from the atmosphere.

After fixation, take the specimen from the fluid (Formalin) and place it directly into the dioxane and leave it there for 3 to 24 hours.

Transfer to the oven at 55-60° C. into a mixture of one-third dioxane and two-thirds paraffin and then into pure paraffin.

Keep the pure paraffin in a dish with gauze a short distance above the bottom as the dioxane tends to sink through it.

Isopropanol.—The use of isopropanol to replace graded alcohols, absolute alcohol, and xylol, except when reference is made to acid alcohol, is also recommended. It is very economical, being considerably cheaper than alcohol. Both isopropanol and dioxane are furnished by the Carbide and Carbon Chemical Corporation, 30 E. 42nd. St., New York, N. Y.

Cutting Paraffin-Embedded Sections*

Metal or wooden object holders are used to mount the paraffin block on the microtome. Metal holders are preferred. Warm the holder enough to melt the paraffin. Press the paraffin block onto the holder, then pass a hot needle around the edges of the base of the block to aid in firmly attaching it to the holder. If the blocks are large, it may be necessary to run a hot needle under the center of the block to aid in attaching it. After sectioning, remove the remainder of the block from the holder, label it with an adhesive or other type label, and store in the refrigerator.

When the object holder and paraffin block have cooled, proceed with the cutting. Set the microtome knife at a 90° angle to the direction of the cut (no slice angle) and tilt it to as little clearance as will give good sections (2 to 6°). Be sure the knife is *sharp* and shows no serrations.

Use the pencil type of camel's hair brush to handle the ribbon (unless single sections are to be made). Sometimes it is necessary to hold the first few sections onto the knife with gentle pressure of the brush until the ribbon forms. Set the automatic lift on the microtome for the desired thickness of the section and begin the cutting process. Raise the end of the ribbon with a dissecting needle over the brush. Withdraw this from the knife (with the left hand) as the ribbon lengthens, turning the microtome wheel with the right hand. Speed of cutting varies with the tissue. Proceed until the ribbon lengthens to a point where it is too long to handle. Place the ribbon lengths on smooth paper or in a shallow box until they are mounted on slides. Experience is required to cut serial sections without the loss of parts of the ribbon. Do not allow the brush to come in contact with the knife, or it will be spoiled. Do not use a dissecting needle in place of the brush, for, in case of accident of this type, the knife will be damaged.

One great inconvenience of paraffin sectioning, particularly in winter or if the atmosphere is dry, is the flying of sections and their sticking to parts of the microtome and other nearby objects due to static electrical charge generated by the friction of cutting. Raise the humidity by boiling water in the room or burning a Bunsen burner near the microtome to alleviate this difficulty. Sometimes it is necessary to ground the microtome to a nearby water pipe, using a wire or a chain.

After cutting the ribbon, it must usually be flattened before the sections may be attached firmly and evenly to the slide. Two methods are in general use:

1. Cut the ribbon into convenient lengths. Place on the slide containing albumin fixative. Add a few drops of water to the slide, and warm it gently until the sections expand to their full size.
2. Place the pieces of the ribbon onto warm water, allow to expand, and recover them by placing a slide containing a fixative under the tissues to pick them up.

Water used for "floating out" should be 5 to 7 degrees cooler than the melting point of the paraffin. Commercial wetting agents may be added to the water if desired. Do not stretch the section with needles, or by gravity by holding the slide perpendicular when draining off the excess water.

Tissue Flotation Bath[1]

The tissue flotation bath, with automatic temperature regulation, is an excellent and convenient apparatus for floating and spreading of tissue sections embedded in paraffin, preparatory to mounting. Bath temperatures can be controlled to within ± 1° C. in the range from room temperature to 60° C. It consists of a Pyrex glass tray, 10½ inches long by 6½ inches wide by 2 inches deep, and a low, insulated, Monel metal stand with flat copper top and built-in heating unit, thermoregulator, and pilot lamp. The top has raised edges, and a black oxidized finish, which aids in the inspection of translucent sections. The glass tray is readily removable for cleaning. The power consumption is 225 watts.

---

*See O. W. Richards: The Effective Use and Proper Care of the Microtome, American Optical Co., Scientific Instruments Division, Buffalo, N. Y.

[1] The tissue flotation bath is obtainable from Arthur H. Thomas Company, West Washington Square, Philadelphia 5, Pa.

See Figs. 616 and 624.

Difficulties in Cutting

1. As block is being cut, there is a gritty feeling or a scratchy noise. Paraffin oven was too hot, or there is dirt in the paraffin.

2. Fixing agent may have crystallized and not washed out with water.

3. Sections jam on the knife: knife is dull, or paraffin is too soft, or paraffin has accumulated on the edge of the knife. Clean with xylol.

4. Paraffin rolls: knife is dull, or sections are too thick.

5. Objects crumble and drop out of the paraffin: insufficient paraffin penetration before embedding.

6. Ridges on specimen: nicks in knife or paraffin accumulated on edge of knife.

7. White patches near tissue in paraffin: caused by xylol carried into paraffin. Re-embed if near tissue. Cut off if near edge of block.

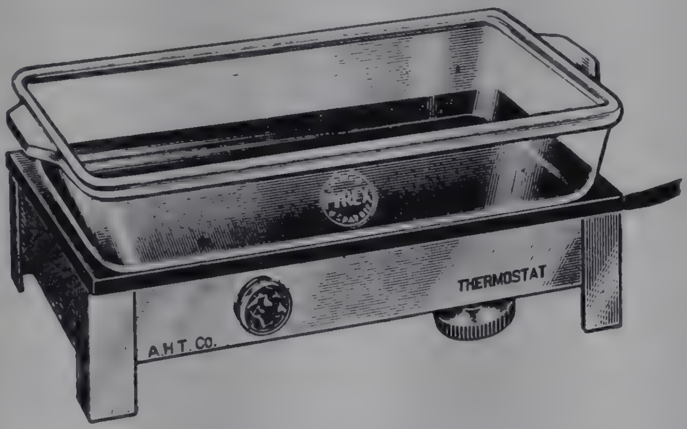

Fig. 624.—The tissue flotation bath. (Courtesy Arthur H. Thomas Co., Philadelphia.)

Difficulties Encountered in Cutting Ribbons

1. Ribbons fail to form. (a) Room is too cold or paraffin is too hard. Use softer (lower melting point) paraffin; warm knife slightly by blowing the breath on it, or immersing in *warm* (not hot) water; or place a desk lamp so that the light and heat fall on the knife and block. (b) Tilt the knife less. (c) Cut thinner sections. (d) Knife may be too dull—resharpen. (e) Dip block into a softer paraffin and trim so that a thin layer remains on the upper and lower edges of the block. (f) Unroll the section and hold it lightly against the knife with a camel's hair brush. If the first few sections can be held down, the ribbon will often form and follow.

2. Crooked ribbons. (a) When sections are wedge shaped the sides of the block are not trimmed parallel. (b) Edge of block may not be parallel to knife edge. (c) Try another part of the knife—sometimes irregularities of the knife edge cause crooked ribbons. (d) Or, the paraffin at one side of the block may be softer than at the other side, especially if the material has been re-embedded in a paraffin of different hardness—re-embed the material and stir the melted paraffin.

3. Sections compressed, wrinkled and jammed together. (a) The knife may be too dull. (b) Or, the room may be too warm; cool trimmed block and knife in very cold or ice water immediately before sectioning, or re-embed in a harder paraffin. (c) Tilt the knife more; the knife tilt may be too slight so facet bevel rubs over block. (d) The knife edge may be gummed with paraffin; wipe with finger or cotton moistened with xylol. (e) Soak block in water from an hour or two to overnight before cutting. (f) If cutting is done too rapidly, thin tissues will wrinkle.

4. Sections crumble and specimen may tear out. (a) Material incompletely dehydrated or not properly cleared. (b) When soft and mushy, material incompletely infiltrated —reinfiltrate and embed. (Salvage rarely possible if material was incompletely dehydrated.) (c) Alcohol not completely removed by clearing fluid. (d) Object too long in paraffin bath or paraffin too hot. (e) Subject hard and brittle due to clearing fluid. Try toluene in place of xylol or a mixture of toluene and cedar oil. (f) Try celloidin embedding or a rubber or asphalt mixture with paraffin for fragile material. (g) Try dioxane method for dehydrating.

5. Split ribbon or lengthwise scratches in ribbon. (a) If there are nicks in knife, resharpen or use another knife. (b) Use less tilt of knife so it will cut rather than scrape. (c) Knife edge may be dirty. (d) Object may be too large for paraffin method—use celloidin. (e) Hard particles in block may cause scratching. If there is dirt in the paraffin, filter or decant melted paraffin. There may be crystals from killing fluid (mercuric chloride); washing was insufficient. If calcareous or silicious particles are present, decalcify or desilicify.

6. Knife rings on up stroke and sections are scratched. (a) Change knife tilt to greater or lesser degree—tilt must be sufficient to clear facet bevel, but not enough to scrape instead of cut. (b) Material is too hard. Soak in water to soften; clearing may be at fault. (c) A thicker or wedge shaped knife may prevent springing of the edge when cutting. (d) Material may be too tough for paraffin method—try celloidin.

7. Sections lifted from knife on up stroke. (a) Increase knife tilt. (b) Room too warm or paraffin too soft—try harder paraffin or cooler room; or cool the block. (c) Knife may be dull—resharpen.

8. Sections stick to knife. (a) Knife edge dirty. (b) Increase knife tilt. (c) Try a sharper knife.

9. Undulations in the surface of the section. (a) Tighten all screws on knife and block holders and see that knife holder is clamped fast to microtome base. (b) Lessen excessive knife tilt to prevent vibration.

10. Scratching noise during cutting. (a) Material may be too hard, or small regions of material may be hard.

11. Sections fly and stick to parts of microtome or other nearby objects, due to static electricity formed from the friction of cutting. This usually occurs only in winter when the air is very dry. (a) Increase humidity of room by boiling water in an open pan, or burn a Bunsen burner in the room. (b) Ground microtome to a water pipe with a wire or a chain. (c) Ionize the air by an electrical method.

12. Sections vary in thickness or are skipped. (a) Knife not tilted enough to clear facet or bevel, or tilted too much, and tissue is compressed until the inevitable expansion gives a thick section. (b) Some of the clamping set screws on the block or knife holder are not tight or knife holder block not clamped firmly. (c) Microtome worn through lack of lubrication, or not in adjustment. (d) Very large blocks or blocks with hard regions may spring knife edge while sectioning—soak block in water to soften, use other methods for softening the material or embed in celloidin. The block will soak quicker if the paraffin is trimmed off one side to expose the tissue. Very little water is absorbed, but this process sometimes makes possible cutting hard or tough material.

TECHNIC OF EMBEDDING AND CUTTING CELLOIDIN SECTIONS[1]

Celloidin methods are used for large tissues and organs and for hard or delicate materials. The celloidin is not removed from the tissues and holds the delicate structures permanently together.

The material to be cut is embedded in one of the commercial celloidins (cellulose nitrate), the slow burning kinds being preferred. The disadvantages of the method are longer embedding time; serial sections cannot be cut, so that each section has to be handled individually; only dyes which do not stain celloidin may be used.

---

[1] See O. W. Richards: The Effective Use and Proper Care of the Microtome, published by American Optical Co., Scientific Instruments Division, Buffalo, N. Y.

For materials not injured by moderate amounts of heat, the rapid process facilitates impregnation and preparation of the tissue. The slower, cold process takes more time and does not damage the tissue. It may not be possible to embed a hemisphere of a brain or a whole lung and harden it sufficiently for cutting in less than six months to one year.

The chief difficulty in celloidin sectioning arises from trying to cut improperly prepared material. Inadequately hardened blocks cannot be sectioned successfully. The blocks should be dense enough to cut at the required thickness. Unless the block is sufficiently hardened, the sections are uneven and distorted. If the block is too hard, irregularities are apt to occur. The surface of the block and the surface of the knife should be kept wet with 70% alcohol and as soon as the sections are removed they should be placed in alcohol.

The sliding microtome is the instrument of choice for cutting celloidin material, using a slice angle of 10 to 40°.

Tilt the knife a little more than for cutting with paraffin though the actual tilt will depend upon the hardness of the tissue. It is convenient to let large sections roll up on the knife. Then lift off of the knife and unroll into 70 per cent alcohol. Or remove the sections from the knife and lay a piece of filter paper on top of the section. It usually adheres to the filter paper and then both may be placed in a Stender dish. If the filter papers are numbered they may be kept in order. Or, stamp a number on the margin of the section with a commercial numbering machine as each one is cut.

The knife for sectioning celloidin-embedded tissue must be very sharp. Any irregularities in the edge will leave marks on the section. Keep the section and materials for embedding free from dust. Dust particles catching on the edge of the knife spoil the section, particularly when very thin sections are required. Remove silicious or calcareous material before sectioning. Do not allow the surface to dry. If it is necessary to stop sectioning for even a short time, cover the block with absorbent cotton and saturate with alcohol, or remove the block and place in alcohol or other storage liquid.

The so-called dry process has been developed to replace the method which requires keeping the block and knife wet with alcohol. After the tissue is embedded and hardened, soak the block in an oil (cedar oil) which lubricates the block during cutting. As the sections are removed from the knife, place them in the same oil. The oil-soaked block may be cut on a rotary microtome, as no slicing cut is required. This method is exceptionally good for making sections of difficult organs, such as the entire mammalian eye.

Special knife holders are available so that the knife can be turned to give a slicing stroke and may be used for cutting small celloidin blocks on a rotary microtome. The position of the block and knife is such, however, that it is difficult to keep the surfaces properly lubricated with alcohol so that the rotary microtome is not very satisfactory for this type of sectioning. If much sectioning in celloidin must be done on a rotary microtome, it is advisable to use the dry method which does not require a slicing stroke.

Celloidin embedded blocks are sometimes embedded in paraffin to hold them for sectioning. The size of the section which may be cut depends on the size of the microtome and the knife and the skill of the operator.

Celloidin Embedding, Method 1

For celloidin embedding we use a thin and a thick solution of celloidin. These two solutions are made as described below and placed in glass-stoppered, dark bottles to prevent the action of light and avoid evaporation of the ether. Entrance of air tends to cloud the celloidin and makes it unfit for use. If there is no need for hurry in the preparation of these specimens, the following technic may be changed so as to place the specimens one day in 1%, one day in 2%, one day in 4%, and several days in the 8 to 10% celloidin.

This method is very useful for certain types of tissue, particularly the eye.

1. Fix tissue in 10% Formalin.
2. 50% alcohol for twenty-four hours.
3. 70% alcohol for twenty-four hours.
4. 80% alcohol for twenty-four hours.
5. 95% alcohol for twenty-four hours.
6. Absolute alcohol for twenty-four hours.
7. Equal parts of absolute alcohol and ether for twenty-four hours.
8. Sections in thin celloidin 3% for twenty-four to forty-eight hours.
9. Place specimens in thick celloidin 6% to 12% for twenty-four to forty-eight hours.
10. The tissue is placed in thick celloidin in a small paper box and then under a bell jar in concentrated sulphuric acid in a dish until the specimen is firm. This removes all of the aqueous contents. If the embedded specimen shows any air spaces in the preparation, it is necessary to open these holes so as to let the celloidin enter better.
11. Remove sulphuric acid and put in chloroform. Let stand twenty-four hours.
12. Trim celloidin off around tissue, but do not trim too close.
13. Place celloidin block in equal parts of chloroform and cedarwood oil for twenty-four hours. Add a few grains of copper sulphate.
14. Mount on block of fiber. This can be carried out by placing a few drops of the thick celloidin on top of the block and then firmly pressing the specimen against it. Then place in cedarwood oil for two days.
15. Cut sections with sliding microtome, with the knife at an angle of 45° to the specimen. The knife should be constantly wet with alcohol while cutting, so that specimens will not be torn.
16. Place sections in 80% alcohol until ready to stain and until oil is removed.
17. Stain. Staining is carried out in just the same manner as paraffin sections are stained. (See page 2129 ff.)
18. Mount stained specimens on slide.

Celloidin Embedding, Method 2

There are various methods of using celloidin as an embedding material. Tissues for this type of embedding must be hardened and dehydrated for 24 hours in 80 per cent alcohol, followed by 24 hours in 95 per cent alcohol, and finally in absolute alcohol for an equal period. They are then soaked in a mixture of equal parts of alcohol and ether for 24 to 72 hours.

Impregnate in medium celloidin solution from 2 to 4 days, depending upon the thickness and consistency of the tissue.

Place in thick celloidin from 3 to 6 days. Blocks are then embedded in paper boxes or are mounted on vulcanized fiber. To harden the celloidin, leave the blocks exposed to the air until the celloidin mass has attained the right consistency. Then place the blocks in a dish containing pure chloroform, where they remain from 2 to 24 hours, and then place them in 80 per cent alcohol.

Directions for cutting celloidin sections are different from those for paraffin sectioning. First, a sliding microtome is used. The cutting movement should be slow and shearing. The surface of the knife should be kept constantly wet with 80 per cent alcohol from an overhanging drop bottle. Sections are removed from the knife, when cut, with a camel's hair brush and placed in 80 per cent alcohol. These sections are not fixed to the slides until they are ready for mounting. In other words, they are stained in watch glasses. It is not necessary to remove the celloidin to stain this type of section. During the process of staining, celloidin sections are likely to swell up and shrink. To flatten them, treat in equal parts of absolute alcohol and oil of cloves for 2 or 3 minutes before placing in xylol.

Thick and Thin Celloidin

Thick celloidin is made by dissolving 30 grams of dry celloidin in 450 c.c. of a mixture of equal parts of ether and absolute alcohol. Shake the receptacle several times a day for one week or longer and stir the sediment with a heavy glass rod at least once a day until solution is complete. Medium celloidin is made by diluting thick celloidin with an equal amount of ether and alcohol mixture. Thin celloidin is made as follows: Dry celloidin—12 grams; ether—200 c.c.; absolute alcohol—200 c.c. Shake until all celloidin is dissolved.

Difficulties Encountered in Handling Celloidin Embedded Material*

1. The chief difficulty comes from trying to cut improperly prepared material. Adequate impregnation of a large organ like a hemisphere of a brain may take a year. Improperly hardened blocks cannot be sectioned successfully. Pressure methods involving heat speed up the process and are available when warming will not injure the material.

2. Lengthwise scratches or splits in the section may be due to:

(a) Nicks in the knife. Use a different part of the knife or resharpen. (b) Particles of hard material in the block. Dust or dirt in the celloidin stock solution—let stand and use only upper portion after the particles have settled out or filter the stock solution. If calcareous or silicious deposits are present, decalcify or desilicify.

3. Specimen falls out of section, is mushy and soft. (a) Dehydration was incomplete. (b) Infiltration was incomplete—refilter, re-embed, and harden. (c) Harden block if too soft, in chloroform, or a mixture of equal parts of 95% alcohol and glycerin.

4. Variation in thickness of sections. (a) Loose screws on knife or block holders—tighten all set screws. (b) Knife holder depressed or raised by the hand while sectioning—hold knife block so as not to move it vertically while cutting. (c) Knife not tilted enough to clear facet of cutting bevel. (d) Knife too dull. (e) Microtome worn and out of adjustment. (f) Material not hardened properly. (g) Slight drying of block between sections.

STAINING TECHNIC FOR PARAFFIN AND CELLOIDIN SECTIONS

Staining Technic for Paraffin Sections

Method No. 1. Recommended Procedure[1]

This method is an adaptation of the staining technic devised by Krajian[2] for staining frozen sections. It gives excellent results. With this method sections are seldom lost during the staining process.

Prepare paraffin sections in the usual manner. Cut them as thin as possible, and mount on a glass slide without fixative. If a fixative is considered necessary, use Mayer albumin fixative. Allow the tissues to dry on the slide. Carry out the process from here in staining jars.

Place slides in xylol No. 1 in a Koplin jar for five minutes.

Transfer to xylol No. 2 in a staining jar for another five minutes to insure removal of paraffin from sections. If necessary, use a third xylol bath.

Place slides in anhydrous isopropanol or absolute alcohol to remove the xylol. This usually requires five minutes.

Blot twice with several thicknesses of Whatman No. 1 filter paper.

Immediately dip twice in thin celloidin (page 2105). Keep the slide perpendicular while dipping, and dip quickly, but not suddenly. Do not turn the slide while dipping in and out. Blow gently over the slide while holding it in a perpendicular position. Continue the gentle blowing until the celloidin is dry. Wipe the celloidin off the back of the slide. The slide is now ready to be stained.

---

[2] Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, St. Louis, 1952, The C. V. Mosby Co.

Carry out the staining technic from this point as for frozen sections, method of Krajian, page 2105.

Method No. 2 for Staining Paraffin Sections

Reagents.—

The **various alcohols** are described on page 2120.

Delafield's Hematoxylin.—

Make a saturated solution of ammonium alum in distilled water.
Dissolve 4 gm. hematoxylin crystals
in 25 c.c. 95% alcohol
Add 400 c.c. saturated solution of ammonium alum.

Place in a Mason jar. Place the cover on lightly, and put in the light and air for one or two weeks.

Add 100 c.c. methyl alcohol (acetone-free)
and 100 c.c. glycerin.

Keep in a bottle exposed to the sunlight until ready for use. It usually requires at least one month for the hematoxylin to ripen.

Harris' Hematoxylin.—See page 2105.

Boehmer's Hematoxylin.—See page 2135.

Ehrlich's Hematoxylin.—

1. Hematoxylin	2 gm.
Absolute alcohol	10 c.c.
Glacial acetic acid	10 c.c.

Dissolve the hematoxylin in the mixture of alcohol and acetic acid.

2. Add 90 c.c. absolute alcohol to
100 c.c. glycerin, and mix
3. Add the hematoxylin solution to the alcohol-glycerin mixture.
4. Dissolve 10 gm. of potassium alum
in 100 c.c. distilled water with heat.
Cool.
5. Add the alum solution to the hematoxylin-alcohol-acetic acid-glycerin mixture, stirring constantly.
6. Expose the solution to light and air to "ripen" for 4 to 6 weeks. If the solution stands in a warm place and is shaken occasionally, oxidation is facilitated, and the ripening process is aided materially. The ripe solution should have the color of port wine.

Mallory's Phosphotungstic Acid Hematoxylin.—See page 2155.

Acid Alcohol.—Add 1 c.c. of chemically pure concentrated hydrochloric acid to enough 70% alcohol to make 100 c.c. total.

Alkaline Alcohol.—

(a) Dissolve 2 grams of sodium bicarbonate in 100 c.c. of 70% alcohol,

or

(b) Add 1 c.c. of concentrated ammonium hydroxide to enough 70% alcohol to make 100 c.c. total.

0.5% Alcoholic Eosin.—

Dissolve 500 mg. of eosin in 100 c.c. 95% alcohol.

Technic.—

All solutions are put in Koplin jars, or large staining jars, Figs. 611 and 625, and the jars arranged in the proper sequence. When transferring slides from one solution to another, catch the excess solution on a cloth as it drains off.

DO NOT LET THE TISSUE DRY DURING THE STAINING PROCESS.

Immerse in xylol five minutes to dissolve the paraffin.

Absolute alcohol	1 minute.
95% alcohol	1 minute.
80% alcohol	1 minute.

70% alcohol -- 1 minute.
50% alcohol -- 1 minute.
Do not make changes too rapidly, or tissue may fall off the slide.
Tap water -- 1 minute.

Hematoxylin. (Delafield's, Harris,' or Ehrlich's. Harris' is preferred. Hematoxylin accomplishes the basic staining of the nuclei—five minutes or longer. If tissue is not the correct shade of purplish blue, replace in the hematoxylin. Look at the section under the microscope to determine the correct intensity of the stain.

Tap water until no more color comes off.

50% alcohol. Wash. Just put the slide in and out.

Acid alcohol. (1% hydrochloric acid in 70% alcohol.) Dip the slide in the jar, then hold it above until the tissue is salmon pink. DO NOT DECOLORIZE TOO LONG.

Alkaline alcohol until blue. (2% sodium bicarbonate in 70% alcohol or 1% ammonium hydroxide in 70% alcohol.)

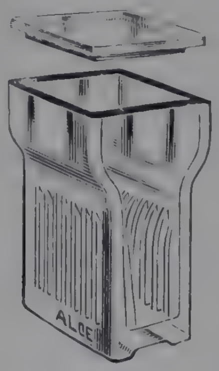

Fig. 625.—Wide top staining jar. (Courtesy A. S. Aloe Co., St. Louis, Mo.)

Look at tissue under microscope to ascertain whether nuclei are sufficiently blue. If they are not replace the slide in acid alcohol, then 50% alcohol, then water, then hematoxylin, then continue on from this point.

80% alcohol -- 1 minute.
95% alcohol -- 1 minute.

0.5% alcoholic (95%) eosin Y. Dip in. About ½ minute or longer.

Wash in 95% alcohol, not too long as the eosin decolorizes.

100% alcohol, not too long otherwise eosin may disappear.

Xylol until clear, usually about 3 to 10 or 15 minutes. Look at the tissue under the microscope. If it is not red enough, go through the alcohols back to the eosin; if not blue enough, go back through the process to the hematoxylin.

Put a drop or two of gum damar dissolved in xylol over the tissue.

Mount with a cover glass without air bubbles.

Label.

Points to Be Remembered.—

Always wipe off excess of solution between each Koplin jar.

In embedding and in preparation for embedding, there should be about 5 times as much solution as tissue.

Solutions and glassware should be clean.

Tissues can remain longer than one hour, if necessary, in any of the alcohols except the absolute.

We suggest the use of Arthur H. Thomas paraffin, melting point 56°-58° C., Tissuemat, or Histowax (see page 2121) for embedding.

Keep the oven at 58°-60° C. (2° higher than the melting point of the paraffin).

If while cutting you obtain no ribbons, put powder on the blades.

Keep the blade at an angle of 45 degrees.

When using the fixative, use a drop of Mayer's and rub. It is immaterial if it dries; do not rub dry. Place tissues on it. Run distilled water under the tissue and bear down slowly until all wrinkles are removed from the paraffin. Heat gently if necessary. DO NOT MELT THE PARAFFIN. Drain off the water. Mark the slide, set it up to dry (two hours).

Slides may be placed in the bacterial incubator to hasten drying.

If a pan of water is used to float the tissues, the water must be hot enough to spread the tissues, but not hot enough to melt them.

Rub off excess fixative.

Never put tissue in the oven when it is in xylol.

Slides must be cleaned before presenting to pathologist. Be sure a history accompanies each specimen.

Difficulties Encountered in Staining

A. If objects do not remain on the slide:

1. Slide may have been dirty or oily.
2. Albumin fixative is too old. (If too old, it loses its clear color. Or it may have an odor. Make it in 1 oz. quantities. This will last two or three months.)
3. Slides might have been carried through the alcohols too fast.
4. Dehydration of the tissue through alcohol may have been too rapid. (If tissue is too small, use 60% alcohol after the 50%.)
5. Paraffin section not thoroughly spread on slide when mounted.

B. If objects do not stain:

1. Stain is at fault. Hematoxylin must ripen. Do not use it too soon after preparation.
2. Stain has deteriorated.
3. Paraffin had not been thoroughly removed from the slide. Leave longer in xylol. It can be run back.
4. Early fixation in alcohols before paraffin was not correct; nothing can be done to remedy this.
5. Fixing agent not thoroughly washed out of tissue before immersing in alcohols.

C. If section is not clear under microscope:

1. Xylol should be replenished.
2. There was water in the absolute alcohol.
3. Moisture on the cover slip.
4. Too much egg albumin on slide.
5. All the acid after acid alcohol decolorization was not removed.
6. A film from the alkaline alcohol was carried along.

To Remedy:

Put in Koplin jar of xylol to dissolve gum damar. Run back through the processes to the jar where the fault lay and use fresh solutions. Then restain.

If the tissue is thoroughly adherent to the slide, it can be taken back several times without danger.

Additional Pointers

When mounting tissues on slides, make several at once.

Thick sections come off the slide.

Occasionally you cannot cut a tissue less than 10 microns thick.

If the tissue is likely to come off:

Put slide in xylol to dissolve paraffin.

Dip in solution of ¾ gm. celloidin in 100 c.c. ether-alcohol (equal parts).

This places a slight film over the slide and does not interfere with the penetration of stain (except carmine).

After cover glass is on, if gum damar creeps out, rub off with xylol cloth.

Keep knives sharp.

If tissue is not embedded well, melt the paraffin in oven and re-embed it.

Rapid Staining Method, Employing Hematoxylin and Eosinol

Krajian[1] has offered a method of hematoxylin and eosin staining which affords a margin of safety between excessive extraction of eosin and complete elimination of water. This method overcomes the difficulty of loss of color of eosin and also has the advantage of saving alcohol and time.

The principle of the modification consists in the dehydration of the section before counterstaining and the application of eosin as a solution in carbol-xylol. Then, since the tissue passes afterward through xylol only, there is no opportunity for decolorization. Alcohol is saved because dehydration can be commenced in the stronger alcohol, discarding the lower gradations. The solution of eosin in carbol-xylol, which constitutes the principal element of modification, may be called, for convenience, ''Eosinol.''

Eosinol Preparation.—Dissolve 5 gm. of yellowish water-soluble eosin in 10 c.c. of distilled water. Precipitate it by adding 10 c.c. of glacial acetic acid, 2 c.c. concentrated hydrochloric acid, and mix with a glass rod. Incubate the resulting coagulum at 56° C. for 12-16 hours, or until all the water has evaporated.

Dissolve this dehydrated acid eosin in 10 c.c. of absolute alcohol and 20 c.c. of acetone, stirring with a glass rod for several minutes. Tightly cover and place in a paraffin oven for 2 hours. Let the undissolved portion, which is to be discarded, settle to the bottom of container (about 10 minutes). Remove clear portion with a clean dry pipette; add it to 1,500 c.c. of carbol-xylol (one part pure melted phenol crystals in three parts of neutral xylol). Some precipitate will form, which will settle to the bottom of the container. The clear portion is ''Eosinol.'' The solution keeps indefinitely. All glassware must be dry.

Owing to the nonuniformity of staining power of the various brands of powdered eosin, it may be necessary to standardize the solution by staining control sections and adjusting the strength of the eosinol by reducing or increasing the amount of carbol-xylol.

The Staining Method.—1. Prepare microscopic sections by one of standard sectioning methods (frozen, paraffin, celloidin) and stain according to directions on page 2105.

Paraffin Tissue Preparation

Method of Hektoen

Fix tissue in following solution:

Saturated solution mercuric chloride	3 parts
95% alcohol	1 part

(Or use Zenker's solution.)

Tissue can remain in mercury and alcohol solution for an indefinite period of time, but not over twelve hours in other solutions. After tissue has been fixed, place and tie in gauze, and wash under running water from two to twelve hours.

Dehydrate by placing in 80%-85% alcohol for one hour.

Remove and place in absolute alcohol or acetone for one hour.

Pour off and repeat same for another hour.

Remove, and place in cedarwood oil for about twelve hours.

Remove and dry oil with blotting paper.

Infiltrate in paraffin four hours in the following manner:

Use soft paraffin. Place 4 different receptacles half filled with paraffin in paraffin oven and keep temperature between 52° and 54° C. to keep paraffin melted, and place tissue in each jar for one hour.

Remove and embed by placing tissue in pan containing

Hard paraffin	3 parts
Soft paraffin	1 part

Place in ice box until paraffin is hard, then cut and mount on hardwood blocks. After specimens are blocked, place in ice box until ready to section.

---

[1] Lab. Digest 1: No. 10, 1938.

Cut with microtome (have knife very cold) and place sections in dish of warm water to straighten ribbon formation before placing on slide.

Use Mayer's fixative. (Page 2115.)

Smear slide slightly with above mixture.

Place ribbon containing 3 to 5 sections of tissue on slide. Place in warm oven overnight to dry. Place in oven about 4 minutes at 80° C.

Stain as follows:

Xylol, five minutes or longer to dissolve paraffin.
2% iodine to remove mercury.
95% alcohol to remove iodine.
Wash under running water two minutes.
Hematoxylin, two minutes.
Running water, five minutes.
2%hydrochloric acid until salmon color.
Wash in running water.
1% solution ammonium hydroxide until blue.
Wash in running water.
1% solution of eosin in distilled water, 1 to 2 minutes, or longer, if desired.

Wash. Examine the tissues under the microscope after each step to determine if the correct color is obtained.

95% alcohol, two to three minutes.
Absolute alcohol and xylol, three to five minutes.
or
Acetone and xylol for three to five minutes.
Xylol to clear, five to ten minutes.
Remove, blot, dry, and mount in Canada balsam.

Liver Biopsy

Liver biopsy is discussed on pages 1228 ff.

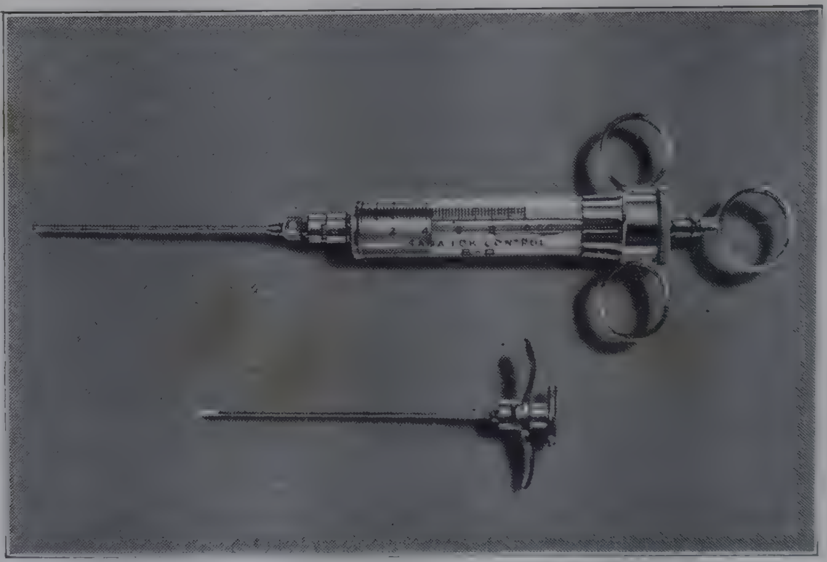

Fig. 626.—B. D. Feder-Wrenn biopsy needle and B. D. biopsy syringe. (Courtesy Becton, Dickinson and Co., Rutherford, N. Y.)

Procuring Tissue From Biopsy With the Feder-Wrenn Needle

The Feder-Wrenn tissue biopsy needle has been successfully used in surgical biopsy work. The method of obtaining the specimen is as follows:

Apply an antiseptic to the skin, then inject a local anesthesia, and insert the stilet and cannula into the skin and into the border of the tumor.

Remove the stilet and introduce the cannula several millimeters further. In this way a small plug of tissue is imprisoned within the bore of the instrument.

Now attach a No. 10SLB biopsy syringe and obtain suction by withdrawing the plunger until the lock catches in place. Due to this aspiration, tissue is drawn into the cannula.

Using the syringe as a lever, apply a gentle rotary motion to break the impaled specimen loose at its base.

Now withdraw the needle from the tissue, release the lock, and use sterile saline solution to flush free adhering particles.

This needle, No. 451LNR, 13G., 3″, may be obtained from Becton, Dickinson, and Company, Rutherford, N. J.

Technic of Making Large Sections of Organs as Originated by Christeller

A specially constructed sliding microtome made by Leitz, with a large freezing table, is used.

Slides are photographic plates 9 × 12 cm. Cover glasses slightly smaller, also furnished by Leitz, are used. These are approximately 8½ × 11 cm. Staining dishes are rectangular-shaped museum jars. There should be about 12 of these. Tissues should be hardened in Formalin, 10%.

Place a moistened piece of good grade lens paper on the microtome block.

Place the tissue to be cut on this, and press down.

Cover with the freezing hood, and freeze slowly.

When the tissue is frozen, remove hood, and cut.

Moisten the fingers. Cut one slide at a time, lifting the slide with the fingers as you cut. Be careful not to cut your fingers during this process.

Place the sections in water with fingers after removing from blade.

Place sections on plates with bent glass rod with blunt end. This is not easy. It takes several days' practice to become efficient in this process.

There must not be a single bent place on the section.

Dehydrate with absolute alcohol. Use a large quantity of alcohol.

Press out all air bubbles with rod.

Dehydrate three or four times.

Cover with a thin layer of very thin celloidin. Let it be thin enough when placed on the back of the hand to make an extremely thin coating.

Run excess back into bottle.

(Make up this celloidin from stock solution, using 2 c.c. to 100 c.c. of equal parts of alcohol and ether.)

Wait until it is almost air dried, but *not* dried.

Solutions for staining are placed in the museum jars (11 × 15 cm.).

Lay the specimens in water directly.

Place in Boehmer hematoxylin (below) for three to four minutes.

Distilled water.

Hydrochloric acid-alcohol, 1 c.c. hydrochloric acid to 100 c.c. 70% alcohol.

Distilled water. Repeat in fresh water to remove acid. Section becomes blue.

Eosin. Aqueous solution.

Water, distilled.

Alcohol 70%, one minute.

Alcohol 95%, one minute. Do not use absolute alcohol, since this re-dissolves the celloidin.

Terpene oil (Kahlbaum) or carbol-xylol, one minute.

Xylol.

Canada balsam. Put balsam in middle of plate and slightly bend the cover glass to middle, let it down on both sides and press, put weight on it overnight.

Label.

Boehmer's Hematoxylin.—

Solution I.—	Hematoxylin crystals	1 gram
	Absolute alcohol	12 c.c.
Solution II.—	Alum	20 grams
	Warm distilled water	200 c.c.

Filter when cool.

After twenty-four hours, mix both solutions. Place in a wide-mouth bottle and expose to air for eight days.

Filter through filter paper.

Preparation of Small Pieces of Skin Tissue[1]

Bouin's Solution.—

Saturated aqueous picric acid	300 c.c.
Formalin (40%)	100 c.c.
Glacial acetic acid	20 c.c.

50% Alcohol, 70% Alcohol, 80% Alcohol.—

See page 2120.

Technic.—

Fix tissues in Bouin's solution overnight. Twenty-four hours is the maximum fixing time.

9:00 A.M. Wash in 50% alcohol.

9:00 A.M. Wash in 70% alcohol containing 3 drops of a saturated solution of lithium carbonate.

12:00 Noon. Put in 70% alcohol. The tissue can be left over the week-end in this solution.

3:00 P.M. Place tissues in 80% alcohol.

5:00 P.M. Place tissues in 95% alcohol and leave until the following day.

Next day, 9:00 A.M. Place in absolute alcohol.

10:30 A.M. Place in amyl acetate.

4:00 P.M. Place in paraffin in the paraffin oven.

5:00 P.M. Pour off the paraffin and leave the tissues outside of the paraffin oven. Never leave tissues in oven overnight. Never re-use any paraffin.

Next day, 9:00 A.M. Put in second paraffin.

12:00 Noon. Put in third paraffin.

2:00 P.M. Embed in paraffin.

Cut and stain with routine hematoxylin and eosin stain (pages 2105 ff.).

Amyl acetate can be used for clearing Formalin-fixed tissues as well as those fixed in Bouin's fixative.

If the tissue is fixed in Formalin, first wash in water from 9:00 A.M. until 10:30 A.M. Then place in 50% alcohol and then in 70% alcohol until 12:00 noon. Follow the technic for Bouin-fixed tissue from this point.

This method is especially recommended to make satisfactory sections of very small pieces of skin, biopsy, etc.

Preparation of Serial Slices of the Breast

Method of Ingleby and Holly[2]

In relation to diagnosis of disease of the breast, it is of paramount necessity to examine as large portions of this organ as possible in order to come to the proper conclusion concerning the pathologic anatomy. In other words, the organs as a whole must first be studied and later any special area should be minutely examined.

Technic.—

Specimen is brought from the operating room or autopsy table.

Suspend it in a jar of formaldehyde (4 per cent) in order to fix it with the normal contour preserved as nearly as possible. Suspending the specimen can be accomplished by means of a gauze sling.

---

[1] Barnard Free Skin and Cancer Hospital of St. Louis, Mo., Lab. Digest 9: No. 10, March, 1946.

[2] Journal of Technical Methods and Bulletin of the International Association of Medical Museums, No. XIX, 1939.

Place the jar containing the breast in the refrigerator room, and leave it there for at least 24 hours.

Remove from the solution, wrap in a wet cloth, and freeze. Freeze rapidly. Use a commercial ice cream freezer for the purpose or place in a freezing unit.

Ingleby and Holly recommend the slicer made by the American Slicing Machine Co. This machine cuts even slices down to about 0.5 mm. in thickness. With this slicer, freezing of the tissue is not absolutely necessary; however, better results are obtained if the specimen is frozen before slicing, especially if the specimen is of soft or uneven consistency, such as fatty breast where skin is present.

Stack sections in order. They may be put back into formaldehyde for further fixation, or they may be tagged and numbered at once. Some sections are difficult to handle. Receive these in a bowl of water and float onto numbered pieces of paper, and stack. In this way, sections can be kept perfectly flat during further fixation.

Fix for a few hours, then wash one hour or more in running water, rinse in distilled water, and place in a single layer in the following filtered solution:

Harris hematoxylin	5 c.c.
Distilled water	100 c.c.

Stain for 24 hours, turning once during this time to insure even staining.

Differentiate in acid alcohol.

Wash until blue.

Place in 70% alcohol	1 to 2 hours,
95% alcohol	6 to 8 hours (two changes),
absolute alcohol	2 to 4 hours (two changes),
benzine	2 to 4 hours (two changes).

Store in mineral oil until required for use. Then transfer to oil of wintergreen 2 parts and benzol benzoate 1 part for about an hour. They are then ready to be examined under the dissecting microscope.

An alternative stain is Masson's iron hematoxylin. This gives excellent results where material to be stained is not too dense. It is the method of choice if photography is contemplated.

Sections must be returned to the mineral oil after study. Oil of wintergreen is an excellent clearing agent, but it extracts the hematoxylin and the sections fade rapidly. In some cases sections may be examined in mineral oil without clearing. Occasionally, especially with the ordinary microscope, mineral oil gives better results than the more brilliant oil of wintergreen.

Advantages of the Method.—

1. It is possible to examine grossly every part of the tissue. In this way small lesions are not missed and if it is not desired to stain whole sections, suitable pieces for paraffin blocks are easily picked out.
2. A three-dimensional view is obtained and structural relations are beautifully shown; no lesion of any importance can be missed.
3. The method is a rapid one. A whole breast could be ready for examination in five days or less.
4. Paraffin sections can be made at any time from any part should higher magnification be desirable.

SPECIAL METHODS OF STAINING

Feder Modification of the Rhamy Stain[1]

The stain developed by Feder for use in connection with frozen-section technic of Rhamy consists of

Toluidine blue	0.8 gm.
Basic fuchsin	0.3 gm.
Eosin Y	0.4 gm.
Alcohol, 95%	33.0 c.c.
Distilled water	77.0 c.c.

---

[1] J. M. Feder: Essentials of Applied Medical Laboratory Technic, Charlotte, N. C., 1940, Charlotte Medical Press, p. 217.

Weigh the dyes and dissolve them in alcohol. Add the water and allow to stand overnight. After thorough agitation to insure solution, filter. Keep the stain in a dropping bottle ready for use.

Set up microtome and knife. Adjust micro gauge to about 7 microns. Do not strive for a very thin section. A 10-micron section showing the structure in its continuity is much better than one of 5 microns that is distorted.

Obtain two glass bowls of about half a pint capacity and about 6 inches in diameter. Fill one of these with 4 per cent Formalin. Fill the other bowl with tap water.

Obtain the desired piece of tissue. It should not be more than the thickness of a quarter-dollar and not over a third of its size. If the material has not been Formalin-fixed, drop it in a dish of 10 per cent Formalin, heat to the boiling point and allow it to remain there for one or two minutes. Wash in water for an instant and transfer to the freezing block of the microtome. The water adhering to the tissue will be sufficient to fix it to the freezing disk. Turn on the CO_2 from the tank and, using the control on the microtome, turn the gas on and off several times until the tissue is frozen half-way through.

With the adjusting wheel, run the tissue up until the knife is in line with a point just above the zone of freezing. Cut here. Wet the knife with water and continue to cut sections until the frozen part is reached. Pick the sections up on the finger tip and transfer them to the bowl containing the 4 per cent Formalin solution. When enough satisfactory sections have been cut, with the aid of a camel's-hair brush, cut to a fine point at the tip, transfer one to a slide. (Some use a glass rod to pick up sections and transfer them to a dish of stain and from this to water but Feder finds that smoother sections can be made by staining them flattened on a slide.)

Cover section with the special stain described, allow it to remain for 20 seconds, then transfer to a bowl containing water by dipping slide into it. Paddle section around for a few seconds with the end of slide to rid it of excess stain, and remount.

Place a drop of mounting fluid on a coverglass (this mounting fluid for frozen sections consists of equal parts of 95 per cent alcohol, glycerin, and distilled water).

Wipe excess fluid from about section and back of slide, gently apply cover glass containing mounting fluid, and the section is ready for examination. The staining reaction closely approximates that of the routine hematoxylin-eosin method commonly used; therefore, the examiner does not have to become accustomed to new color combinations.

Twenty-Minute Method of Staining Treponema Pallidum in Frozen Sections—Krajian

(For the Diagnosis of Syphilis)

In 1939, Krajian described his excellent and practical method of demonstration of the *Treponema pallidum* in biopsy material particularly designed to facilitate the diagnosis of primary syphilis. It is the best and most simple method yet devised. It gives a very clear-cut picture of the organism of syphilis, and that, too, in many instances where dark field examinations have failed to show the organism.

It might be mentioned that the dark field method is positive in about 90 per cent of cases in the first week of the lesion, 50 per cent in the fifth week. The morphology of the spirochetes found on the surface of mucosal lesions, by dark field and smear methods, may be of less significance than those found deep in the tissues of biopsy sections, because here their recognition is not affected by saprophytic organisms and free oxygen.

The twenty-minute method of Krajian follows:[1, 2]

---

[1] Krajian, A. A.: Am. J. Syph. 23: 617, 1939.

[2] Krajian, A. A. and Gradwohl, R. B. H.: ed. 2, The C. V. Mosby Co., 1952.

Reagents.—

Primary Solution

Uranium nitrate	1 gm.
Formic acid, c.p., 85%	3 c.c.
Glycerin, c.p.	5 c.c.
Acetone, c.p.	10 c.c.
Alcohol, 95%	10 c.c.

10% Silver Nitrate Solution.—

Dissolve 10 gm. of silver nitrate, c.p., in enough distilled water to make 100 c.c. of solution. The 1% solution is made from this.

1% Silver Nitrate Solution.—

The 10% silver nitrate solution will keep for months. Dilute it just before using by adding 3 c.c. of 10% silver nitrate solution to enough distilled water to make 30 c.c. of solution. This solution may be used a maximum of three times during the course of the same day. Do not use it if it has a brownish cast.

Developing Solution.—

Hydroquinone	0.31 gm.
Sodium sulphite	0.1 gm.
Acetone	2.5 c.c.
Formaldehyde, 40%	2.5 c.c.
Pyridine	2.5 c.c.
Saturated solution of gum mastic in 100% alcohol	2.5 c.c.
Distilled water	15.0 c.c.

Dissolve the hydroquinone in formaldehyde and acetone, then dissolve the sodium sulphite in this solution. Then add the other reagents and mix. Finally add the gum mastic. With the addition of the water, the mixture assumes a smooth creamy appearance.

This solution may be used a maximum of three times during a day's work, but should preferably be used in small quantities and used only once. The stock solution, if kept out of the light, will remain good for at least one or two weeks. Keep out of the cold to prevent separation of the gum.

Saturated Alcoholic Solution of Gum Mastic.—

Saturate 25 gm. of gum mastic with 35 c.c. of absolute alcohol. Shake several times a day for 3 to 5 days until clear. Allow to precipitate and use only the clear supernatant portion. Clarification can be hastened by centrifuging.

Technic of Staining.—

If the tissue has not been previously fixed in 10% Formalin, boil a small piece of biopsy material in 10% Formalin in a Pyrex test tube, agitating it for one minute. Or, drop blocks of tissue about 5 mm. thick in a 10% Formalin solution at 67° C., and place in an oven at 67° C. for 10 minutes.

Freeze and cut immediately. Cut frozen sections about 7 to 10 microns. Wash in distilled water.

Place the *Primary Solution* and the *Developing Solutions* in small Stender dishes in the paraffin oven at 60° C. to keep them warm. Have three small Stender dishes containing distilled water. Place about 5 to 10 c.c. of 95% alcohol in another Stender dish. In another Stender dish, place 5 c.c. of 95% alcohol and add about 3 drops of saturated solution of gum mastic solution from the end of a small glass lifter. The 1% silver nitrate solution should be in a 250 c.c. Pyrex beaker.

Place the tissue in the Primary Solution at 56 to 60° C. for 5 minutes. This can be kept in the paraffin oven to maintain its temperature.

Rinse in distilled water. The tissue should open up and float on the water in the Stender dish.

Pick up with the glass lifter, and keeping it on the lifter, pass three times gently but quickly through the weak gum mastic mixture.

Place in another Stender dish of distilled water. The tissue should open up and float.

Transfer section to a wide-mouth 250 c.c. Pyrex beaker containing 30 c.c. of 1% silver nitrate solution. The beaker should be on an asbestos board over a low flame and under a 60-watt electric light. The light should be about 4 feet above the beaker. Heat the silver nitrate solution under the electric light until bubbles form, keeping the temperature between 70 and 73° C. for seven minutes.

Without washing, carry individual sections with the glass rod lifter to the warm developer solution. This solution should be kept hot over the burner. Alternately lift in and out of the solution, exposing every part of the tissue to the electric light. When replacing each time, be sure the section opens out on the developer solution. This cannot be accomplished unless the solution is quite warm. Repeat this alternate exposing and developing process about eight times. The tissue turns brown.

Transfer to the 95% alcohol in a Stender dish to remove excess gum mastic.

Transfer to a Stender dish containing fresh distilled water. The tissue should straighten out here. If it does not, replace for a few seconds in the alcohol, then replace in the distilled water.

Place once more in the cooled silver solution and expose to the electric light for an additional 10 to 30 seconds. This will cause the spirochetes to assume a good black color.

Transfer to a large bowl of distilled water. **Do not use tap water.**

Transfer to a glass slide. Dehydrate by dropping a few drops of isopropanol over the surface, blow gently at first, then blow a little harder to remove water.

Blot under several thicknesses of No. 1 Whatman filter paper, place isopropanol over the slide, and allow to dehydrate for at least one minute. Again blot with Whatman No. 1 filter paper after draining off the excess isopropanol.

Dip once in thin celloidin (page 2105). Wipe the bottom of the slide dry. Blow over the surface of the celloidin until it is thoroughly dry.

Place the slide on a staining dish and cover with isopropanol for sixty seconds to dehydrate.

Place in xylol for several minutes. Place in a second xylol to clear. Clean excess celloidin from around the tissue and mount with gum damar. Examine with the oil immersion objective.

Pointers.—

The spirochetes should stain black against a light brown background. If they are brown either the second silvering process was not carried out properly or the developing solution was too cold. Or the developer might have separated, in which case make fresh developer.

When the gum mastic separates out of the developer, make a fresh solution. The Primary Solution keeps indefinitely.

If some of the spirochetes are brown and some are black, you have not spread the sections properly in the developing solution. Be sure the solution is hot so that the tissues will open properly.

If some portions of the tissue do not show spirochetes and you feel that they must be there, it may be due to improper fixation of the tissue. Unfixed portions of the section would not permit staining of the spirochetes.

When gum mastic is old or is in solution, it deteriorates.

If the lesion has been covered or treated with Mercurochrome or other chemicals the staining will be affected.

Dirty glassware will cause precipitates to appear in the section. Clean with sulphuric acid dichromate cleaning solution.

If the tissue suddenly shrinks when it is removed from the silver nitrate solution and placed in the water, it may be due to the fact that the water is not really distilled water, or the silver nitrate for the second silvering process was too hot and the temperature change too sudden. Sometimes going back to hot developer then through the other solutions will help unfold such a tissue. Or too weak a gum mastic solution was used.

It is good practice to stain a known positive section along with the specimen for diagnosis as a check on the solutions.

Never use a metal needle for removing tissues. Use the glass rod lifter.

This method is also applicable for paraffin sections, provided period of staining in each step is doubled. It has been used with success by us in demonstrating spirochetes in primary sores where dark-field examinations have been negative. A small piece of tissue of the chancre, after injection of few drops of Novocain solution, is snipped off with pair of sharp scissors, and the above technic carried out.

Krajian's Method of Demonstrating Treponema Pallidum in Smear Preparations

Clean the lesion and scrape off material from ulcerated surface and prepare smears. Flood smears with warm (60° C.) primary solution (p. 2139) for 5 minutes. Dry in air.

Wash in distilled water.

Treat with a weak solution of gum mastic for 2 minutes (3 drops of saturated alcoholic solution of gum mastic mixed with 7 c.c. 95% alcohol).

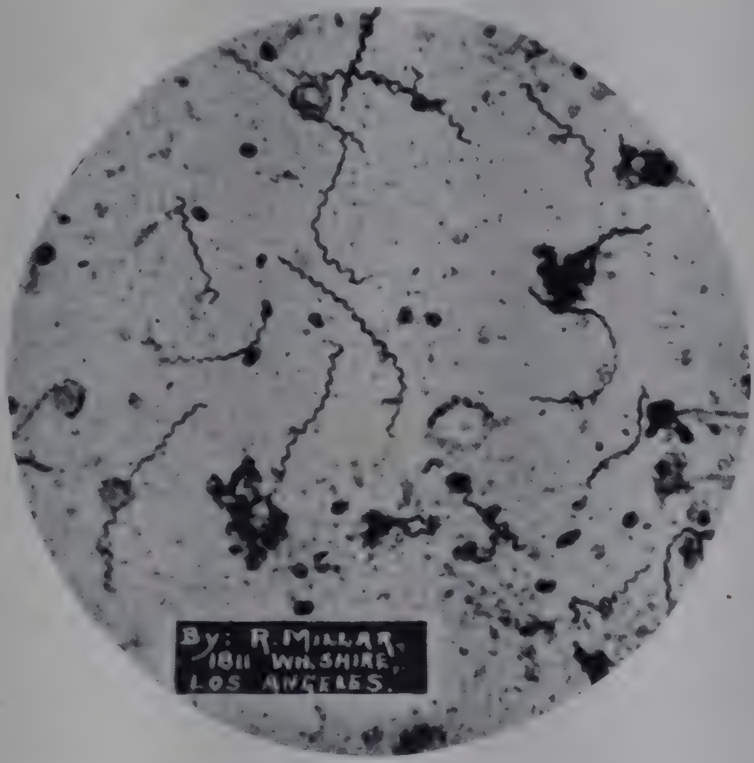

Fig. 627.—*Treponema pallidum* in smear preparations. Krajian's method.

Pour off gum, glow breath over surface of the smear and rinse in distilled water.

Set slide on metal stand or tripod, flood with a 1% silver nitrate solution and heat from under until bubbles arise. (Do not boil.) Keep at that temperature for 3 minutes. Repeat the process once more.

Pour off silver and without washing apply a thin coat of developing solution and leave under electric light for 2 minutes, warming gently with a flame.

The Developing Solution:

Hydroquinone	0.31	gm.
Sodium sulphite	0.06	gm.
Solution of formaldehyde 40% neutral	2.5	c.c.
Pyridin	2.5	c.c.
Saturated solution of gum mastic in 95% alcohol	2.5	c.c.
Distilled water	15.0	c.c.

See page 2139 for directions for making.

Wash with distilled water, dry in filter paper, and examine with oil mimersion lens.

For permanent mounts, dehydrate with absolute alcohol, blot clear in xylol, mount in gum damar.

Staining Mycobacterium Tuberculosis in Sections

Stain for Acid-Fast Bacilli, Method of Fite[1, 2, 3]

(Fuchsin-Formaldehyde Method)

Reagents.—

Fixative.—

Equal parts of 95% alcohol and 10% neutral Formalin.

Carbol Fuchsin.—

New fuchsin (Magenta III)	0.5 gm.
Phenol crystals	5.0 gm.
Methyl alcohol	10.0 c.c.

Distilled water to make 100 c.c. solution.

40% Neutral Reagent Grade Formalin.—

Acid Alcohol.—

See page 2105.

1% Aqueous Potassium Permanganate Solution.—

Dissolve 1 gram of potassium permanganate in enough distilled water to make 100 c.c. of solution.

2% Aqueous Oxalic Acid.—

Dissolve 2 grams of oxalic acid, reagent grade, in enough distilled water to make 100 c.c. of solution.

Harris Hematoxylin.—

See page 2105.

Van Gieson's Mixture.—

Acid fuchsin	0.01 gm.
Picric acid	0.5 gm.

Distilled water to make 100 c.c.

95% Ethyl Alcohol.—

Absolute Alcohol, for paraffin sections.—

98% Isopropanol, for frozen sections.—

Xylol.—

Gum damar.—

See page 2106.

Technic for Frozen Section.—

Fix tissues 24 hours in equal parts of 10% Formalin and 95% alcohol.

Cut frozen sections 10 to 15 microns thick.

Mount in thin celloidin in the usual manner for frozen sections. Page 2104.

Before drying is complete, place in carbol fuchsin for 15 minutes to 48 hours at room temperature, or, better, for 1 hour in the paraffin oven at 58 to 60° C.

Dip in distilled water.

Wash in 40% neutral reagent grade Formalin for 5 minutes. Section turns blue.

Dip briefly in distilled water.

Wash in acid alcohol for 5 minutes. Take care not to lose the section at this point.

Wash by dipping briefly in distilled water.

Wash in 1% aqueous potassium permanganate for 2 to 5 minutes. Section turns brown.

Dip in distilled water.

Wash in 2% aqueous oxalic acid for 40 to 60 seconds or until just a trace of brown remains.

Dip in distilled water.

Stain in Harris hematoxylin for 2 to 5 minutes.

Wash in distilled water.

Place in modified van Gieson's mixture for 3 minutes.

---

[1] Fite, G. L.: Am. J. Path. 14: 491, 1938.

[2] Fite, G. L.: J. Lab. & Clin. Med. 25: 743, 1940.

[3] Tilden, I. L., and Tanaka, M.: Am. J. Clin. Path. 15: 95, 1945.

Without washing, place in 95% ethyl alcohol for 2 minutes, then blot the tissue.

Dehydrate in 99% ethyl alcohol or isopropanol. Blot. Absolute alcohol dissolves the celloidin.

Clear in 2 changes of xylol for 5 to 10 minutes each.

Mount in gum damar.

Nuclei stain brown; muscle is yellow; collagenous connective tissue is red; acid-fast bacilli stain deep ultramarine blue; non-acid-fast organisms are unstained.

Technic for Paraffin Sections.—

Fix tissues in equal parts of 95% alcohol and 10% neutral Formalin. Embed.
Cut paraffin sections in the usual manner and mount on the slide.
Stain in carbol fuchsin (above) for 24 to 48 hours at room temperature.
Wash and place in 40% neutral Formalin for 5 minutes.
Wash and place in acid alcohol for 10 minutes.
Wash and place in 1% potassium permanganate for 2 to 5 minutes or until brown.
Wash and place in 2% oxalic acid 20 to 30 seconds.
Wash and stain in Harris hematoxylin for 2 to 3 minutes.
Wash and stain in van Gieson's mixture for 3 minutes.
Do not wash after treatment with van Gieson mixture.
Dehydrate in 95% alcohol for *1 minute only.*
Then place in absolute ethyl alcohol to dehydrate completely.
Clear in several changes of xylol.
Mount in gum damar.
For staining characteristics with this method, see above.

In following this technic be sure that the section turns a deep blue color in Formalin. If this color fails to develop, use a different supply of Formalin. This is the most important step in the procedure.

Staining of Lepra Bacilli in Paraffin Sections

Owing to the lesser degree of acid-fastness of lepra bacilli as compared with tubercle bacilli, Fite, Cambre, and Turner[1] worked out a staining method for demonstration of lepra bacilli in tissues regardless of the technics of fixation and embedding.

Technic.—

Remove paraffin with two changes of the following mixture, allowing a minute or two for each change:

Cottonseed (or peanut or olive) oil	1 part
Xylol	2 parts

Drain, wipe off excess oil and blot to opacity. The residual oil in the section helps to prevent shrinkage and injury of the section.

Remove mercury crystals (if present) with strong solution of iodine, U.S.P. (2 minutes), followed by a hyposulphite or thiosulphate solution rather than alcohol. Wash in tap water.

Stain cold 15 to 30 minutes in any standard preparation of carbol-fuchsin (Ziehl-Neelsen) but not in a concentration solution such as Kinyoun's. Wash.

Decolorize with 1% concentrated hydrochloric acid added to 70% alcohol—not to the point of totality, but leaving a faint pink color. One to two minutes will be required. Wash.

Counterstain with Loeffler's alkaline methylene blue about 30 seconds. Wash in tap water.

Blot, let stand a few minutes to dry, mount directly in a synthetic mounting medium, such as Clarite or Permount.

---

[1] Arch. Path. 43: 624, 1947.

Krajian Stain for the Demonstration of Acid-Fast Organisms in Tissue Sections

This method is applicable to both frozen and paraffin sections fixed in ordinary fixatives.

Reagents.—

Carbol Fuchsin.—(See page 1403.)

Krajian Decolorizing Agent.—

Arsenic acid	1 gm.
60% ethyl alcohol	100 c.c.

Loeffler's Methylene Blue.—(See page 1403.)

Anhydrous Isopropanol or Absolute Alcohol.

Iso-Creosote Mixture.—

Equal parts of anhydrous isopropanol or absolute ethyl alcohol and beechwood creosote.

Xylol.

Gum Damar.

Technic.—

Cut frozen sections 7 to 10 microns.

Transfer to a slide, dehydrate, blot in filter paper, dip once in celloidin, and blow over the surface until dry. (See page 2104 for this method of handling frozen sections.) Wash in tap water until the surface is wet.

Place the slide on a tripod or on a warming table, apply carbol-fuchsin, and steam gently with a flame for three minutes.

Discard the staining solution, wash with tap water, and apply arsenic acid alcohol with a medicine dropper two to four times, agitating the slide constantly for even destaining, or until most of the red color is removed.

Wash in tap water. Apply Loeffler's methylene blue solution for two minutes.

Wash in tap water. Dehydrate with three applications of anhydrous isopropanol or absolute ethyl alcohol.

Immediately apply iso-creosote, two or three applications, agitating the slide constantly for even differentiation. This removes the excess blue stain from the tissue as well as from the organisms. This is the crucial step. If overdifferentiated, the background will be very light blue without affecting the organisms; light blue is the right color.

Blot immediately in filter paper.

Clear in three changes of xylol, one minute each.

Mount in gum damar.

For paraffin sections, remove paraffin with two applications of xylol, two minutes each, remove xylol with two applications of isopropanol or absolute ethyl alcohol, wash in tap water, and proceed with method described.

Acid-Fast Tubercle Bacilli Stain*

Gradwohl Modification of Krajian Stain

Cut frozen or paraffin sections. If paraffin sections are used, put through two changes of xylol to remove paraffin.

Place section on slide.

Dehydrate *thoroughly* with isopropanol. Blow and blot.

Dip twice in celloidin. Blow celloidin dry.

Stain lightly with Harris hematoxylin (15 to 20 dips).

Wash in tap water.

Place slide on staining pan and flood with carbol-fuchsin. Steam gently ten minutes.

Pour off carbol-fuchsin and wash thoroughly in tap water.

Decolorize with acid alcohol. *Note:* Make sure that section is thoroughly decolorized—until no further red washes off. Two changes of acid alcohol may be necessary to decolorize completely.

---

*This method, which is a modification of Krajian's original method, has been successfully worked out in our laboratories.

Dehydrate with isopropanol.
Dip in 2% aqueous sodium cyanide until background becomes blue (15 to 20 dips).
Wash in tap water.
Dehydrate again.
Clear in two or three changes of xylol.
Mount in gum damar.

Fluorescence Method of Demonstrating Mycobacterium Tuberculosis in Tissues (Tanner)

The use of fluorescence in microscopy for demonstrating *Mycobacterium tuberculosis* in smears has been described on pages 1609 ff. The use of fluorescence microscopy for demonstrating this organism in tissues has been reported in European literature.[1, 2, 3] Tanner[4] gives an excellent method of using this technic for the demonstration of tubercle bacilli in tissue.

Reagents.—

Auramine Stain.—

Solution A.—

Distilled water	87 c.c.
Phenol	3 c.c.

Solution B:—

95% ethyl alcohol	10.0 c.c.
Auramine-O	0.1 gm.

Add solution B to solution A.

Decolorizing Solution.—

70% alcohol	100 c.c.
Hydrochloric acid, c.p., conc.	1 c.c.
Sodium chloride, c.p.	0.5 gm.

0.1% Aqueous Solution of Methylene Blue.—

Dissolve 100 mg. methylene blue in 100 c.c. distilled water, grinding in a mortar, and adding small portions of the solvent until all the dye is in solution. Filter after 24 hours.

Technic.—

Cut sections of tissue blocks, fixed in Formalin and embedded in paraffin, at 5 microns. Mount on clean glass slides with a minimal amount of egg albumin. When the sections are dry, remove the paraffin in the usual manner and cover the deparaffinized sections with the auramine staining solution for five minutes.

Wash the sections and cover with the decolorizing solution for twenty minutes.

At the end of this time, wash the sections with tap water and cover with fresh decolorizer for another twenty minutes.

Wash the tissue with tap water and counterstain with 0.1% aqueous solution of methylene blue for one minute.

Wash. Dry. Examine with the fluorescence microscope without using a coverglass.

The methylene blue gives a black or dark blue background but does not interfere with the fluorescence of the organisms.

Some sections, according to Tanner, gave satisfactory results without the methylene blue, but the use of that counterstain gave a better contrast and it is recommended as a routine procedure in tissue sectioning. The results with both methods are satisfactory, the bacilli standing out as bright yellow rods on a nearly black background. The organism can be identified readily by using an 8 mm. objective and a ×25 ocular.

[2] Schallock, G.: München. med. Wchnschr. 87: 102, 1940.
[3] Finke, L.: Arch. f. Hyg. 123: 381, 1940.
[4] Proc. Staff Meet., Mayo Clinic 16: 839, 1941.

Richards* prefers glycerine mounts, made semipermanent by ringing with gold size. This method permits one to examine adequately about three times as quickly by the fluorescence method as by the carbol-fuchsin method. Tanner found eight more positives by the fluorescence method than by the carbol-fuchsin stain. Ease of preparation and speed of examination are important advantages of the fluorescence method for demonstrating *Mycobacterium tuberculosis* in tissue sections.

Staining Tubercle Bacilli in Tissues (Fuller)

Method No. 1

It is believed by some authorities that fixation of tissues in Formalin renders them unsuitable for staining acid-fast bacteria. Fuller[1] has developed a method which gives good staining of the bacteria with either Formalin or Zenker-formol fixation. With Formalin-fixed tissues the green counterstain is prone to fade in a few months but the bacteria and nuclei remain well stained indefinitely. With tissue fixed in Zenker-formol, all structures retain the dyes for prolonged periods. The methods is as follows:

Solutions.—

Iron Alum, 5% Aqueous.—

Dissolve 5 gm. iron alum in distilled water and dilute to 100 c.c. with distilled water.

Hematoxylin.—

Dissolve 1 gm. certified hematoxylin
in 80 c.c. hot distilled water.
Cool and add 10 c.c. glycerin
and 10 c.c. 95% alcohol.

Picric Acid Solution.—

Add 2 parts of saturated alcoholic solution of picric acid
to 1 part of 95% alcohol.

Fuchsin Solution.—

Add 16 c.c. of saturated alcoholic solution of fuchsin, basic,
to 84 c.c. of aniline water.

Acid Alcohol.—

Add 3 c.c. of nitric acid to enough 95% alcohol to make 100 c.c. of solution.

Alkaline Water.—

Add a few drops of ammonium hydroxide to 100 c.c. distilled water.

Light Green Solution.—

Dissolve 1 gm. light green in enough distilled water to make 100 c.c. of solution.

Technic.—

Run slides down to water as usual and rinse in distilled water.

Mordant in iron alum solution in the paraffin oven for 5 minutes (45° to 50° C.).

Rinse in tap water.

Stain in hematoxylin, also in the paraffin oven, for 5 minutes.

Put directly into the picric acid for 5 minutes, or longer if necessary, until the stain remains only in the nuclei.

Wash thoroughly in running water (15 minutes or longer) until the sections are thoroughly free of the picric acid.

Place on the heating bar and pour the fuchsin solution over them. Heat until steam comes off, but do not boil. Let cool for 3 minutes, heat again, and again allow to cool for 3 minutes.

Destain in acid alcohol for a few seconds, until the fuchsin starts coming off in clouds; rinse in tap water and continue destaining until the sections are barely pink.

Rinse in water and put into alkaline water for a few seconds.

---

*Personal communications.

[1] J. Lab. & Clin. Med. 23: 416, 1938.

Wash thoroughly in running water for 10 minutes or more.

Stain in the light green solution for 5 minutes.

Rinse in water and dehydrate quickly through increasing strengths of alcohol and xylol; mount as usual.

This method is excellent for purposes of photomicrography, as tubercle bacilli are stained brilliantly red while nuclei and cytoplasm take different values of green so that excellent contrast is obtainable. For ordinary microscopic examinations, the red-green contrast has been found superior to other staining methods. This method is satisfactory even for tissues such as the brain and meninges which have been very difficult to handle by the usual tubercle bacilli sectional methods of staining.

Method No. 2

Tissue must not have been in Formalin too long.

Overstain in hematoxylin	20 to 30 minutes.
Distilled water	30 minutes.
Carbol-fuchsin	30 to 60 minutes in the incubator at 37° C.
Following solution of hydrochloric acid	1 minute.
Hydrochloric acid	1 part
70% alcohol	100 parts
Wash in 70% alcohol	2 to 3 minutes.

Wash in distilled water.

Dilute lithium carbonate solution until blue.

Concentrated lithium carbonate solution	1 part
Distilled water	10 parts
Distilled water	5 to 10 minutes.
90% alcohol	5 minutes.

Absolute alcohol until dehydrated.
Xylol until clear.
Mount in Canada balsam.

Tubercle bacilli stain red and are characteristic.

Method No. 3

Embed in paraffin or use fixed frozen sections and cut sections 5 microns.
Hydrate through decreasing strengths of alcohol down to water in usual manner.
Place in hot carbol-fuchsin and steam 5 to 10 minutes.
Decolorize in 25% hydrochloric acid.
Wash in distilled water.
Blot.
Place in Loeffler's methylene blue for 1 minute.
Wash in water.
Blot.
Wash in 96% alcohol.
Wash in aniline oil.
Wash in mixture of one-third aniline oil and two-thirds xylol.
Wash in xylol.
Mount in Canada balsam.

Kinyoun Carbol-Fuchsin Method for the Demonstration of Tubercle Bacilli in Tissue

Solution 1.—

Basic fuchsin	2 gm.
Phenol crystals	8 gm.
95% alcohol	20 c.c.
Distilled water	100 c.c.

Solution 2.—

Prepare a 0.5% solution of acetic acid by adding 0.5 c.c. of glacial acetic acid to distilled water and diluting it to 100 c.c. with distilled water.

Dissolve 0.5 gm. methylene blue in this 0.5% acetic acid solution.

Solution 3.—

Add 15 c.c. hydrochloric acid to 95% alcohol and dilute to 100 c.c. with 95% alcohol.

Technic.—

Remove the paraffin from the sections by passing them through three changes of xylol in the usual manner.

Place slides for 1 minute each in the following solutions: absolute alcohol, 95% alcohol, 70% alcohol, distilled water.

Stain with Kinyoun's carbol-fuchsin for 1 hour at room temperature.

Rinse with distilled water.

Decolorize in the hydrochloric acid solution until pink.

Counterstain in the methylene blue solution 1 minute.

Wash in distilled water.

Dehydrate in the usual manner.

Mount in balsam, gum damar, or Clarite.

Methods for the Differential Staining of Gram-Positive and Gram-Negative Bacteria in Tissue Sections

1. Differentiation of Gram-Negative and Gram-Positive Organisms in Frozen Sections (Krajian*)

Krajian has emphasized the importance of a staining method for the demonstration of gram-positive and gram-negative organisms in tissue sections. Ever since Christian Gram[1] in 1884 devised his method for the demonstration of bacteria in tissue sections, various attempts have been made to demonstrate both gram-positive and gram-negative organisms in paraffin sections of tissue fixed in Zenker's solution or in Formalin. Methods have been reported by MacCallum,[2] Lyon,[3] Lillie,[4] Brown and Brenn,[5] Rudnikoff and Stowsky,[6] Glynn,[7] and others. Weigert's[8] modification has been satisfactory for the demonstration of fibrin and bacteria, but it demonstrates only gram-positive organisms.

The methods alluded to have used the original stains of Gram, but no attempt had been made to describe a differential stain for bacteria until Krajian published his method, using a different dye and different chemicals. This method is easy to apply to frozen sections and gives excellent simultaneous staining of both gram-positive and gram-negative organisms. He found that it was successful in staining four different frozen sections mounted on the same slide, one each of a kidney containing colon bacilli, a lung with Friedländer bacilli, a kidney with staphylococci, and a brain containing torulas. The method has been successfully applied to tissues containing streptococci, Welch bacilli, influenza bacilli, monilias, actinomycetes, meningococci, gonococci, and Negri bodies. This method is recommended because it has been found very efficient in our laboratories.

---

*This is the modified brilliant green formula. This solution is stable. The original formula for brilliant green solution was 0.3 gram of brilliant green dissolved in 10 c.c. of copper-zinc sulphate solution. This solution remained in good working order for only 24 hours.

[1] Fortschr. d. Med. 2: 185, 1884.

[2] J. A. M. A. 72: 193, 1919.

[3] J. A. M. A. 75: 1017, 1920.

[4] Arch. Path. 5: 828, 1928.

[5] Bull. Johns Hopkins Hosp. 48: 69, 1931.

[6] Arch. Path. 19: 543, 1935.

[7] Arch. Path. 20: 896, 1935.

[8] Ztschr. F. wissensch. Mikr. 4: 512, 1887.

Reagents.—

Harris Hematoxylin.—(Page 2105.)

Acid Alcohol, 1% hydrochloric acid in 70% alcohol (page 2105).

Copper-Zinc Sulphate Solution.—

Copper sulphate	7 gm.
Zinc sulphate	4 gm.
Distilled water	100 c.c.

Dissolve with heat.

Brilliant Green Solution.*—

Hematoxylin crystals	0.3 gm.
Commercial Formalin (40%)	10.0 c.c.

Dissolve and add

Brilliant green	0.3 gm.

Mix thoroughly. If a precipitate forms, filter.

This solution keeps indefinitely.

Ammonium Nitrate, 5% Solution.—

Dissolve 5 gm. ammonium nitrate in 100 c.c. of distilled water.

Carbol Fuchsin.—(See page 1403.)

Dioxane.—This may be obtained from the Carbide and Carbon Chemicals Corporation, 30 E. 42 St., New York 17, N. Y.

Creosote-Xylol Mixture.—

Mix equal parts of beechwood creosote and chemically pure xylol, using dry glassware and dry container. Take care that no water enters the mixture.

Technic.—

Prepare frozen sections in the usual manner (pages 2102 ff.).

Stain in Harris hematoxylin for two minutes. It is easy to carry out this procedure in Stender dishes, using a glass lifter to move the sections from one solution to the other.

Wash in tap water until blue and decolorize rapidly in acid alcohol, dipping in and out five to seven times.

Rinse in tap water.

Place in copper-zinc sulphate solution for 3 minutes.

Stain in brilliant green solution for 5 minutes.

Rinse in water.

Fortify with 5% aqueous ammonium nitrate for one minute.

Rinse in tap water, and mount on a glass slide.

Stain in carbol-fuchsin for 2 minutes.

Pour off, and without washing, apply creosote-xylol mixture, changing the mixture several times and agitating the slide for even differentiation until the background appears to be clear red with no more stain leaving the section. This step requires about one minute. It should be controlled under the microscope.

Clear in pure xylol for two minutes.

Mount in gum damar.

Nuclei are bluish red, gram-positive organisms bluish green, gram-negative organisms red, monilias and actinomycetes green, and Negri bodies bright red with greenish chromatin bodies.

---

*See footnote * p. 2148.

2. Gram Stain of Tissues and Smears

(Second Method of Krajian)

This method is applicable to both sections and smears. It is recommended.

Reagents.—

Loeffler's Methylene Blue.—(See page 1403.)

Isopropanol, Anhydrous.

Creosote-Xylol Mixture.—

Creosote	1 part
Xylol	3 parts

Creosote-Fuchsin.—

Creosote	1 part
Xylol	3 parts

Use 50 c.c. of this mixture to 3 c.c. of 6% alcoholic solution of basic fuchsin.

Gum Damar.

Technic.—

Stain section or smear (fixed in the usual manner by heat) with Loeffler's methylene blue for 2 minutes.

Wash, and dehydrate with isopropanol, two applications.

Dip in creosote-xylol for 10 seconds or until most of the color has been removed.

Apply creosote-fuchsin for 10 to 15 seconds, agitating the slide until background is deep red.

Pour off.

Apply creosote-xylol until section or smear is clear.

Xylol for further clarification.

Mount in gum damar. (The last two steps are unnecessary when dealing with smears.)

3. Gram-Weigert Method (Weigert)

Fix in Zenker's fluid.

Embed in paraffin or celloidin.

Cut sections and stain as follows:

Reagents.—

Alum Hematoxylin.—

Dissolve 1 gm. hematoxylin crystals in 100 c.c. distilled water by the aid of gentle heat.

Dissolve 20 gm. ammonium or potassium alum in 300 c.c. distilled water.

Add the solution of hematoxylin to the alum solution and mix.

Add 1 gm. thymol to prevent growth of molds.

Ripen for ten days in a flask or bottle lightly stoppered with a plug of cotton.

Keep in a tightly stoppered bottle.

2.5% Aqueous Solution of Eosin.—

Dissolve 2.5 gm. eosin Y in 100 c.c. distilled water.

Aniline Crystal Violet, Sterling.—

Crystal violet, 85% dye content	5.0 gm.
Aniline	2.0 c.c.
Alcohol	10.0 c.c.
Distilled water	88.0 c.c.

Mix the aniline with the alcohol and dissolve the dye in the mixture. Then add the distilled water, mix well, let stand 24 hours or more, and filter.

Gram's Iodine Solution.—(See under Method 4.)

Aniline, c.p.

Xylol.

Canada Balsam.

Technic.—

Stain sections lightly in alum hematoxylin.
Wash in several changes of tap water.
Put sections in 2.5% aqueous eosin for 5 to 15 minutes in the paraffin oven.
Stain in Sterling's crystal violet for ½ hour.
Wash in water.
Treat with Gram's iodine solution 1 to 2 minutes.
Wash in water.
Blot with filter paper and decolorize and clear in several changes of aniline.
Rinse in xylol and mount in Canada balsam.

With this stain, gram-positive organisms are deep violet, nuclei blue to violet, connective tissue red, gram-negative bacteria unstained.

4. Krajian's Modification of the Gram-Weigert Method

Reagents.—

1% Aqueous Eosin Solution.—

Dissolve 1 gm. of eosin Y in enough distilled water to make 100 c.c. solution.
Filter after 24 hours.

Sterling's Gentian Violet.—

Gentian violet	5 gm.
95% alcohol	10 c.c.
Aniline oil	2 c.c.
Distilled water	88 c.c.

Dissolve the aniline oil in the distilled water by shaking violently until solution is effected. Then filter through filter paper. Dissolve the gentian violet in the alcohol. Now add the aniline-oil water to the dissolved gentian violet. Shake well, but do not filter. The solution will keep for several weeks to several months.

Gram's Iodine Solution.—

Iodine	1 gm.
Potassium iodide	2 gm.
Distilled water	300 c.c.

Mix the iodine and the potassium iodide thoroughly in mortar. Add the water a small amount at a time until all the iodine is in solution. Filter after 24 hours.

Aniline Oil-Xylol.—

Mix equal parts of aniline oil and xylol in a clean dry container.

Technic.—

Cut frozen sections as directed, and mount on a slide under celloidin (page 2105).
Stain in 1% aqueous solution of eosin for 5 minutes.
Wash in water.
Stain in Sterling's gentian violet for 3 minutes.
Wash with Gram's iodine solution, then stain in Gram's iodine solution for 3 minutes.
Blot with several thicknesses of Whatman No. 1 filter paper.
Decolorize several times in aniline-oil-xylol mixture.
Clear in 2 changes of xylol.
Clean excess celloidin from around section and mount in gum damar.
Gram-positive organisms and fungi stain violet.

5. Brown and Brenn[9] Gram Staining of Tissues

Reagents.—

Harris Hematoxylin.—(Page 2105.)

3% Acid Alcohol.—

Add 3 c.c. hydrochloric acid, conc., c.p., to enough 95% alcohol to make 100 c.c. solution.

---

[9] Bull. Johns Hopkins Hosp. 48: 69, 1931.

Ammonia Water.—

Add 1 c.c. ammonium hydroxide, c.p., to 100 c.c. distilled water.

5% Aqueous Solution of Sodium Bicarbonate With Phenol.—

Dissolve 5 gm. sodium bicarbonate, c.p., anhydrous, in 100 c.c. of 0.5% phenol.

1% Aqueous Gentian Violet.—

Dissolve 1 gm. gentian violet crystals in 100 c.c. distilled water.

Lugol's Solution (Page 1401).

Decolorizer.—

Add 1 part of ether to 3 parts of acetone.

Rosanilin Hydrochloride.—

Dissolve 0.005 gm. rosanilin hydrochloride in 100 c.c. distilled water.

Dilute Basic Fuchsin Solution.—

Add 0.1 c.c. saturated alcoholic solution of basic fuchsin to 100 c.c. distilled water.

Acetone.

Picric Acid Differentiater.—

Dissolve 0.1 gm. of picric acid in 100 c.c. acetone.

Acetone-Xylol Mixture.—

Equal parts of acetone and xylol, made in dry containers.

Xylol.

Balsam.

Technic.—

Prepare paraffin sections.

Stain in freshly filtered Harris hematoxylin for 2 to 5 minutes.

Wash in acid alcohol until light pink.

Wash in ammonia water until blue.

Wash in water.

Mix, in a small vial, 5 drops of the sodium bicarbonate-phenol solution with about 0.75 c.c. of 1% aqueous solution of gentian violet. Immediately pour the mixture onto the slide and stain for two minutes.

Wash quickly with water.

Cover with Lugol's solution for one minute.

Wash with water. Blot.

Decolorize in ether-acetone, dropping it onto the slide until no more color comes off. Blot.

Stain for 5 minutes with rosanilin hydrochloride or basic fuchsin.

Wash in water. Blot but do not allow the section to dry.

Pass through acetone.

Decolorize and differentiate by dropping over the section the 0.1% picric acid in acetone until the section becomes a yellowish pink. This is the most critical stage of the process and should be carried out by holding the slide over a white plate or dish. Most of the fuchsin should be decolorized from the tissue, but the gram-negative bacteria should remain red.

Pass successively through acetone, equal parts of acetone and xylol, and xylol.

After clearing in xylol mount in balsam.

(Beginning with the fifth step it is best to work with only one slide at a time.)

Cell nuclei should be stained dark reddish brown; cytoplasm, yellowish; gram-positive bacteria, deep violet or almost black; gram-negative bacteria, bright red.

Leukocytes generally stand out plainly with a dusky, yellowish cytoplasm. Basophilic granules stain red. Red blood cells may be yellow or red, depending upon the degree of decolorization in picric acid. Cartilage stains pink. Striated muscle and fibrin generally stain yellow but may retain more or less of the red stain. The tissue stain has many of the characteristics of van Gieson's stain.

By this method it is possible to stain successfully sections of tissue showing influenza bacilli, pneumococci, and streptococci; pertussis bacilli crowded among the cilia of the epithelial cells of the trachea and bronchi; gonococci, staphylococci, and streptococci in heart valve vegetations; meningococci in the meninges; *Corynebacterium pyogenes, Actinomyces necrophorus, Bacillus arthracis, Clostridium perfringens,* and *Clostridium septicum* in animal tissues.

6. MacCallum's Modification of Goodpasture's Method

Fix in Zenker's solution and embed in paraffin.

Goodpasture stain used in this technic is as follows:

Basic fuchsin	0.59	gm.
Aniline	1.0	c.c.
Phenol crystals	1.0	gm.
Alcohol, 30 per cent	100	c.c.

Technic.—

Stain sections for 10 to 30 minutes in Goodpasture's stain.

Wash in water.

Differentiate in strong Formalin for a few seconds, until the bright red color changes to a clear rose.

Wash in water.

Counterstain in a saturated aqueous picric acid solution (about 1.22 per cent) 3 to 5 minutes or less, until section assumes a purplish yellow color.

Wash in water.

Differentiate in 95 per cent alcohol. This causes the red color to reappear; some of it is washed out together with some of the yellow color.

Wash in water.

Stain for 5 minutes in Sterling's crystal violet solution. (Page 2151.)

Wash in water.

Immerse in Gram's iodine solution for 1 minute.

Blot dry without washing in water.

Treat with equal parts of aniline and xylol until no more color comes away.

Rinse with 2 changes of xylol and mount in balsam.

With this method, gram-positive organisms are blue; gram-negative organisms, red; all other tissue elements, various shades of red to purple.

Staining Iron Pigments in Frozen Sections (Krajian)[1]

Reagents.—

Potassium Ferrocyanide in Hydrochloric Acid.—

Freshly prepared 2% aqueous solution of potassium ferrocyanide	1 part
Hydrochloric acid, 1%	3 parts

Heat the mixture in a clean Pyrex test tube until beads of vapor form on the inner surface of the glass (about 70° C.). Use this mixture while hot.

Eosin, 1% Aqueous.—(1 gm. eosin Y in 100 c.c. distilled water.)

Technic.—

Prepare frozen sections in the usual manner. (See page 2104.)

Place single sections in hot potassium ferrocyanide in hydrochloric acid either in a Pyrex test tube or in a small Stender dish and leave in the hot solution for ½ to 2 minutes.

Wash thoroughly in several changes of distilled water.

Now mount on a glass slide, dehydrate, and dip in celloidin as directed on page 2105.

Counterstain to the correct color with 1% aqueous eosin.

Rinse in distilled water.

Dehydrate through two changes of absolute alcohol.

Clear in pure xylol.

Mount in gum damar.

Nuclei and hemofuscin stain bright red; hemosiderin stains blue.

---

[1] Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, The C. V. Mosby., 1952.

Staining of Iron or Hemosiderin in Paraffin or Frozen Sections

Make paraffin or fixed frozen section as usual.

Dehydrate through xylol and decreasing strengths of alcohol down to water as usual.

Stain in warm potassium ferrocyanide 2% fresh solution (doubly distilled water) for 3 minutes until a blue color appears. Heat in beaker but not enough to turn color.

Wash in several changes of doubly distilled water.

Stain 10 to 30 minutes in fuchsin:

Fuchsin	0.5 gm.
Alcohol (95%)	50.0 c.c.
Water	50.0 c.c.

Or 0.5% basic fuchsin in 50% alcohol for 10 to 20 minutes.

Differentiate and dehydrate in 95% alcohol.

Wash in absolute alcohol.

Wash in xylol.

Mount with balsam.

Hemosiderin or iron is blue or blue-green.

Weigert's Myelin Stain

Use Formalin-fixed tissue embedded in celloidin. After cutting:

Wash in water.

Place in the following mordant for 12 to 24 hours:

Potassium bichromate	2.0 gm.
Flurochrome	2.5 gm.
Water	100 c.c.

Wash in water 2 to 3 hours (few minutes to 1 to 12 hours).

Wash in 70% alcohol for 10 to 15 minutes.

Wash in water 10 to 15 minutes to 12 hours.

Immerse in copper acetate one-half saturated solution 1 hour (filter) until blue.

Wash in water a few minutes to remove copper.

Stain two hours:

Hematoxylin	0.75 gm.
Alcohol (96%)	10.00 c.c.
Water	90.00 c.c.

Make fresh each time.

Decolorize in:

Borax	2.0 gm.
Potassium ferricyanate	2.5 gm.
Water	200.0 c.c.

Dilute the decolorizer 1:4 or 1:10 if the tissue is to be left overnight.

Wash thoroughly in running water.

Dehydrate in 80, 96, and 99% alcohols.

Wash in carbol-xylol and xylol.

Mount in balsam.

The Oxydase Staining of Tissues

Method of Winkler, W. Schultze

Reagents.—

10% Formalin.—(4% formaldehyde)—Dilute 10 c.c. Formalin (40% formaldehyde) to 100 c.c. with tap water.

1% Aqueous Alpha-Naphthol.—Place 1 gram of alpha-naphthol in 100 c.c. of 1% potassium hydroxide. Heat. Only a part dissolves. Filter.

Diluted Lugol's Solution.—Dilute Lugol's solution with an equal volume of distilled water and filter.

Lithium Carbonate Water.—Use a saturated solution.

1% Dimethyl-para-phenylenediamine.—Hermetically sealed ampules containing 0.5 gm. each may be purchased. Solution does not keep longer than a few days.

Dissolve the contents of one ampule in 50 c.c. of either distilled water or physiologic saline.

Allow to stand one hour, shaking frequently.

Filter.

Weak alum hematoxylin, such as Delafield's hematoxylin diluted, may be used.

Technic.—

(A) **Rapid Method—Not Permanent.**—Fix the tissue in the 4% formaldehyde (10% Formalin).

Freeze and cut.

Place in 1% alpha-naphthol for several minutes, depending on thickness.

Place in 1% dimethyl-para-phenylenediamine solution for a short time, until the leukocytes turn blue. When the leukocytes are blue, rinse, and examine in water or glycerine under a cover glass.

(B) **Permanent Stain.**—Carry out the above technic.

Pour the rinsed preparations into dilute Lugol solution for 3 minutes.

Flood with a large volume of lithium carbonate water for 24 hours.

Counterstain with weak hematoxylin.

Mallory Phosphotungstic Acid-Hematoxylin Stain

Zenker fixation is preferred for general use, although Formalin- or alcohol-fixed tissues can be used for some purposes.

Staining Solution.—

Hematoxylin	1 gm.
Phosphotungstic acid	20 gm.
Distilled water	1000 c.c.

Dissolve the ingredients in separate portions of the water.

Dissolve the hematoxylin with gentle heat.

Cool and mix. No preservative is necessary. Allow to ripen for several weeks, or ripen at once by adding 0.177 gm. of potassium permanganate or 10 c.c. of a freshly prepared 0.25% aqueous solution of potassium permanganate for every 100 c.c.

Technic.—

If Zenker-fixed tissues are used, treat cut sections in the usual manner with iodine to remove the mercury precipitate.

Extract the iodine with alcohol or with a 0.5 per cent solution of sodium thiosulphate for several minutes.

Rinse thoroughly in water.

Place sections in 0.25 per cent aqueous solution of potassium permanganate for 5 to 10 minutes.

Wash in water.

Place in 5 per cent aqueous solution of oxalic acid for 10 to 20 minutes.

Wash thoroughly in several changes of water.

Stain in phosphotungstic acid-hematoxylin for 12 to 24 hours.

Place directly in 95 per cent alcohol, then transfer to absolute alcohol to dehydrate. Dehydrate quickly because alcohol readily extracts the red part of the stain.

Clear in xylol and mount in balsam or gum damar.

If celloidin sections are used, clear with xylol after the 95 per cent alcohol, by means of filter paper and blotting. Origanum and other oils cause the blue stain to fade.

Nuclei, centrioles, achromatic spindles, and fibroglia, myoglia and neuroglia fibrils, fibrin and the contractile elements of striated muscle are stained blue; collagen (including reticulum) and the ground substances of cartilage and bone stain varying shades of yellowish to brownish red. Coarse elastic fibrils are sometimes colored a purplish tint.

Peritoneal or Pleural Fluid, etc.

See **Puncture Fluids**, Chapter VII, page 1222 for other methods of preparation.

The serumizing technic of Krajian (page 2107) is recommended for the sediment. Another method is as follows:

1. Centrifuge material to obtain the sediment.
2. Accumulate enough fairly solid sediment to work with.

3a. Fix in Formalin, etc., as above, and proceed

or

3b. Make a smear of the sediment and stain as a paraffin section after preliminary heating in the flame. Mount after staining.

Blood and Uterine Scrapings

Use the Krajian Serumizing Method, page 2107.

In sectioning the above, do not allow xylol and paraffin mixture to become warmer than merely the melting point, otherwise the blood will crack.

Decalcification of Bone for Paraffin Sections

Place a specimen in 5% nitric acid and change daily until the specimen becomes soft. This requires from one to five days. Be sure to use a very large quantity of solution.

Wash in running water twenty-four hours and then carry through the alcohols from 80 to 95 per cent to absolute.

Place in cedarwood oil for clearing until it becomes transparent and sinks.

Place in xylol for thirty minutes.

Place in paraffin in oven for two hours.

Embed in paraffin and cut sections as usual.

Stain preferably with eosin-methylene blue.

Instead of using 5 per cent nitric acid and washing in running water for twenty-four hours, the following decalcifying solution may be used, taking care to use 100 times volume of tissue:

Hydrochloric acid	4 c.c.
Glacial acetic acid	3 c.c.
Chloroform	10 c.c.
Water	10 c.c.
Alcohol (95%)	73 c.c.

Pass tissue immediately into fresh absolute alcohol (two changes), then into cedarwood oil; the rest of the technic is as above.

A rapid method of decalcification is to place the tissue in the following solution:

Formalin	1 part
Nitric acid	1 part
Water	9 parts

Wash in running water and then begin dehydration in 80% alcohol and continue through the alcohols a little more slowly.

Bone Tissue (or Calcified Nodules)

Decalcify in 5% nitric acid or

10 c.c. formaldehyde (40%)
90 c.c. distilled water
20 c.c. nitric acid.

If the bone is not too large, keep in for two or three hours. It may be kept in the solution as long as forty-eight hours without harming it. There should be at least ten times as much solution as tissue. Change the solution frequently.

Wash in running water twelve to twenty-four hours.

80% alcohol.

Proceed as for paraffin embedding, pages 2120 ff.

If tissue is soft, it is ready for process.

Bone Marrow Puncture

Bone marrow puncture is discussed on pages 914 ff.

Amyloid Stain

Amyloid Stain of Frozen Sections (Krajian)[1]

Reagents.—

Harris Hematoxylin.—(See page 2105.)

Congo Red Solution.—

Congo red, 4% aqueous solution	9 c.c.
Glycerin, redistilled	3 c.c.

Technic.—

Cut frozen sections in the usual manner. (See page 2103.)
Stain unmounted sections in Harris hematoxylin in a small Stender dish for 1 minute.
Wash in tap water until blue.
Stain in a small Stender dish of the Congo red solution for 10 minutes.
Wash rapidly but thoroughly.
Transfer the section to a slide as directed on page 2104.
Blot with several thicknesses of Whatman No. 1 filter paper.
Dehydrate rapidly, applying isopropanol from a drop bottle several times.
Dip in thin celloidin (page 2105).
Blow breath over section to dry.
Dehydrate twice again with anhydrous isopropanol from a drop bottle.
Clear in a staining jar of xylol for 2 minutes.
Remove excess celloidin from around the tissue, and mount in gum damar.
Amyloid is rose color; nuclei are blue.

Amyloid Stain for Paraffin Sections, Method of Lieb

Crystal Violet Solution.—

Saturated alcoholic solution of crystal violet	10 c.c.
Hydrochloric acid	1 c.c.
Distilled water	300 c.c.

Abopon.—

Mix 100 gm. Abopon with 50 c.c. distilled water.

Technic.—

Deparaffinize the section as usual.
Stain for 2 minutes with crystal violet solution.
Rinse in distilled water.
Mount in Abopon.
Amyloid stains red.

Stains for Fat

The staining of fat necessitates the use of fixatives which will not dissolve fat globules. Fat globules are soluble in ether, chloroform, alcohol, xylol, benzine, etc. Formalin fixes the whole fat-containing material without dissolving it.

Sudan III Method

Place frozen sections in 50% alcohol for a few minutes.

Stain in a saturated solution of Sudan III in hot 70% alcohol which should be filtered before use for 5 to 10 minutes.

One minute in 50% alcohol.

Counterstain in Delafield's hematoxylin 3 to 5 minutes.

Differentiate in 3 to 5% hydrochloric acid, followed by distilled water to which has been added a few drops of ammonia.

---

[1] Krajian and Gradwohl: Histological Technic, The C. V. Mosby Co., 1952.

Wash in water 10 minutes.
Mount in gelatin or glycerin gelatin.
Fat stains yellow or yellowish red.

Scharlach R Fat Stain, Frozen Sections (Krajian).[1] Method No. 1

Reagents.—

70% Alcohol.—

70 c.c. of 95% alcohol diluted with distilled water to make a total of 95 c.c.

Scharlach Red.—

Scharlach Red	5 gm.
70% alcohol	50 c.c.
Acetone	50 c.c.
Benzoic acid	1 gm.

The benzoic acid content prevents deterioration of the staining solution and serves to deepen the staining qualities.

Harris Hematoxylin.—(See page 2105.)

2% Sodium Cyanide.—

2 gm. of sodium cyanide dissolved in 100 c.c. distilled water. *POISON.*

Glycerin Jelly (Kaiser).—

French sheet gelatin	10 gm.
Distilled water	60 c.c.

Dissolve the gelatin in the water with heat. Then add a mixture of

Pure glycerin	70 c.c.
Carbolic acid	1 c.c.

Stir the mixture until smooth. Filter through cotton moistened with hot water, carrying out the filtration while the solution is still hot. Store in a cork-stoppered bottle. To melt, place the bottle in the paraffin oven for 15 minutes.

Technic.—

Fix tissues in Formalin, and cut frozen sections in the usual manner (page 2103).
Place sections in a bowl of tap water.
Pick up sections with glass lifter and pass through 70% alcohol quickly.
Stain in a Stender dish containing the Scharlach R solution for 3 to 5 minutes.
Pick sections out of the stain with the glass lifter and pass quickly through 70% alcohol.
Rinse in tap water.
Stain in Harris hematoxylin for thirty seconds.
Lift out with glass lifter and wash with water.
Differentiate with 2% aqueous sodium cyanide for ten seconds.

Wash in water. Place on glass slide. Stand slide against dish to drain off the excess water. Do not allow it to become too dry; a slightly moist surface is desirable.

Mount in warm glycerin jelly.
Fat globules are brilliant red. Cholesterins are less intensely stained.
Nuclei are dark blue. This is a rapid and permanent stain.

Scharlach R Stain for Fat.* Method No. 2

The most commonly used stain for fat is Scharlach R (scarlet red). Sudan III was used originally, but it is less brilliant.

Fix tissues in 10% formaldehyde and cut frozen sections in usual manner.

Pass the sections quickly through 70% alcohol.

Place them in the following staining solution from 3 to 5 minutes: Scharlach R (saturated) in equal parts of 70% alcohol and pure acetone.

Wash quickly in 70% alcohol.

---

[1] Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, The C. V. Mosby Co., 1952.

*Quoted from Krajian, A. A.: Histological Technic, 1940, page 114.

Rinse in water.

Counterstain in Harris' hematoxylin for 15 to 25 seconds.

Wash in water until blue.

Differentiate in 2% potassium iodide solution (aqueous).

Wash in water, transfer to slide and drain off water.

Mount in warm glycerin jelly.

True fats stain intensely, cholesterins less intensely.

This is a rapid and permanent stain. It is highly recommended.

Osmic Acid Method

Flemming Solution.—

A. 1% aqueous chromic acid 11 parts, glacial acetic acid 1 part, distilled water 4 parts.

B. Osmic acid 2% in 1% chromic acid solution.

Just before using, mix four parts of (A) with one part of (B).

Use ten times the volume of the object.

Fix in Flemming's solution 2 to 72 hours.

Wash in water 24 hours.

Make paraffin sections.

Make contrast stain with a saturated alcoholic safranin (saturated in absolute alcohol and diluted with equal parts of distilled water before use) 24 hours.

Wash in water.

Acid alcohol (3 drops of concentrated hydrochloric acid to 100 c.c. of alcohol).

Absolute alcohol until no more color comes off.

Xylol.

Balsam.

Nuclear structures are red and fat is black.

Osmic Acid Method for Frozen Sections (Krajian)

Fix in 10% Formalin for 24 hours or longer.

Cut frozen sections.

Place sections in a 1% aqueous solution of osmic acid for 24 hours. (Flemming's or Marchi's solution may be used instead.)

Wash under running water for 6 to 12 hours.

Place in absolute alcohol for several hours to obtain the secondary staining of fat not yet colored.

Oil Red O Method for Fat in Paraffin Sections

Reagent.—

Oil red O	1 gm.
Acetone	50 c.c.
70% alcohol	50 c.c.

Technic.—

Stain for 1 minute in oil red O solution.

Wash in distilled water.

Counterstain in Harris hematoxylin for 1 to 2 minutes.

Develop the blue of the hematoxylin in tap water.

Blot as dry as possible.

Clear in aniline.

Mount in glycerol.

Fat is stained red.

Cajal's Sublimate-Gold Method for Neuroglia[1]

Harden fresh pieces of human cerebrum for 2 to 6 days in:

Ammonium bromide	2 gm.
Formol	14 c.c.
Distilled water	100 c.c.

Section by freezing microtome.

---

[1] Ramon-Cajal: Histology, English Translation, Fernan-Nunez, Williams and Wilkins Co., 1933, p. 685.

Wash rapidly in distilled water, and place in:

Gold chloride, 1% aqueous solution	10 c.c.
Mercuric chloride (needles)	8-10 gm.
Distilled water	40-50 c.c.

Allow tissues to remain (in darkness or subdued light) from four to ten hours, or until they acquire an intense purple tone. A temperature of 18° to 22° C. favors the reaction. When the method is used in tissues difficult to stain, such as the lower vertebrates, the temperature is elevated to 25° or 30°. (Castro).

Wash in distilled water, and fix in:

Sodium hyposulphite (saturated solution)	10 c.c.
Sodium bisulphite (normal solution)	2-3 drops

Wash the sections in 50% alcohol. Dry on the slide with fine, clean filter paper. Dehydrate in absolute alcohol, oleum origani cretici, xylol, balsam.

If the reaction turns out well, the cells of neuroglia are stained purple, with the neurones and vessels a light violet. The nerve fibers are little or not at all visible.

This procedure gives especially good results with the adult human cerebrum. However, acceptable preparations are obtainable in the cat and dog, but not very good ones in the rabbit. Fresh tissues are essential.

Method for Staining Nerve Protoplasm*

Nissl's Method for Chromatic Granules

Harden in 95% alcohol.

Section without embedding. To secure the tissue to the cork block, for cutting, use a concentrated solution of gum arabic, which will harden in the alcohol.

Cover sections with the following stain and warm until steam is given off:

Methylene blue	3.75 gm.
Venetian soap (or castile soap)	1.75 gm.
Water	1,000.0 c.c.

A 0.5% aqueous solution of toluidin blue may replace the methylene blue.

Dry the sections with filter paper on the slide and differentiate in:

Aniline oil	10 c.c.
Alcohol 95%	90 c.c.

Dry again, clear in cajuput oil, and then in benzene.

Mount in resin damar dissolved in xylol.

The chromatic granules and the nucleoli stain an intense blue.

In Nissl's method the unembedded sections are difficult to handle. The following modification is preferable:

Harden small pieces of fresh nerve centers 4 to 8 days in 95% alcohol.

Dehydrate, and embed in celloidin.

Stain very fine sections for 10 minutes or longer, in a saturated or very concentrated solution of toluidin blue (Nissl) or thionin (Lenhossek).

Wash in 95% alcohol until of a light blue shade. A little aniline oil may be added to the alcohol to accelerate the decolorization. The background may be stained with erythrosin for contrast.

Clear in xylol and mount in xylol-balsam or gum damar.

Method for Demonstration of Neurones[1]

Cajal's Modification of Golgi's Rapid Method

Harden very small pieces for 1 to 3 days in

Potassium bichromate, 3%	20 c.c.
Osmic acid, 1%	6 c.c.

---

*Ramon-Cajal: Histology, English Translation, Fernan-Nunez, Williams and Wilkins Co., 1933, p. 680.

[1] Ramon-Cajal: Histology, William Wood & Company, 1933, p. 681.

Wash for 2 to 4 seconds in distilled water.

Immerse for 30 hours in a 20% solution of crystallized silver nitrate.

Harden for 30 minutes in 95% or absolute alcohol.

Mount superficially in a paraffin block, or between 2 pieces of willow pith for sectioning with the microtome. Make thin sections.

Collect the washed sections in 95% alcohol or absolute alcohol, which is changed 6 or 8 times during the 30-minute period.

Clear for 2 to 5 minutes in oil of cloves.

Transfer rapidly to the slides, and irrigate for same seconds with xylol to remove the oil of cloves.

Apply resin damar dissolved in xylol to the sections.

The sections are dried in the open, so that the varnish may harden in the depths of the tissue and the cells appear as if incrusted in glass. Slow hardening of the varnish, or mounting in the ordinary way, ruins the staining. In order to use the immersion lens, it is advisable to mount the preparations on a coverslip over a perforated piece of wood, with the sections underneath.

Myelin Sheath Stain, Krajian*

Fix tissues in 10% Formalin, cut frozen sections 10 to 15 microns.

Place sections in a 4% Congo red in glycerin, 10 minutes (Congo red 4%, 8 c.c.; glycerin 2 c.c.).

Wash thoroughly in tap water.

Place in a 2% aqueous solution of potassium iodide for 2 minutes.

Wash and place in a 3% aqueous solution of potassium cyanide for 2 minutes.

Wash thoroughly in tap water.

Place in a 10% aqueous ferric ammonium sulphate for 10 minutes at 55° C.

Wash in tap water.

Place in a 20% ripe hematoxylin solution for 5 minutes (2 c.c. ripe hematoxylin, 8 c.c. distilled water).

Wash in tap water.

Destain in a 2% aqueous ferric ammonium sulphate solution until section appears light blue. This takes place in 30 to 45 seconds.

Wash thoroughly in tap water.

Differentiate in a 0.15% aqueous potassium permanganate 10 to 20 seconds.

Wash in tap water.

Place in a 3% aqueous sodium cyanide solution until sections flatten out and assume a light blue appearance.

Wash in tap water, attach to the glass slide.

Dehydrate in 2 changes of absolute alcohol.

Oil origanum 2 minutes.

Pure xylol 2 to 5 minutes.

Mount in gum damar.

The above method has all the advantages of the longer methods, showing very fine details of the fibrils, and yet it can be completed in one hour. It is very highly recommended.

Demonstration of Urea Crystals in Brain Tissue

The following technic, originated by Krajian,[1] is very useful in differentiating at autopsy actual cases of uremia from nonuremic cases. In other words, it has been found that cases with urea crystals in brain tissue are followed by uremic death, while cases that have simulated it do not show urea crystals in the brain tissue.

---

*Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, The C. V. Mosby Co., 1952.

[1] Krajian, A. A.: Histological Technique, Handbook, Published by A. A. Krajian, Los Angeles.

Fix very thin brain tissue, about 2 mm. in thickness, in xanthydrol (5 gm. of xanthydrol is dissolved in 100 c.c. of pure glacial acetic acid) for 6 hours.

Wash under running water for one hour.

Fix in 10% Formalin 6 hours or longer. (In urgent cases, a rapid fixation with heat could be resorted to.)

Wash in tap water.

Cut frozen sections 5 to 10 microns.

Transfer to glass slide.

Pour several drops of absolute alcohol over section from a drop bottle, and blot. Repeat this process once more.

Cover with thin celloidin, dipping slide in a wide mouth bottle containing the celloidin.

Fix to slide by blowing the breath over section.

Stain in 1% aqueous eosin solution for several minutes. (1 gm. eosin in 100 c.c. distilled water.)

Wash in tap water.

Dehydrate in three changes of absolute alcohol (drop bottle method).

Place in carbol-xylol for 2 minutes.

Clear in two changes of pure xylol, 1 minute in each.

Mount in gum damar.

Fixation of very thin blocks in xanthydrol solution is very important on account of its poor penetrating power. Staining nuclei with hematoxylin has caused the disappearance of urea crystals; for this reason, staining the background with eosin will be satisfactory.

Van Gieson Stain

10% Hematoxylin.—

Hematoxylin	10 gm.
Absolute alcohol	90 c.c.

Ferric Chloride-Hydrochloric Acid Mixture.—

Ferric chloride ($FeCl_2 \cdot 6H_2O$), 48.3% aqueous solution	4 c.c.
Distilled water	95 c.c.
Hydrochloric acid	1 c.c.

Hematoxylin for Use (Iron-Hematoxylin).—

Mix equal parts of the 1% hematoxylin and iron chloride solutions.

Van Gieson Mixture.—

Concentrated aqueous acid fuchsin	3 c.c.
Saturated aqueous solution of picric acid	150 c.c.

Test this stain for color tone by placing a drop on a piece of filter paper. The proper color tone is seen when there is a yellow center with a lighter peripheral ring.

Technic.—

Stain 3 to 5 minutes in iron-hematoxylin mixture.

Wash in distilled water.

Stain in van Gieson mixture 2 to 3 minutes.

Wash in distilled water.

Dehydrate through increasing strengths of alcohol.

Clear in xylol and mount in gum damar or balsam.

This stain shows the nuclei of the connective tissue as dark greenish; the muscle fibers are light red; and amyloid tissue is brownish yellow.

Van Gieson Stain of Frozen Sections, Krajian Modification[1]

Reagents.—

Elastic Tissue Stain (see page 2163).

Acid Alcohol (see below).

Van Gieson Stain (see page 2163).

Oil Origanum.—Equal parts of oil origanum and absolute alcohol or isopropanol.

---

[1] Krajian, A. A. and Gradwohl: Histopathological Technic, The C. V. Mosby Co., 1952.

Technic.—

Cut frozen sections in the usual manner and mount under celloidin. See pages 2102 to 2105 for details.

Stain in the elastic tissue stain for 5 minutes.

Wash in water.

Decolorize in acid alcohol until no more color comes off.

Wash in water for a few seconds.

Dehydrate with isopropanol from a drop bottle and recelloidin the slide. This step prevents the tissue from coming off the slide.

Wash in water.

Stain for 5 to 10 minutes with van Gieson stain.

Wash in water.

Blot dry with several thicknesses of Whatman No. 1 filter paper.

Place in oil origanum for 5 minutes.

Clear in xylol. Remove excess celloidin with a towel.

Mount in gum damar.

Nuclei stain dark brown, collagen fibers bright red, muscle, red cells, and other tissues a transparent yellow.

Elastic Tissue Stain of Frozen Sections, Krajian[1]

Reagents.—

Elastic Tissue Stain.—

Hematoxylin	3 gm.
95% alcohol	25 c.c.

Dissolve the hematoxylin thoroughly.

Ferric chloride	3 gm.
Ferric ammonium sulphate	3 gm.
Potassium iodide	3 gm.
Distilled water	25 c.c.

Dissolve the chemicals in the distilled water.

Mix the two solutions together. Ready for use.

Acid Alcohol.—1% hydrochloric acid in 70% alcohol.

10% Citric Acid.—

Dissolve 10 gm. of citric acid, c.p., in enough distilled water to make a total of 100 c.c. This solution may develop a growth of molds, in which case a fresh solution must be made.

Saturated Aqueous Solution of Picric Acid.—

Dissolve 1.22 gm. picric acid in 100 c.c. distilled water, with a little heat. Filter when cold.

Van Gieson Stain.—

Saturated aqueous solution of picric acid	100 c.c.
1% aqueous solution of acid fuchsin	5 c.c.

This solution keeps well. If it becomes weak upon long standing, add a few drops of fresh acid fuchsin solution.

Creosote-Isopropanol Mixture.—

Add 50 c.c. of anhydrous isopropanol to
50 c.c. beechwood creosote. Be sure all glassware used is dry.

Isopropanol, xylol, and **gum damar** are also used in this stain.

Technic.—

Cut frozen sections in the usual manner as directed on page 2103.

Place sections on slide under thin celloidin as directed on page 2104.

---

[1] Krajian, A. A., and Gradwohl, R. B. H.: Histopathological Technic, St. Louis, 1952, The C. V. Mosby Co.

Staining solutions are in staining jars.

Stain for 3 to 5 minutes in the elastic tissue stain.

Dip in and out of acid alcohol, turning the slide frequently for even decolorization, until the background clears.

Wash in tap water for a few seconds.

Decolorize in 10% citric acid for a few seconds, up to 2 minutes.

Dip in tap water.

Dehydrate quickly in isopropanol from a drop bottle. If the celloidin comes loose at this step, dip once more into the celloidin and dehydrate with anhydrous isopropanol from a drop bottle.

Dip in and out of van Gieson stain about 10 to 15 times, or until the section takes on a good counterstain.

Wash rapidly in a large container of tap water, then blot with several thicknesses of Whatman No. 1 filter paper.

Dehydrate with isopropanol.

Differentiate in equal parts of creosote and isopropanol for 2 minutes.

Place in xylol to clear. Remove excess celloidin with a towel.

Mount in gum damar.

Elastic tissue is black. Amebae stain a pale red with brown nuclei. Connective tissue is dark red.

Weigert's Elastic Fiber Stain[1]

Reagents.—

Weigert's Elastic Fiber Stain.—

Mix and dissolve 2 c.c. of carbolic acid and
1 gm. of basic fuchsin
in 100 c.c. of distilled water, and bring the mixture to a boil. When boiling, gradually add 12.5 c.c. of 30 per cent ferric chloride. A precipitate forms; to render the precipitate more granular, continue the boiling at least 5 minutes.

Cool and filter. Wash the precipitate on the filter paper with distilled water until no more color is seen. Dry the precipitate in the paraffin oven at 55° C. and keep this dry powder in a bottle for making up the staining solution.

Weigh 0.75 gm. of dry powdered precipitate and dissolve in 100 c.c. of 95 per cent alcohol. Boil the mixture in a flask, plugged with cotton wool, in a water bath for 20 minutes. Then cool, filter, and add 2 c.c. of concentrated hydrochloric acid.

Technic.—

Fix tissues in formaldehyde or alcohol. Zenker-fixed tissues stain slowly, and there is greater tendency to diffuse coloring of collagen fibrils. Embed tissues in paraffin or celloidin, or cut frozen sections from formaldehyde-fixed tissues.

Stain sections 20 minutes to 1 hour in Weigert's elastic fiber stain.

Wash in 95 per cent alcohol.

Blot with filter paper and add xylol quickly.

Repeat the blotting, followed by xylol 2 or 3 times, until the section is cleared.

Mount in gum damar.

The elastic fibers appear dark blue, almost black, on a clear background. The nuclei can be stained red with carmine, before or after staining of the fibers. Carmine stain is difficult to obtain after Zenker's fixation. A light nuclear stain, with some alum hematoxylin, after the fibers have been colored, is preferable. This is a very useful and permanent stain.

Weigert Elastic Stain Method, Raubitschek[2]

Basic fuchsin	2 gm.
Resorcin	4 gm.
Distilled water	200 c.c.

---

[1] Krajian, A. A., and Gradwohl: Histopathological Technic, St. Louis, 1952, The C. V. Mosby Co., p. 131.

[2] Personal communication by Dr. Hugh V. Raubitschek, formerly Professor of Pathology, University of Vienna, Austria.

Boil. While briskly boiling, add 25 c.c. of 10 per cent ferric chloride and boil again for 2 to 5 minutes. A precipitate forms. Cool and filter. Discard the filtrate. Dry the precipitate on the filter paper. Put the paper with the dry powder in a beaker with 200 c.c. of 95 per cent alcohol and heat carefully on a waterbath. Fish out the paper, cool, and filter. Add alcohol to the filtrate to make up to 200 c.c. Add 4 c.c. of hydrochloric acid. Since the staining power of every batch is different, it is well to test the stain before using on a specimen and record the staining time on the label of the bottle.

Masson's Trichrome Stain, DeCoursey[1]

Reagents.—

Weigert's Hematoxylin.—

Solution A:

Hematoxylin	1.5 gm.
95% alcohol	100 c.c.

Solution B:

Iron chloride, 29% aqueous solution	4 c.c.
Distilled water	95 c.c.
Hydrochloric acid	1 c.c.

For use, mix equal parts of solutions A and B.

Ponceau-Acid Fuchsin Mixture, Krall.—

Ponceau de xylidene (Krall-Eimer and Amend, N. Y.)	Approximately	0.9 gm.
Acid fuchsin	Approximately	0.1 gm.
Glacial acetic acid		1 c.c.
Distilled water		100 c.c.

Phosphomolybdic Acid Solution.—

Phosphomolybdic acid	1 gm.
Distilled water	100 c.c.

Aniline Blue Stain.—

Aniline blue	2 or 3 gm.
Boiling distilled water	100 c.c.

Add 2 or 3 gm. of aniline blue to 100 c.c. boiling distilled water. Boil for a while longer to dissolve the dye.

Add Glacial acetic acid ---------- 2.5 c.c.

Cool and filter.

Fixation.—

Bouin fixative is preferred, but any fixative may be used.

Carry paraffin sections through xylol and the decreasing strengths of alcohol in the usual manner, to distilled water, then immerse overnight in Bouin solution. This overnight immersion is carried out even with Bouin-fixed tissue.

Just before staining, wash in running water for 20 minutes to remove the picric acid.

Staining.—

After soaking paraffin sections in Bouin's solution overnight and washing as directed above, stain as follows:

Weigert hematoxylin, freshly mixed ----------5 to 10 minutes.
Rinse quickly in distilled water. Tap water causes a precipitate.
Differentiate in 1% acid alcohol under a microscope.
Wash in tap water.
Ponceau-acid fuchsin mixture ----------5 minutes.
Rinse in distilled water.
Phosphomolybdic acid solution ----------2 hours or longer.

This acid decolorizes the collagen and prepares the collagen for aniline blue.

Without rinsing, immerse in aniline blue or light green.

---

[1] Simmons, J. S., and Gentzkow, C. J.: Laboratory Methods, Lea and Febiger, 1944.

Leave for 5 to 10 minutes or longer until a deep color is obtained.

Rinse in distilled water.

Return to phosphomolybdic acid 2 to 5 minutes.

This step is important; it removes the blue from the cytoplasm. If light green is used, omit this step.

Rinse with distilled water.

1% acetic acid (in a Koplin jar) 2 to 5 minutes.

This eliminates the phosphomolybdic acid and sets the acid red and blue.

Dehydrate in the usual manner.

Clear with toluene or xylol.

Mount in Canada balsam or gum damar. Just before mounting, pour on a few drops of salicylic acid-toluene or -xylene. The salicylic acid acidulates the balsam and prevents the acid colors from fading.

Aniline Blue Stain of Frozen Sections, Krajian[1]

(For Connective Tissue and Hyaline)

Reagents.—

Mordant.—

Thorium nitrate	2 gm.
Saturated aqueous solution of picric acid	30 c.c.
Acetone	15 c.c.

Dissolve the thorium nitrate in the picric acid solution, then add the acetone.

Azocarmine-Fuchsin Stain.—

Azocarmine solution	1 part
Acid fuchsin, 2 per cent	1 part

Add phenol in 5 per cent proportion (5 c.c. for every 100 c.c. of mixture).

The azocarmine solution is made by dissolving 1 gm. of azocarmine in 100 c.c. distilled water, heating the mixture for 15 minutes, then cooling. Filter and acidify with 1 c.c. of glacial acetic acid.

3% Stannous Chloride.—

Dissolve 3 gm. stannous chloride in enough distilled water to make 100 c.c. of solution.

10% Phosphotungstic Acid Solution.—

Dissolve 10 gm. of phosphotungstic acid in enough distilled water to make a total of 100 c.c. of solution.

Aniline Blue Solution.—

Aniline blue (water soluble)	0.5 gm.
Acetic acid, glacial	8.0 c.c.
Orange G	2.0 gm.
Distilled water	100.0 c.c.

Dissolve with heat. Filter after cooling.

Clearing Agent.—

Creosote (beechwood)	1 part
Xylol	1 part

Technic.—

Fix tissues in 10% Formalin in the usual manner and freeze and cut according to the technic on page 2103. Sections are 7 to 10 microns thick.

Place in mordant for 5 minutes.

Rinse rapidly in tap water.

Transfer to a glass slide as directed in the routine staining method.

Blot under several thicknesses of Whatman No. 1 filter paper.

---

[1] Krajian, A. A.: Personal communication.

Dehydrate for a few seconds with anhydrous isopropanol.

Blot again and dip once in thin celloidin (page 2104). Blow over surface until dry.

Rinse in tap water and stain for 5 minutes in the azocarmine-fuchsin stain in a jar.

Wash thoroughly in tap water.

Treat with 3% stannous chloride for 3 minutes.

Rinse and differentiate for 3 to 5 minutes in a 10% phosphotungstic acid solution.

Rinse in tap water.

Stain for 10 to 12 minutes in aniline blue solution.

Rinse in tap water rapidly and thoroughly.

Treat for 2 minutes with 3% stannous chloride solution.

Wash and dehydrate with 3 applications of isopropanol for a few seconds of each application.

Differentiate and clear for 3 minutes in the clearing agent.

Clear for 2 minutes in xylol.

Remove excess celloidin from edges of slide with a towel and mount in gum damar.

Collagen fibers stain deep blue; reticulum, light blue; hyaline, bright red; nuclei, red; erythrocytes, golden yellow; elastic fibers, dark red.

Caution: Keep the solutions in tightly stoppered bottles. They may be used a dozen times.

Staining of Reticulin Fibers in Frozen Sections
Krajian Method

For the demonstration of reticulum and collagen fibers, numerous methods have been devised, but unfortunately most of the methods require paraffin embedding. The paraffin method not only delays the results but may in some manner obscure some of the reticulin fibers which might be demonstrated if the frozen section technic were used.

Morhardt and Krajian[1] have offered an argument in favor of a more detailed study of reticulum or the reticulin fiber network in tissues for the purpose of differentiating various types of neoplasm. They are convinced that any undifferentiated cellular tumor which is without obvious characteristics is incompletely examined unless a reticulum stain is performed. They believe that carcinoma is never productive of an increase in reticulum and that all sarcomas provoke an increase in reticulum. Benign tumors show no changes in reticulum. In their experience with tumors with increased reticulum, they offer the following list: testicular seminoma; pleural mesothelioma; periphery of glioblastoma; spinobasilar chordoma; periphery of astrocytoma; plasma cell myeloma; periphery of metastatic melanblastoma in brain; leiomyosarcoma; leiomyoblastoma; reticulum cell sarcoma; osteosarcoma; lymphosarcoma; retroperitoneal sarcoma, neurogenic; giant cell tumor, osteoclastoma; neurofibrosarcoma; testicular lymphosarcoma; monocytic leukemia (liver); plasma cell leukemia (liver); Wilms' tumor (sarcomatous component); and malignant lymphoma.

Those with normal reticulum are as follows: carcinoma of lung, primary; fibroadenoma of breast; neuroma; uterine adenomyosis; hemangioma; lipoma; neurilemoma; dysgerminoma (ovarian seminoma); carcinoma of thyroid gland; adamantinoma; carotid body tumor.

Tumors with diminished reticulum, that is, displacement of normal tissue, are as follows: hepatoma; carcinoma of ovary; carcinoma of testis; neuroepithelioma; glioblastoma, central portion; glioma, central portion; chorioepithelioma; carcinoma adrenal, metastatic; medulloblastoma (center area);

---

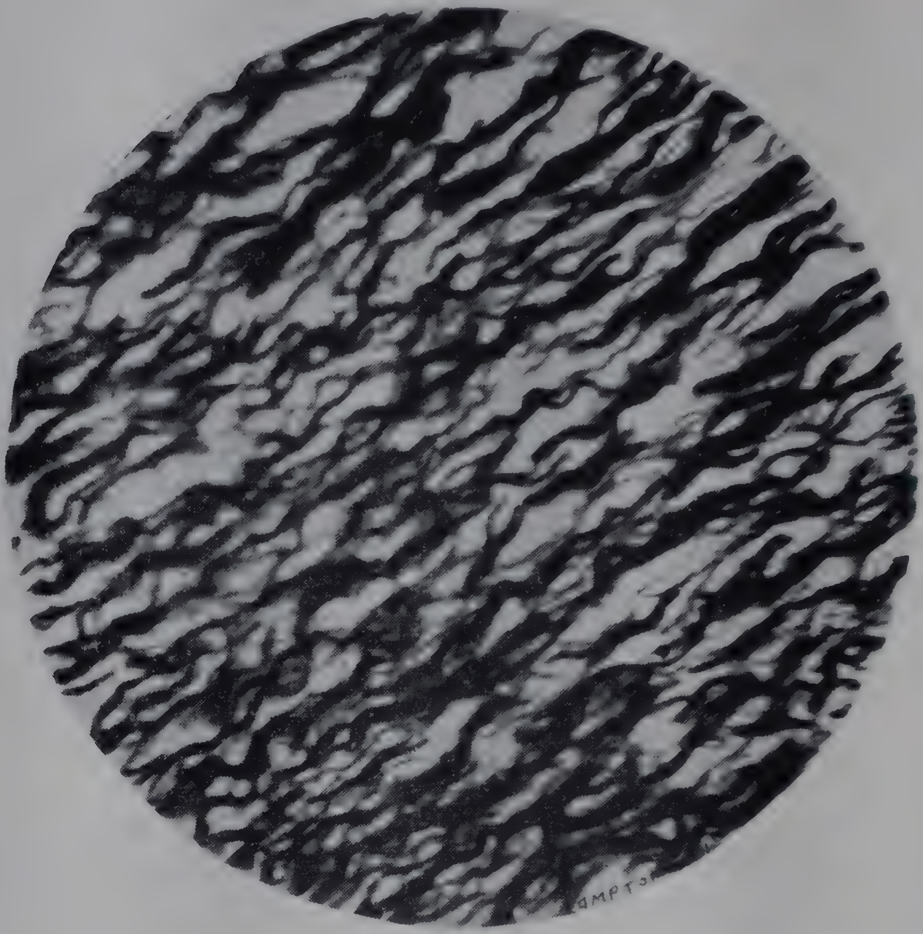

Fig. 628.—Leiomyosarcoma, reticulum stain, Krajian method, high power.

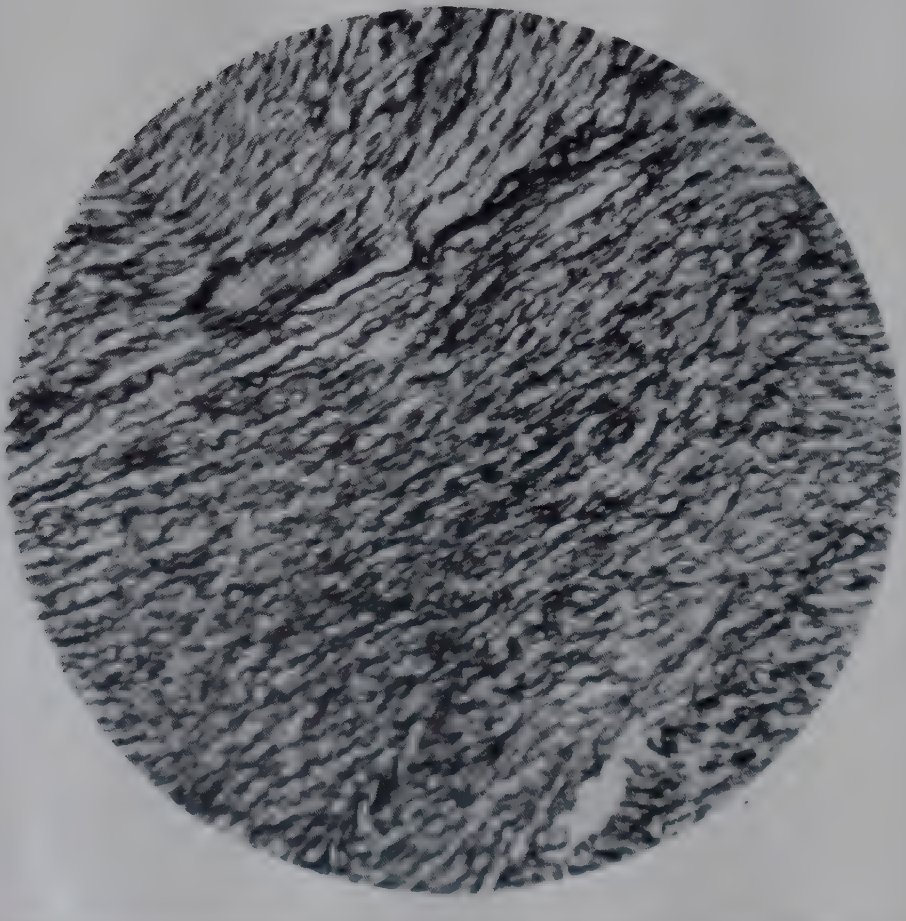

Fig. 629.—Leiomyosarcoma, reticulum stain, Krajian method, low power.

malignant melanoma, lymph node; adrenal cortical adenoma; Ewing's tumor, lymph node; carcinoma pituitary, metastatic; cystic disease of breast; carcinoid in liver; carcinoma of stomach.

Reagents.—

Creosote-Xylol Mixture.—

Add 2 parts of xylol to 1 part of creosote.

10% Formalin.—See page 2102.

10% Ammonium Hydroxide Solution.—

Dilute 10 c.c. of ammonium hydroxide, c.p., to 100 c.c. with distilled water.

0.25% Potassium Permanganate Solution.—

Dissolve 0.25 gm. potassium permanganate, c.p., in 100 c.c. distilled water.

3% Oxalic Acid Solution.—

Dissolve 3 gm. oxalic acid in 100 c.c. distilled water.

Ammoniacal Silver Solution.—

Place 10 c.c. of 10% silver nitrate solution in a Stender dish. Add concentrated ammonium hydroxide solution drop by drop while agitating the container or while stirring with a glass rod until the precipitate disappears.

20% Formalin.—

Dilute 20 c.c. Formalin (40% formaldehyde) to 100 c.c. with water.

0.5% Gold Chloride Solution.—

Dissolve 0.5 gm. gold chloride, reagent grade, in 100 c.c. distilled water.

5% Sodium Thiosulphate Solution.—

Dissolve 5 gm. sodium thiosulphate, c.p., in 100 c.c. distilled water.

Technic.—

Cut frozen sections 7 to 10 microns thick.

Place in a warm 10% ammonium hydroxide solution in the paraffin oven at 56° C. for 10 minutes.

Wash rapidly in distilled water.

Place sections in 0.25% potassium permanganate solution for 10 minutes.

Wash in distilled water and decolorize in 3% oxalic acid until most of the brown color is removed.

Wash in distilled water.

Place in warm ammoniacal silver solution and place in paraffin oven for 40 minutes at 56° C.

Wash in distilled water and place in a 20% warm Formalin solution for 3 minutes (for reducing).

Wash in distilled water and place in 0.5% gold chloride solution for 3 minutes.

Wash in distilled water and place in 5% sodium thiosulphate solution for 5 minutes.

Transfer to glass slide and dehydrate with two applications of anhydrous isopropanol or absolute ethyl alcohol.

Blot twice and dip in thin celloidin, blow over the surface to dry the section, and blot again.

Dehydrate twice with anhydrous isopropanol or absolute ethyl alcohol, and apply creosote-xylol mixture for 3 minutes.

Clear in xylol for 3 minutes and mount in Permount or gum damar.

Reticulin fibers stain black.

Romanowsky Staining of Tissues With Buffered Solutions

The Romanowsky staining of tissue sections has been unsatisfactory because of the necessity of individual regressive differentiation of each section with alcohol, colophonium alcohol, or dilute acetic acid to the desired point. It is often necessary to control this differentiation under the microscope.

Lillie and Pasternack[1] during the course of staining a batch of sections with the MacNeall-French tetrachrome Giemsa modification in 1931 noticed well-stained specimens without any necessity of further differentiation. This accident was found to be due to an unusually acid sample of distilled water. This experience led them to try the effect of various buffer mixtures on stains of the eosin-polychrome-methylene-blue class, and the following procedure was worked out:

Reagents.—

Eosinate of Polychrome Methylene Blue.—

Dissolve 1 gm. eosinate of polychrome methylene blue, prepared by the Balch silver oxide method (10 gm. eosin Y, 9 gm. methylene blue)
in 25 c.c. anhydrous glycerin
and 75 c.c. methyl alcohol, chemically pure.

Phosphate Buffer pH 5.3.—

M/15 Na_2HPO_4	26 c.c.
M/1 NaH_2PO_4	65 c.c.
Distilled water	909 c.c.

Buffered Stain for Use.—

Eosinate of polychrome methylene blue	2 c.c.
Phosphate buffer pH 5.3	50 c.c.

Technic.—

Dehydrate paraffin sections of formaldehyde-fixed or Orth-fixed material in the usual way, down to distilled water.

After the distilled water step, stain for 2 hours in the buffered eosinate of polychrome methylene blue solution.

Rinse in distilled water.

Dehydrate with acetone.

Clear in xylol.

Mount in liquid petrolatum, heavy, U.S.P.

Seal with a pyroxylin cement.

Staining for shorter periods than two hours with the same or more concentrated or heated solutions has not given as satisfactory differential staining. Staining overnight in a solution containing 1 c.c. of stock stain to 50 c c. of buffer is very satisfactory and possibly slightly more differential than the two-hour period, but the greater time requirement is an objection.

When it is especially desired to bring out such tissue elements as red corpuscles and eosinophilic leukocytes, a buffer of pH 4.8 may be employed, but nuclear staining is not as satisfactory as at pH 5.3. On the other hand, a buffer of pH 5.6 stains nuclei and bacteria more deeply, but suppresses eosinophiles and red corpuscles. Basophilic cells are satisfactorily demonstrated at from pH 5.3 to 4.8 and are more conspicuous at the more acid level. Mucin is better shown with less acid buffers.

With a pH 5.3 phosphate buffer, red corpuscles are orange red; eosinophile granules, red; nuclei and tigroid granules, blue; muscle and connective tissue, pink; glia and nerve fibrils, faint pink; pancreatic secretion granules, red; liver cell cytoplasm, light blue; necrotic cells, pink, and bacteria and Rickettsiae, blue. The method has proved particularly satisfactory for the study of tissues of the central nervous system.

Giemsa Staining of Tissues

(Schilling Method, Modified by Gradwohl)

Susa Fixative.—

Mercuric chloride	4.5 gm.
Sodium chloride	0.5 gm.
Trichloroacetic acid	2.0 gm.

---

[1] Arch. Path. **14**: 515, 516, 1932.

Glacial acetic acid	4.0 c.c.
Formalin	20.0 c.c.
Distilled water	80.0 c.c.

Fixation, Dehydration, and Embedding.—

Immerse the tissue in Susa fixative for 5 to 48 hours, depending on the size.[1]

Wash in tap water for three to five hours, changing the water frequently.

Place in 50% alcohol for half a day, changing the alcohol several times.

Transfer to 70% alcohol (several changes) for half a day.

Transfer to 95% alcohol for half a day, changing the alcohol several times.

Place in absolute alcohol not longer than one hour. (The sections may be left in this alcohol, if they are very large, for a longer period.)

Clarify in neutral xylol. The tissue must become transparent.

Place the tissues in a mixture of equal parts of paraffin and xylol at a temperature not to exceed 37-40° C. over night. Use special embedding paraffin with a melting point of 56-58° C. Tissuemat or Histowax may be used.

Keep the paraffin oven at a temperature two degrees above the melting point of the paraffin.

Place the tissues in pure paraffin or Tissuemat or Histowax in the paraffin oven for 4 hours.

Transfer to fresh paraffin or Tissuemat or Histowax in the paraffin oven for 2 to 4 hours.

Embed in fresh paraffin or Tissuemat or Histowax in the usual manner.

Staining.—

Cut the sections and mount on slides using Mayer's albumin fixative.

Allow to dry thoroughly.

All solutions for staining sections should be in staining jars.

Place the slides in xylol for 5 minutes to remove the paraffin.

Carry through

Absolute alcohol	1 minute
95% alcohol	1 minute
80% alcohol	1 minute
70% alcohol	1 minute

Place in iodine-alcohol (100 c.c. 70% alcohol and 1 c.c. tincture of iodine) for one to two hours, or until the tissues become a brown color.[1] This removes the mercury.

Treat briefly with 0.2% sodium thiosulphate solution not longer than 10 to 15 minutes, or until the brown color is removed.

Wash for 30 minutes in a jar of tap water.

Wash for 30 minutes in a jar of distilled water.

Dilute Giemsa stain by adding 1 drop of Giemsa stain to each c.c. of neutral distilled water, shaking briefly after the addition of each drop. Avoid shaking too vigorously.

Stain for 30 minutes on a staining bridge, flooding the slide with Giemsa stain.

Renew the stain at the end of the 30 minute staining period, diluting a fresh supply for the re-staining process. Re-stain 30 minutes.

Wash briefly in a jar of distilled water.

Place the slide under the low power objective of the microscope and decolorize as follows:

Decolorization, Dehydration, and Clarification.—

Carried out under microscopic control. This requires very rapid handling.

Avoid over-decolorization.

Use a weak acetic acid solution for decolorizing. This is made by adding a few drops of 1% acetic acid to 50 c.c. distilled water.

---

[1] If Formalin-fixed tissues are used, omit the iodine-alcohol-thiosulphate steps in the staining process.

Have on hand a jar of slightly alkaline water, made by adding 2 or 3 drops of 1% potassium carbonate solution to 100 c.c. tap water.

Place the Giemsa-stained slide under the microscope, low power magnification.

Flood the slide with the weak acetic acid solution, and *as soon as* the pink color of the eosin is observed, place the slide in the jar of slightly alkalinized water. The rapidity of this change is very important, because the section will continue to be decolorized as long as the acid remains not neutralized on the tissue.

Dehydration is carried out in staining jars. The solutions are as follows:

1. Xylol	5 parts
Acetone	95 parts
2. and 3.	
Xylol	30 parts
Acetone	70 parts

Place the slide in solution No. 1 for about 5 to 10 seconds,
in solution No. 2 for about 5 to 10 seconds,
in solution No. 3 for 10 seconds or more.

Place in xylol. If the section does not become transparent, place again for a few seconds in solution No. 3 then back in xylol. Continue this process until the tissue is clear, then leave in xylol for several minutes. (Keep the acetone solutions tightly stoppered to prevent absorption of undue amounts of moisture.)

Mount in gum damar.

Butyl Alcohol in Dehydration and Clearing Specimens That Have Been Embedded in Paraffin (Zirkle[1])

Zirkle[1] describes the use of butyl alcohol in dissolving some of the superfluous xylol which adheres to the slides and is carried on them into the absolute alcohol. This method prevents a milky precipitate which is commonly seen.

Water	1 part
Xylol	1 part
N-butyl alcohol	1 part
Ethyl alcohol	2 parts

The ethyl alcohol-butyl alcohol mixture dissolves both water and xylol, keeps them in solution at the same time, and forms a single clear liquid. Use for cleaning slides to remove both water-soluble (glycerin, glucose, etc.) and fat-soluble material (immersion oil, balsam, etc.). Dilute ammonium hydroxide may be substituted for the water and carbon tetrachloride for the xylol. This combination forms a potent cleanser.

A very useful addition to cytologic technic is the application of n-butyl alcohol in the hydration and dehydration of cut sections. It has often been observed in staining paraffin sections that carrying the slides through xylol, then absolute alcohol, then decreasing strengths of alcohol results in clouding of the section because of the small amount of xylol which remains after the first step. Some xylol is also carried to the alcohols, so that when they come in contact with the water, clouding occurs. The following series will serve to eliminate such cloudiness and precipitation:

1. Xylol 100%.
2. Xylol 95%, n-butyl alcohol 5%.
3. Absolute ethyl alcohol 90%, n-butyl alcohol 10%.
4. Absolute ethyl alcohol 100%, etc.

Zirkle states that he has often passed more than a hundred slides through a single series of Koplin jars without a precipitate and without renewing any of the solutions.

---

[1] Science, p. 481, Nov. 23, 1934.

VAGINAL SMEARS IN THE DIAGNOSIS OF UTERINE CANCER

The vaginal smear method in diagnosis of uterine cancer has become a valuable laboratory procedure. According to Meigs,[1] delay is responsible for a majority of deaths from cervical cancer, a delay to which both patient and physician contribute. He used a simple method described by Papanicolaou[2, 3, 4] for making a presumptive diagnosis of uterine carcinoma. With this method a diagnosis of uterine carcinoma may be made by examination of the vaginal smear. In Meigs's report, 200 women were studied, using the technic described by Papanicolaou.[2]

PAPANICOLAOU TECHNIC[2]

Attach a slightly curved glass pipette, 8 inches long, to a 3-inch rubbed suction bulb. The pipette must be absolutely dry, and the patient must not have douched that same day. These precautions are necessary since water in the vaginal smear destroys the cellular detail.

Compress the rubber bulb and then insert the pipette into the vagina as far as possible in order to reach the fornix.

Release the bulb and withdraw the pipette slowly. Blow the material on a previously marked slide and drop the slide immediately into a bottle of fixative. The fixative is made by mixing equal parts of ether and 95% alcohol.

Since drying destroys cellular detail it is essential that the slide be placed immediately in the fixative. Fixation for 15 minutes is sufficient, but slides may be left in the fixative without deterioration for as long as 2 weeks, and 1 hour is suggested as a routine fixing period.

Reagents.—

Harris Hematoxylin.—

Prepare Harris hematoxylin in the usual manner (page 2105) but omit the acetic acid.

Dilute with an equal volume of distilled water.

Filter through filter paper.

From time to time, as it is in use, add more Harris hematoxylin in order to maintain standard staining results.

0.25% Hydrochloric Acid Solution.—

Add 0.25 c.c. of concentrated hydrochloric acid, c.p., to distilled water, and dilute to 100 c.c. with distilled water.

OG 6.—

0.5% alcoholic solution of orange G	100 c.c.
Phosphotungstic acid	0.015 gm.

EA 36.—

Light green SF yellowish, 0.1% alcoholic	45 c.c.
Bismarck brown, 0.5% alcoholic	10 c.c.
Eosin Y, water and alcohol-soluble, 0.5% alcoholic	45 c.c.
Phosphotungstic acid	0.2 gm.
Lithium carbonate, saturated aqueous solution	1 drop

NOTE: All stains are certified stains.

Alcohol-Xylol Mixture.—

Equal parts of absolute alcohol and xylol.

EA 50.—

This is a stain comparable to EA 36.*

Technic.—

Carry out the staining process in staining dishes.

After fixation, transfer the slides, without drying, directly from the alcohol-ether mixture to 80% alcohol.

Dip 4 times in 80% alcohol.
Dip 4 times in 70% alcohol.
Dip 4 times in 50% alcohol.
Dip 4 times in distilled water.
Stain for 6 minutes in the Harris hematoxylin (prepared as given above).
Rinse in distilled water.
Dip 6 times in 0.25% hydrochloric acid solution.
Place in running tap water for 6 minutes.
Rinse in distilled water.
Rinse in 50% alcohol.
Rinse in 70% alcohol.
Rinse in 80% alcohol.
Rinse in 95% alcohol.
Stain for 1½ minutes in OG 6.
Rinse in 95% alcohol.
Rinse in 95% alcohol in another staining dish.
Stain in EA 36 for 1½ minutes. (Or use EA 50.)
Rinse in 95% alcohol.
Rinse in 95% alcohol in another staining dish.
Rinse in 95% alcohol in another staining dish.
Rinse in alcohol-xylol.
Rinse in xylol.

Mount in Permount, gum damar, or Canada balsam, or any other satisfactory neutral mounting medium.

The original methods of staining and preparing stains as described by Papanicolaou have been materially changed and much improved by the work of Pharr and others.[1] There has been great difficulty in suspending dry, powdered stains in various solvent agents such as water, alcohol, and glycerin, with resulting variations in weight of stain per volume of stock solution. This has caused difficulties with the employment of cytologic stains used in the Papanicolaou method.

Eosin, light green S.F. yellowish (EA), and orange G are readily soluble in water; this would be the stock solution of choice except for two reasons: the aqueous stock solutions are not sufficiently stable to be of practical value; and these stains tend to lose their sharpness of color when suspended in water. Pharr and associates have found the use of a mechanical stirrer a valuable adjunct in their work. The mechanical stirrer used in their study was the Waring blendor.

STAINING METHOD OF PHARR, WOOD, AND TRAUT[1]

Preparation of the Stain.—

Orange G.—

Heat 380 c.c. of 95% ethyl alcohol to the boiling point and pour sufficient heated alcohol into the stirrer cup to cover the blades. This prevents the powdered stain from adhering to the blades.

Add 1 gm. of orange G (National Aniline R*).

Fill the stirrer cup with the heated alcohol to approximately one-fourth its volume.

---

*National Aniline Division, Allied Chemical & Dye Corp., 40 Rector St., New York City.

[1] Pharr, S. L., Wood, D. A., and Traut, H. R.: Am. J. Clin. Path. 24: 2, 1954.

Mix the solution for 1 or 2 minutes, turning the motor off and on several times for maximum mixing.

Pour off the supernatant fluid after allowing the unsuspended stain to settle momentarily.

Add additional alcohol to the remaining undissolved stain and pour off after mixing.

Repeat until all alcohol has been used and all stain is in solution.

Allow the solution to *cool*, and then filter. There will be a slight precipitate of orange G, since the stain is present in excess.

Add 0.4 gm. of phosphotungstic acid

and 3 c.c. of glacial acetic acid to the filtered solution.

The orange G working solution is now ready for use and is stable for one month to six weeks. Store excess working solution in an amber-colored bottle to prolong its stability.

EA Stain.—

Cover the blades of a clean, *dry* mechanical stirrer with a portion of a measured 380 c.c. of 95% ethyl alcohol. Do not heat the alcohol.

Add 2 gm. of eosin (National Aniline R)

and 1 gm. of light green S.F. yellowish (National Aniline R)

and fill the stirrer cup to approximately one-fourth its volume with alcohol. Note that the Bismarck brown has been omitted as a constituent of this stain.

Mix the solutions, as previously described, until all the stain is in solution.

Allow to stand overnight, but DO NOT FILTER.

Add 0.4 gm. of phosphotungstic acid

and 3 c.c. of glacial acetic acid.

The EA working solution is stable for one month to six weeks if it is covered to protect it from deterioration by light or if it is poured back into a dark bottle after use.

It is essential that the stirrer cup be clean and dry to obtain a sharp, bright stain. Spraying from the forceful pressure of the stirrer blades is avoided by placing a filter paper or paper towel under the stirrer cover.

Since these stains are water soluble, the stirrer cup and blades are easily cleaned.

Stains prepared in this manner have been consistent from one batch to another and have not precipitated during use.

Mayer's Hematoxylin.—

Distilled water	1,000 c.c.
Hematoxylin (National Aniline R)	1 gm.
Ammonium or potassium alum	50 gm.
Sodium iodate	0.2 gm.
Citric acid	1.0 gm.
Chloral hydrate	50 gm.

Dissolve the hematoxylin in 1,000 c.c. of distilled water that has been heated to 55° to 60° C., and rotate until all the stain is in solution.

Add the alum and sodium iodate, taking care that the 0.2 gm. of sodium iodate has been accurately weighed.

Rotate until the alum has dissolved.

Add the citric acid and the chloral hydrate. The order of mixing must not be changed.

Allow the solution to stand overnight before use.

This solution is stable for two months if the staining time is gradually increased from an initial 6 minutes to 8 minutes after prolonged use. Occasional filtering may be necessary to remove accumulated cellular debris.

Staining Technic.—

Prepare slides and fix immediately in equal parts of ether and 95% ethyl alcohol for a minimum of 30 minutes.

Immerse in 70% ethyl alcohol for approximately 10 dips, or until glossy.

Immerse in 50% ethyl alcohol for approximately 10 dips, or until glossy.

Wash in *distilled* water for approximately 10 dips, or until glossy. This water should be replaced frequently.

Stain with Mayer's hematoxylin for 6 to 8 minutes, according to the age of the stain.

Wash in a gentle stream of running tap water for a minimum of 20 minutes. If this time is increased to 45 minutes, there will be slightly improved nuclear detail.

Dehydrate in graded ethyl alcohol, 50%, 70%, 80%, and 95%, immersing for 10 dips each.

Stain in orange G for 1½ minutes, agitating intermittently.

Immerse for 10 dips each in 3 changes of 95% ethyl alcohol.

Stain in EA for 1½ minutes, agitating intermittently.

Immerse for 10 dips each in 3 changes of 95% ethyl alcohol.

Dehydrate in absolute ethlyl alcohol 10 dips.

Dehydrate in a mixture of equal parts of absolute ethyl alcohol and xylol, 10 dips.

Clear in xylol, immersing for approximately 10 dips or until glossy.

Mount in gum damar, Clarite, etc.

If it is found that the local tap water used in washing slides following staining with hematoxylin is not sufficiently alkaline, that is, approximately pH 7.4, the lithium carbonate method of alkalinizing must be employed.

Another safeguard is to avoid prolonged standing in the alcohol washes following staining with EA, which results in decolorization of both the eosin and the light green. The stained slides may stand in xylol for short periods without significant effect, but standing several hours in this solution decolorizes the eosin.

Take care to prevent water absorption and evaporation, by keeping the staining dishes covered when not in use.

For staining tissue sections by the Papanicolaou method, remove the paraffin with xylol------------5 minutes.

Wash twice in absolute alcohol.

Dehydrate, beginning with 70% ethyl alcohol, and carry out the usual routine staining procedure.

Increase the hematoxylin staining time to 15 minutes.

It is better to stain paraffin sections on the same day that they are cut. Do not place them on a heated drying rack.

The Ayre Surface Biopsy in the Diagnosis of Uterine Cancer

Ayre[1] modified the original technic of Papanicolaou by taking smears directly from the cervical os. A kind of rubbing technic is particularly useful where there are erosions or visible evidence of pathology around the cervix. He uses a hollowed out end of an ordinary wooden tongue depressor, so that the hollowed out end of this applicator rubs directly over the cervix and procures cells directly from this part. The pointed portion of the other end of the applicator removes malignant cells likely to be found in the mucus at the external cervix portal in cases of cancer. The cytology of the canal is considerably different from that of the vagina. In malignant cases there are fewer squamous epithelial cells and a greater quantity of leukocytes but, more significantly, a greater concentration of malignant cells is to be found. This, Ayre believes, will increase the percentage of positive cases and reduce the percentage of error.

This method is preferable to the ordinary biopsy which carries with it possibility of trauma, bleeding, and distention. If a positive diagnosis is made by vaginal smear, then the biopsy can be made and radium therapy begun. In some cases the presence of sepsis presents a definite contraindication to cervical biopsies and in such cases smears can be taken immediately without stirring up the infection. Ayre found this procedure quite useful in differentiating between a degenerating malignancy and fundal cancer with secondary infection.

Papanicolaou Endocervical and Endometrial Smears

This affords an opportunity to obtain malignant cells coming from the fundus through to the endocervical canal. Papanicolaou[2] states that these malignant conditions within the fundus or cervical canal are highly proliferative. Technic for obtaining this material is to use a small pliable laryngeal cannula attached to an ordinary syringe. Insert this cannula directly within the canal as high up as desired, and pull out the secretion. Eject this upon a glass slide and proceed in the same manner as in fixing and staining vaginal smears.

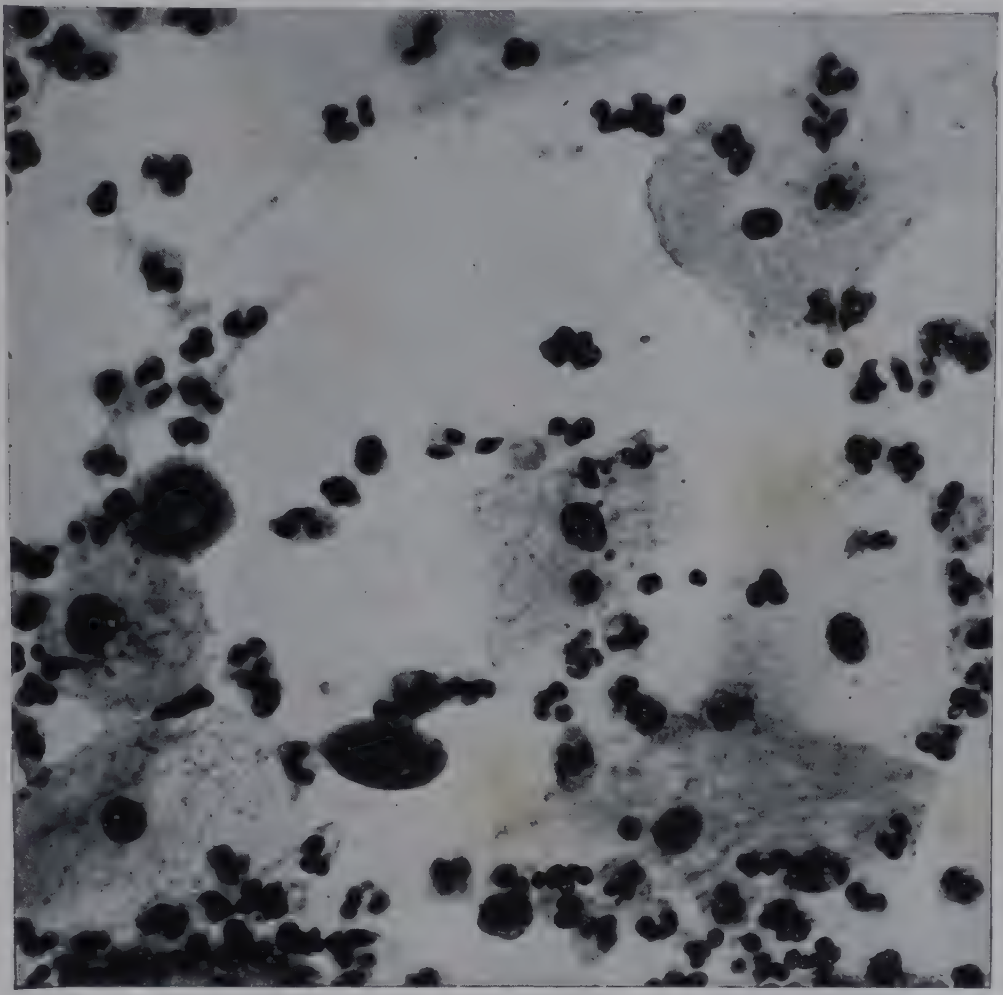

Fig. 630.—Negative smear showing cornified and precornified cells and two basal cells in lower left hand corner (×825). (Courtesy Surgery, Gynecology, and Obstetrics.)

DIAGNOSTIC CRITERIA

Meigs emphasized that in order to recognize the atypical cells found in carcinoma of the cervix and endometrium, one must know the *normal cells.* These normal cells may be divided into three groups: the cornified series; the basal cells; and the endometrial cells. Cornified cells are again divided into two groups, precornified and fully cornified. The precornified cells are large waferlike cells with abundant thin green cytoplasm and a vesicular nucleus (Fig. 630). The fully cornified cells are similar to the precornified cells with the exception that the cytoplasm stains pink and the nucleus is pyknotic. The cytoplasm may show some signs of degeneration such as wrinkling and granulation (see Fig. 630).

Basal cells are smaller, round or oval cells with green cytoplasm and a vesicular nucleus (see Fig. 631). With extreme atrophy of the genital tract the nuclei of the normal basal cells may contain chromatin in large clumps. Endometrial cells are the smallest of the normal cells, showing a small vesicular nucleus with very little cytoplasm. They show little variation in size and shape (see Fig. 632).

---

[2] Personal statement.

For the diagnosis of *carcinoma of the cervix,* the criteria are as follows: the cells show great variation in size, shape, and form—much greater variation than is usually seen in the pathologic section of the same tumor. The most striking variation in shape appears in the tremendously elongated "tadpole" cells (see Fig. 633), which have a rounded head containing the nucleus and a long thin tail. Long fiberlike cells may be found (see Fig. 634). These cells are extremely elongated, with tapered ends, and contain an elongated nucleus, or two or three nuclei. They may be found singly or in groups.

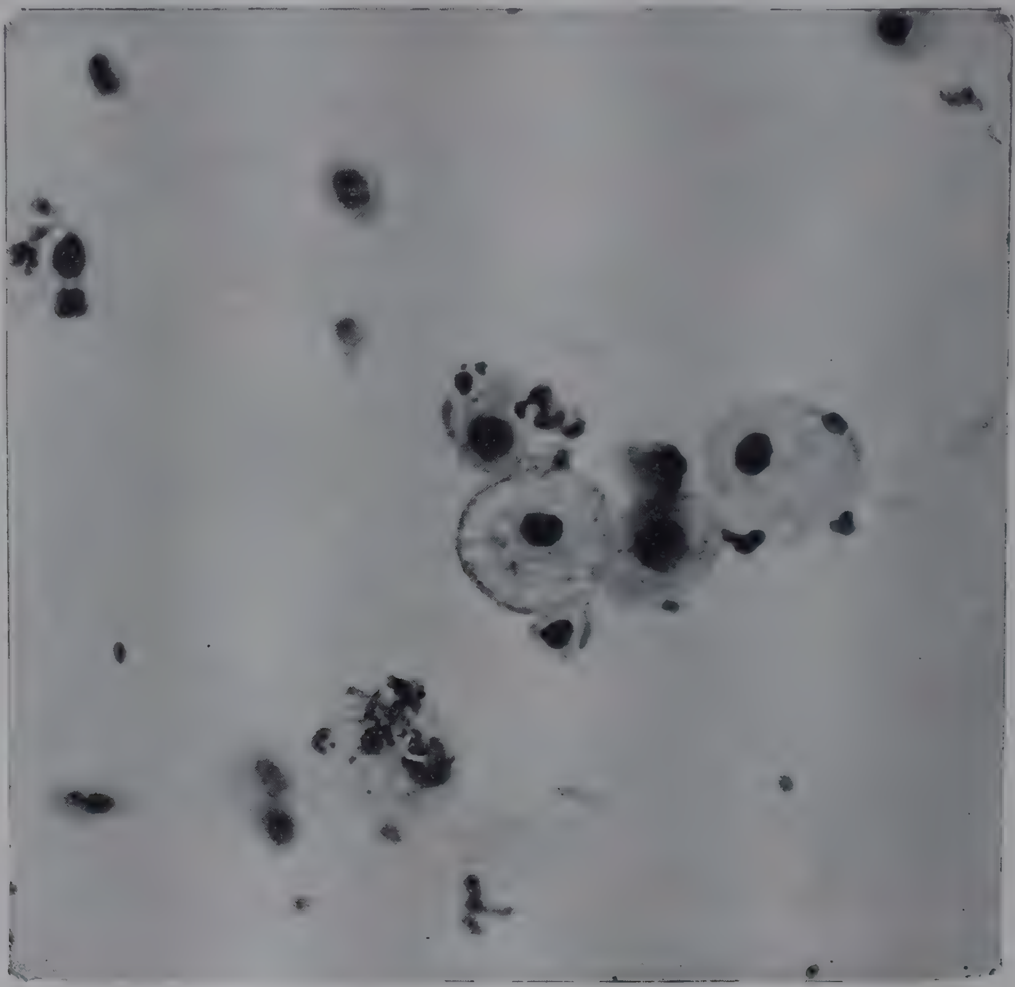

Fig. 631.—Negative atrophic smear showing a field of basal cells (×825). Courtesy Surgery, Gynecology, and Obstetrics.)

Many atypical cells have vacuolated cytoplasm with a foamy appearance, but cellular vacuolization is not diagnosed as malignancy. Staining characteristics of the cytoplasm are not diagnostic, since in the vaginal smear the atypical cells may have either basophilic or acidophilic cytoplasm. This variation in staining is due to differences in the acidity of the vagina as the result of either infection, parasitic infestation, or estrogen elaboration.

The nuclei of abnormal cells show marked variation in shape and size, and bizarre forms occur. Increased activity of the nuclei may be noted, indicated by clumping of the chromatin, granularity of the nucleus, and occasionally an apparent increase in the amount of nuclear material. Nucleoli are seen occasionally but not consistently enough to make observation of the nu-

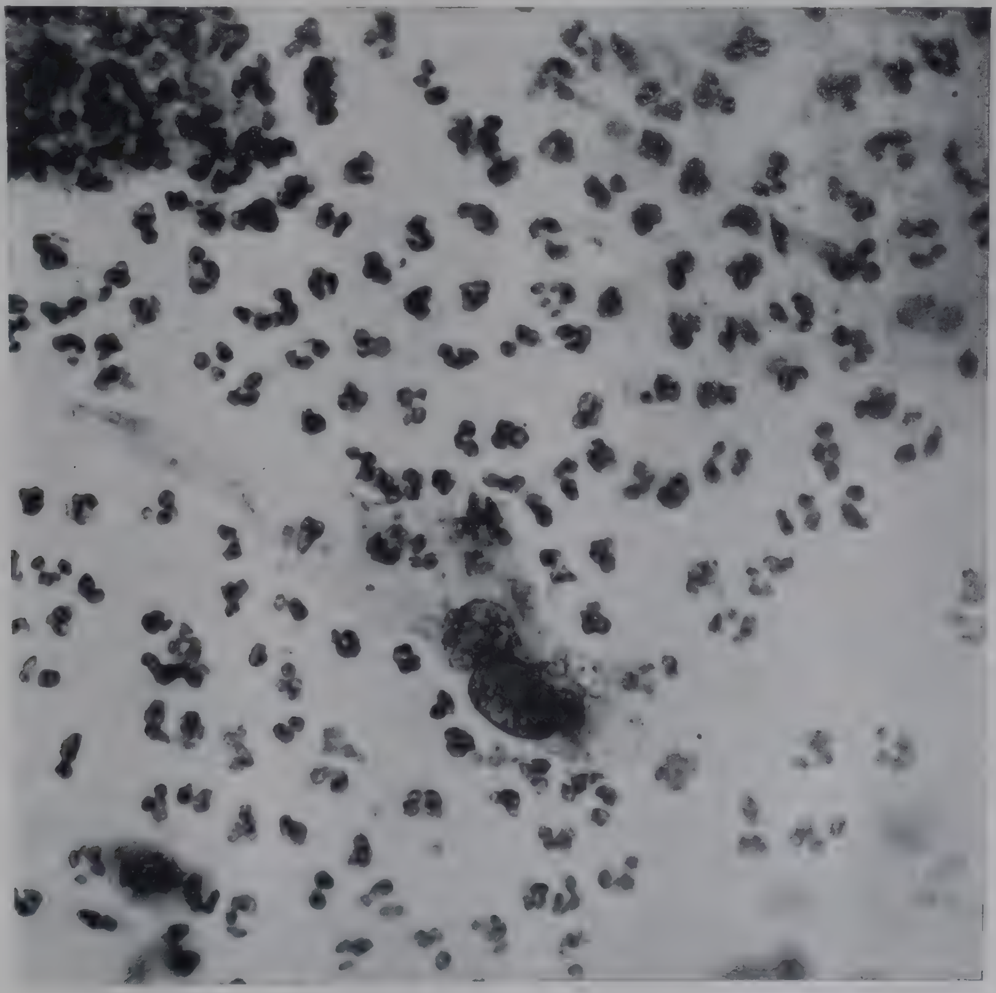

Fig. 633.—Carcinoma of the cervix. A huge bizarre-shaped cell with double nuclei illustrating the marked variation in size and shape of cells encountered in carcinoma of the cervix. ("Tadpole" cell.) (×825.) (Courtesy Surgery, Gynecology, and Obstetrics.)

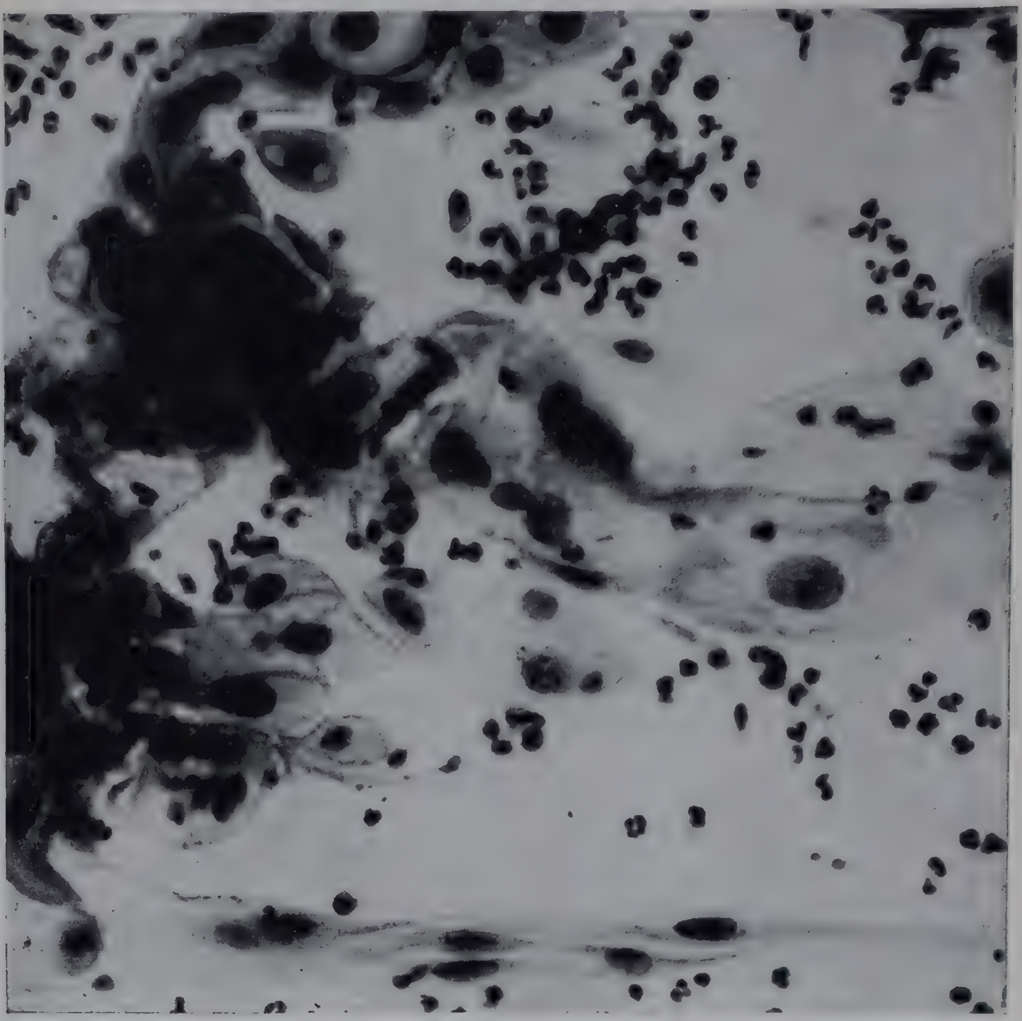

Fig. 634.—A group of atypical cells seen in epidermoid cervical cancer. The long fiber-like cells in the lower portion of the photomicrograph are abnormal cells encountered frequently in positive smears (×825). (Courtesy Surgery, Gynecology, and Obstetrics.)

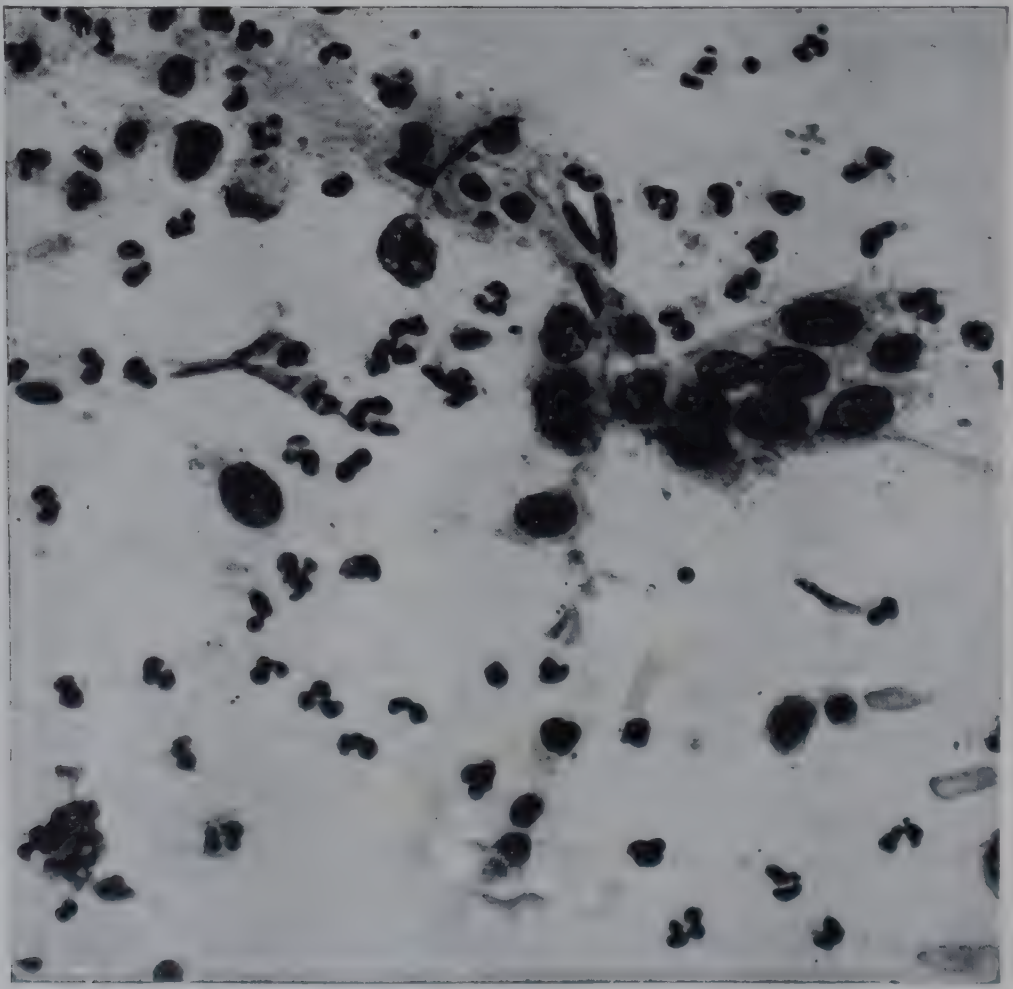

Fig. 635.—Atypical cell group seen in epidermoid carcinoma of the cervix, illustrating the abnormal variation in size and shape of the nuclei (×825). (Courtesy Surgery, Gynecology, and Obstetrics.)

cleolus an important aid in diagnosis. Mitoses may occur but are very rare. The most frequent variation of the nucleus is its size. In the abnormal cell the nucleus often fills the entire cell, leaving a thin but distinct rim of cytoplasm (see Fig. 635). Often multinucleated giant cells are seen, occasionally containing as many as a dozen nuclei (see Fig. 636). Histiocytes are often present in positive smears (see Fig. 637). They vary in size. They often contain phagocytosed cellular elements such as red blood cells, leukocytes, and cellular debris. They frequently have acidophilic cytoplasm. Remember that histiocytes may appear in normal smears. Leukocytes are usually present but their numbers vary. Red blood cells are present in every positive smear. Meigs stated that he has never made a diagnosis of malignancy without some evidence of blood.

For the diagnosis of *endometrial cancer,* the same general criteria apply: evidence of blood must be present; an increase in leukocytes is usually seen; histiocytes are frequently found. The variation in size of individual atypical cells in endometrial cancer is not as great as in cervical. The cells are more like those seen in stained sections of the same tumor. Abnormal endometrial cells are usually found in clumps which can be easily seen under low power. The nuclei vary tremendously in size. Haumeder found the nuclei of cells in carcinoma of the endometrium to be twice as large as those found in hyperplasia of the endometrium. Occasionally in endometrial carcinoma large cells are seen with an abundant amount of cytoplasm and large vesicular nuclei (see Fig. 638), but they are rare. Mitoses (see Fig. 639) are very rare.

The authors attempted to determine whether the abnormal cells seen in the vaginal smear were actually tumor cells or whether they represented a tissue reaction secondary to the presence of cancer. Smears taken from the tumor at operation were compared with those made from the vaginal secretion. In seven cases of cervical cancer and in three cases of endometrial cancer, the same types of cell were found in the vaginal secretion as in the smear from the tumor itself.

Important Points.—

It is important when a negative smear is obtained to repeat the examination because one negative smear cannot be depended upon to exclude the presence of cancer. Sixteen smears were taken over a period of seven days from one patient with cervical cancer. Cancer cells appeared in six smears only.

In three cases cancer was indicated by the smear, but curettage proved negative. In another case the smear was positive but no cancer was found on routine pathologic examination after complete removal of the uterus. Serial sections were not made. It must be remembered that failure to demonstrate cancer on routine pathologic examination of the excised specimen does not exclude the presence of cancer. The proof rests upon a negative result following complete serial section of the uterus.

Should operation for uterine cancer be made solely on the evidence of a positive vaginal smear? This question was answered by Meigs in these words, "The positive smears should be confirmed by biopsy or curettage."

This method should be a part of every routine physical examination in office, outpatient department, and hospital.*

Papanicolaou Technic for Staining Urine Sediment, Gastric and Bronchial Aspirates, Pleural and Peritoneal Fluids, etc., for Malignant Cells.—

Fix the fluid immediately after aspiration in an equal amount of 95 per cent alcohol (50 c.c. of each is usually sufficient).

Centrifuge as soon as possible at medium speed for 20 minutes, and remove the supernatant fluid.

If smears cannot be prepared immediately, cover the sediment with absolute alcohol, and place in the refrigerator. Prepare the smears from the sediment on slides which have been previously coated with a thin film of Mayer albumin fixative. Spread the smear with another slide as evenly as possible. When it begins to dry around the edge but is still moist in the center, fix the slide in alcohol-ether for a minimum of one hour and stain as for vaginal smears.

COLLECTION, PROCESSING, AND STAINING OF SPUTUM FOR CYTOLOGIC DIAGNOSIS[1]

Sputum.—A deep cough specimen is collected into a wide-mouth bottle containing 70% alcohol. Because of the hardening effect of the alcohol, the specimen should be sent to the laboratory and smears made without delay.

Bronchial Aspirants or Washings.—Bronchial secretions are collected at the time of bronchoscopy by aspiration or by lavage into a small-mouthed jar with a physiologic saline solution. Aspirated bronchial secretions or bronchial saline washings are mixed immediately with at least an equal quantity of 95% alcohol. Rinse the collection tube 2 or 3 times with 95% alcohol, and add these washings to the specimen. The type of each specimen and the site at which it was collected should be accurately recorded on each label.

In cases in which secretion is scant, Clerf and Herbut recommend obtaining the material from the smaller bronchi by means of a small gauze spoon affixed to the tip of a carrier. Such material is smeared directly on slides which are fixed immediately in alcohol-ether solution.

Aspiration of tracheal bronchial secretions by catheter is another method reported by Cahan and Farr. This method is the particular one for cases in which adequate ''deep cough'' sputum is not produced or bronchoscopy is for any reason undesirable. It has the additional advantage that it is feasible as an office or clinical procedure.

Papanicolaou Method for Sputum Smears.—

Collect the sputum directly in 70 per cent alcohol.

Spread it on slides which have been coated with albumin. If there are hard masses they may be crushed slightly with another slide.

Fix the smear in alcohol and ether for a minimum of one hour and stain as for vaginal smears.

Caution.—

In the staining methods used for all this material—vaginal smears, cervix biopsy material, endocervical and endometrial secretion, urine, gastric, bronchial, pleural, peritoneal fluids, and sputum—be sure that the smears are never allowed to dry at any time.

[1] Papanicolaou: Atlas of Exfoliative Cytology, published for The Commonwealth Fund by Harvard University Press, Cambridge, Mass., 1954.

Preparation of Sputum With Trypsin for Cytologic Study.—

Because of the physical character of sputum, it is often difficult to make sputum examinations according to the method of Papanicolaou. If one examines sputum in the ordinary way, nasal and oral materials are usually present, and the true bronchial sputum is minimal and may be entirely overlooked in the selection of material for screening. It is believed that a negative cytologic report is not justified in the usual test, unless at least fifteen different slides have been studied.

Farber, Pharr, Wood, and Gorman[1] suggested the use of trypsin for its mucolytic and digestive action in the preparation of sputum for cytologic study. Trypsin is chiefly known for its selective enzymatic digestion of nonviable organic material.

Reagents.—

Trypsin Solution.—

Dissolve 125 mg., or 125,000 Armour units, of trypsin
in 12.5 c.c. of Sorensen buffer, pH 7.1.
This amount will liquefy 8 to 10 c.c. of sputum.

Caprylic Alcohol.—

Human Plasma.—

Technic.—

Add the trypsin solution to 8 or 10 c.c. of sputum in a centrifuge tube with a capacity of two or three times the total amount of mixture.

Add 1 or 2 drops of caprylic alcohol, depending upon the agitation time. This reduces surface tension and prevents foaming upon agitation. The time required to liquefy a specimen thoroughly depends upon its initial viscosity, but the most tenacious specimens usually respond within 15 minutes.

The tubes must be simultaneously heated and agitated. Place them in a serologic water bath at 57° C., and force air through. Use a portable compression tank to the faucets of which are attached glass droppers by means of rubber tubing. Insert the droppers into the centrifuge tubes containing the sputum-trypsin mixture. Regulate the pressure to a forceful stream.

After the specimen has been agitated, layer 0.5 to 1 c.c. of human plasma to the bottom of the centrifuge tube, using a pipette or capillary dropper. The plasma not only aids in arresting the digestive process, but also acts as an adhesive agent, replacing the liquefied mucus, and prevents the loss of cells from the slide during fixing and staining.

Centrifuge, after digestion is complete, and collect the sediment on glass slides.

Fix in equal parts of alcohol and ether, and stain in the usual manner by the Papanicolaou method.

Trypsin has a marked effectiveness in reducing the number of mature, nonviable squamous cells, and at the same time it does not alter the staining characteristics of the cellular material, nor does it have any noticeable bad effect on the appearance of malignant cells.

DIAGNOSIS BY CYTOLOGIC STUDY OF BRONCHOSCOPICALLY REMOVED SECRETIONS

The value of examination of bronchoscopically removed secretions in the early diagnosis of bronchogenic carcinoma is set forth fully by Herbut and

---

[1] Science **117**: 687, 1953.

Clerf.[1] This method has been used with considerable success in countries other than our own. In England[2] positive diagnoses were reported in as high as 68 per cent of cases of bronchogenic carcinoma, in Russia,[3] 70 per cent, in Denmark,[4] 85 per cent, and equally enthusiastic reports have been published in Latin American literature.[5] As these writers state, this has not been a popular method in this country as witnessed by the following statements: "Only exceptionally may the diagnosis be made from a study of the cytology of the sputum."[6] "The pathologist may on rare occasions make a diagnosis from fragments of tumor discovered in the sputum."[7] "Rarely portions of growth are expectorated and can be submitted to microscopy."[8] "With exception of the two cases (in a series of 175) just mentioned there has been no case in which the examination of the sputum has revealed tumor cells."[9] "Sometimes fragments of tumor tissue acceptable for diagnostic purposes are obtained by bronchial aspiration."[10] "It has been of value in a few of our cases."[11]

Contrasted with these rather discouraging remarks are the enthusiastic words and definite scientific proof found in this article by Herbut and Clerf. In order to obtain reliable material, one must examine bronchial secretions rather than sputum for tumor cells. Sputum is more dilute than are bronchial secretions, and thus the chances of finding cancer cells are considerably diminished. Furthermore, expectoration of sputum does not occur until late in the disease, at which time a diagnosis can be easily made by other means. Bronchoscopy, on the other hand, is performed routinely in all modern clinics in every case of suspected pulmonary carcinoma. One must obtain secretions which come from the region of the suspected tumor for this examination. This material is more likely to contain cancer cells than are the more dilute secretions found in the trachea and the even more dilute sputum.

Material and Method.—

Herbut and Clerf first made a number of experimental observations on cadavers, obtaining bronchial secretions by aspiration prior to autopsy. In this way, they became familiar with the appearance of cancer cells in smears.

As soon as the material was obtained from actual cases later on, it was sent to the laboratory, where smears were made immediately and, while still wet, were fixed in equal parts of 95 per cent alcohol and ether and stained by the Papanicolaou technic[12] (page 2174). When the amount of material obtained was small, all was removed from the collector and smeared, but when the amount was greater than could be utilized, it was first poured into a Petri dish, placed on a black background, and only those portions that resembled bits of sloughed tissue, or that were streaked with blood were smeared. All sputa secured from patients with positive bronchial smears were treated in the latter manner. At first thick smears were made, but it soon became apparent that thinner ones were more valuable, for in these all cells could be adequately studied. In preparing the smears the material was placed in the center of the slide and gently crushed with another slide, care being taken that any granules which may have been present did not escape peripherally. Every portion of the slide was systematically examined.

Pathology

Macroscopic.—In all cases reported by these authors in which cancer cells were found, the secretions were quite characteristic although not necessarily pathognomonic. The amount varied from a few drops to 4 c.c. The color ranged from gray and watery to somewhat creamy and opaque, but invariably it was either streaked with or diffusely mixed with bright red, pink, or dark brown partially disintegrated blood. It was always tenacious and adhered closely to the side of the collector and glass slide. It should be noted, of course, that blood-tinged secretions are not always indicative of cancer.

Microscopic.—One must mention the **noncancerous flora** of bronchial secretions. Most patients undergoing bronchoscopy have some pulmonary disease and therefore one can always expect to find leukocytic cells. The most commonly encountered and readily recognized are polymorphonuclear leukocytes (Fig. 650). They differ from those in blood films only in that their cytoplasm appears light green. Lymphocytes are small, round, and uniform, and contain a scant amount of light green cytoplasm. Plasma cells are present in varying numbers and show excentric nuclei and well-defined abundant light green staining cytoplasm. Mononuclear phagocytes are sometimes scanty but at other times are numerous. Their cytoplasm is always abundant, is sharply defined, stains light green, and frequently contains carbon or other phagocytosed material. Their nuclei are relatively small, round, evenly stained, and central or excentric in position.

Attention is called to the fact that every bronchial secretion contains sloughed epithelial cells which can be readily recognized as noncancerous. In most sputa one finds large, polygonal, sharply defined, pavement cells with relatively small round evenly stained nuclei. Occasionally a few of these cells are also found in nonneoplastic bronchial secretions, where they probably arrived by aspiration from the upper air passages. Ciliated columnar epithelial cells are practically always present (Fig. 650). They have a long slender shape with a pointed base, a central, round or oval, evenly stained nucleus, abundant light green cytoplasm, and a broad, sharply defined inner border often covered with numerous cilia. When these cells undergo degeneration their outlines break; the cytoplasm becomes irregular and frayed, and the nuclei become swollen, round, and faintly stained. Sometimes columnar cells appear in dense clusters and superficially resemble groups of stratified squamous epithelial cells. Single or small groups of cells, probably derived from the intermediary layers of the epithelium, are not uncommonly present and are important to recognize

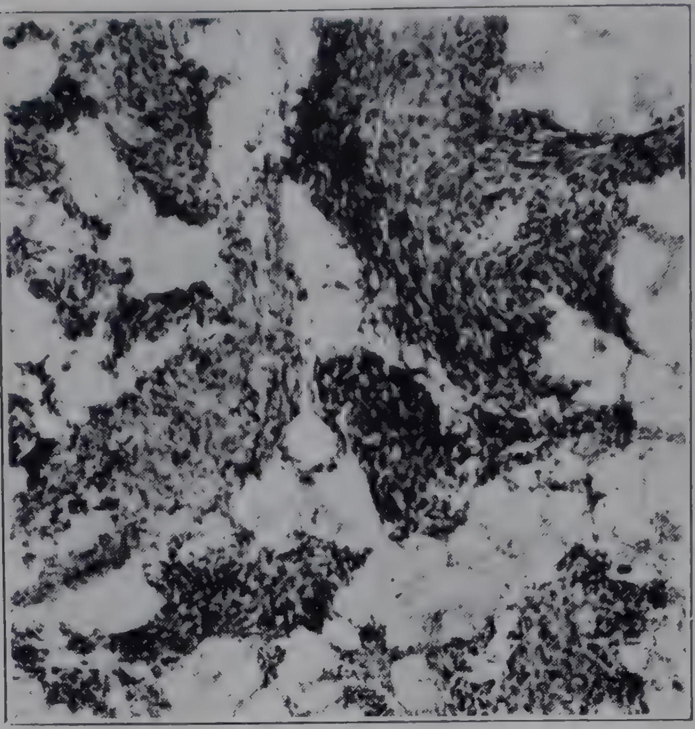

Fig. 640.

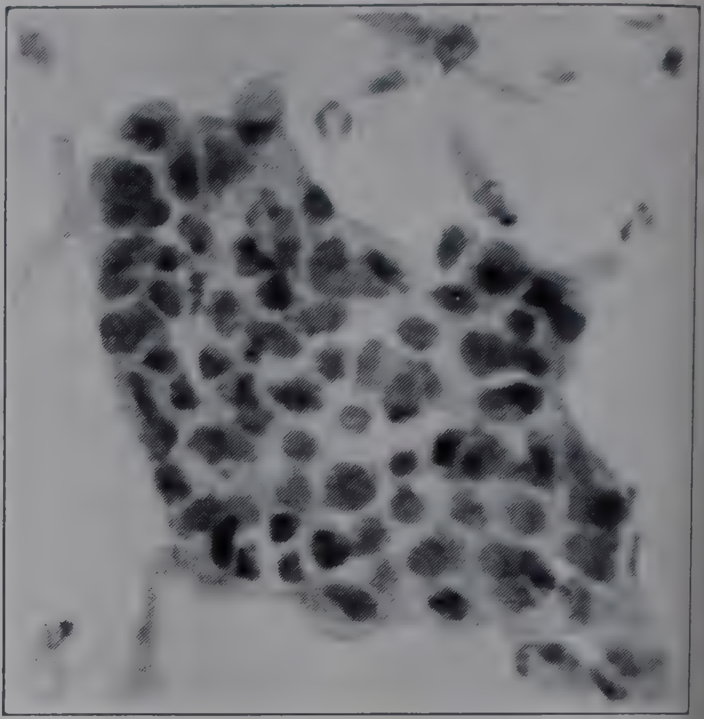

Fig. 641.

Fig. 640.—Smear of secretions removed endoscopically from a proved case of carcinoma showing four large pieces of tumor in squamous cell formation. The cells stain from pink to orange. Papanicolaou stain ×100. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

Fig. 641.—A group of neoplastic cells in squamous formation removed endoscopically from another case of proved bronchogenic carcinoma. The cells are more compact and the nuclei are more irregular and relatively smaller than are those of noncancerous intermediary epithelium shown in Fig. 651. The cytoplasm of the cells illustrated in Fig. 641 stains pink to orange, whereas that in Fig. 651 stains a bluish green. Papanicolaou stain ×400. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

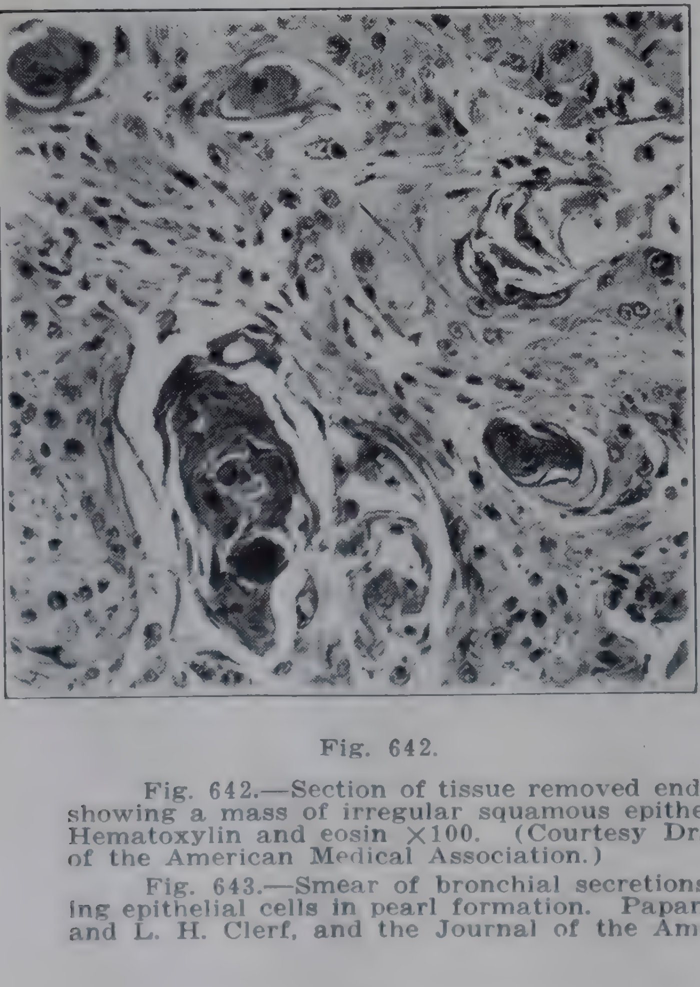

Fig. 642.

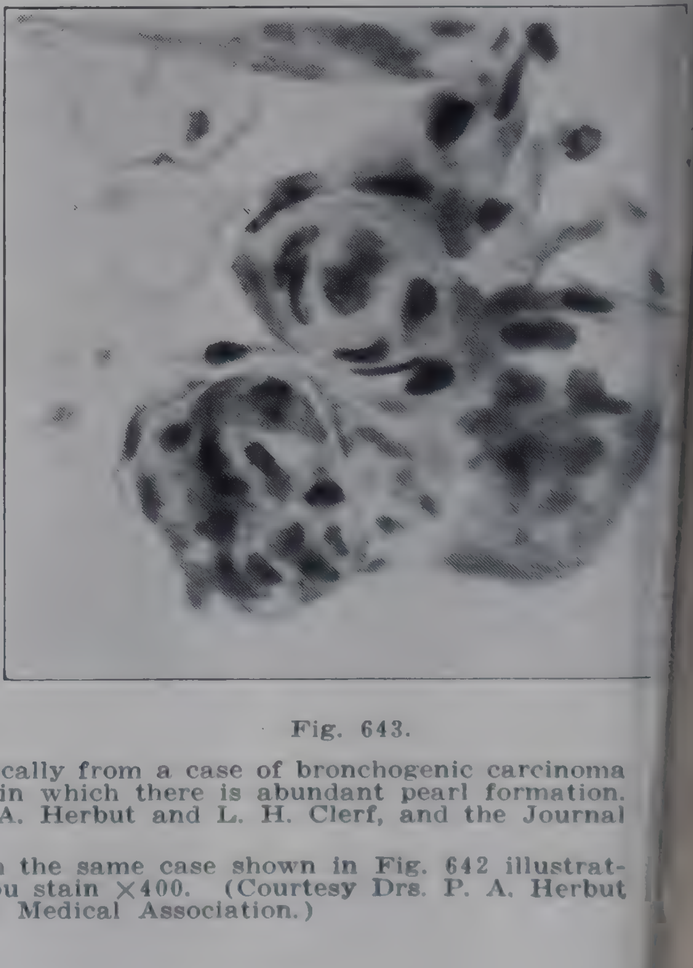

Fig. 643.

Fig. 642.—Section of tissue removed endoscopically from a case of bronchogenic carcinoma showing a mass of irregular squamous epithelium in which there is abundant pearl formation. Hematoxylin and eosin ×100. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

Fig. 643.—Smear of bronchial secretions from the same case shown in Fig. 642 illustrating epithelial cells in pearl formation. Papanicolaou stain ×400. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

as such (Fig. 651). They are of moderate size, round, oval, or polygonal, have sharply defined outlines, blue to green or gray cytoplasm, and relatively large, round or oval, evenly stained nuclei.

Cancerous Flora.—There is a certain appearance, difficult to describe precisely, but which gives one the impression that the preparation should contain cancer cells. In such slides leukocytic elements and fibrin are usually absent. This is particularly true of the macrophages. When these are numerous, cancer cells are not found. Pavement cells, most of which take an orange stain, are often increased in secretions containing cancer cells when the tumor is of a squamous cell variety. Finally, in cancerous secretion erythrocytes are usually fairly abundant.

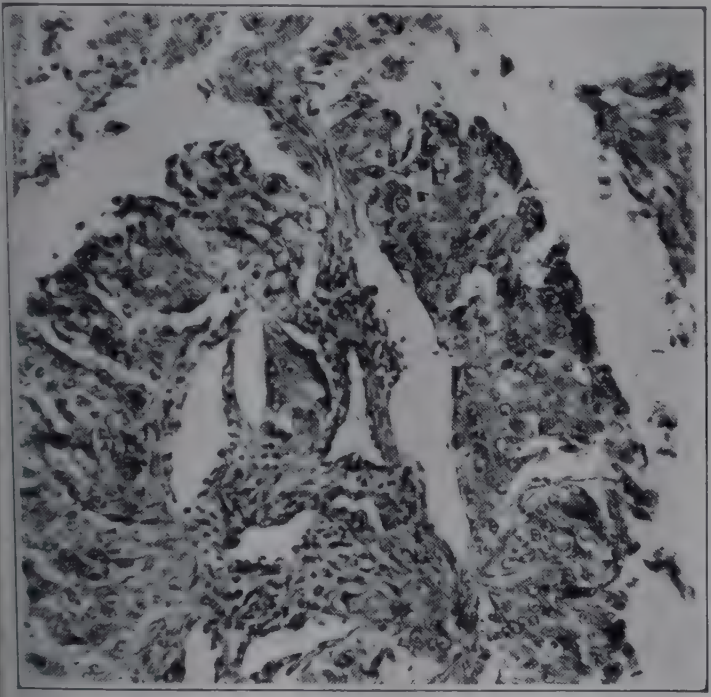

Fig. 644.

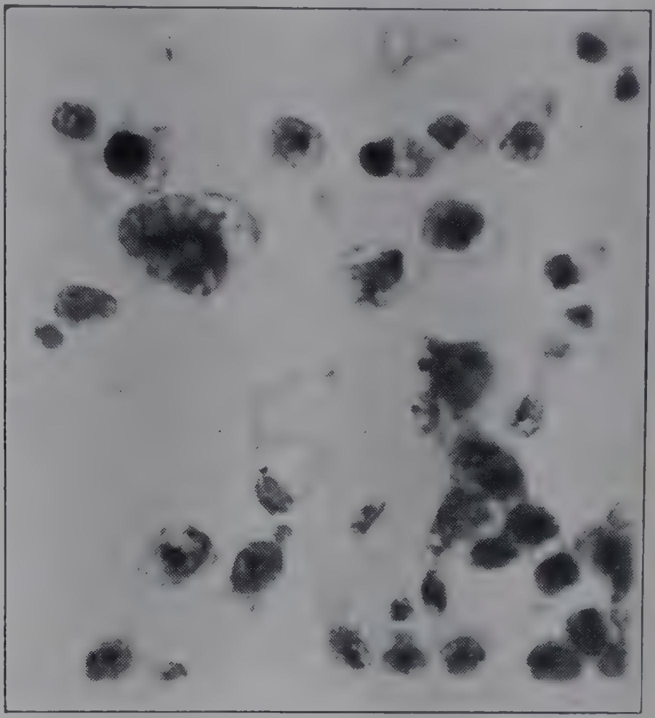

Fig. 645.

Fig. 644.—Section from a case of bronchogenic carcinoma obtained at necropsy showing groups of neoplastic cells partly differentiated into squamous cells but without keratinization or pearl formation. Hematoxylin and eosin ×100. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

Fig. 645.—Smear of tumor from the same case illustrated in Fig. 644 showing a group of cancer cells of varying shapes and sizes. The nuclear membrane is quite distinct and the nucleoplasm is somewhat "washed out" and clumped. The cytoplasm is relatively scanty. Papanicolaou stain ×400. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

Cancer Cells.—These writers recognized three more or less separate groups of cancer cells in bronchial secretions: (1) clusters of cells which are present in squamous cell carcinoma; (2) large irregular single cells found in the more dedifferentiated tumors and in those with an adenomatous formation; and (3) smaller, more uniform cells present in the so-called "oat cell" carcinoma.

In squamous cell carcinoma there are usually small or large pieces of stratified squamous epithelium evenly distributed throughout all slides or present only in one portion of one slide (Figs. 640 and 641). If they happened to have been crushed at right angles to the surface one can see the keratinizing cells on the surface, the intermediate prickle cells, and even the basal cells. Usually, however, they are seen as a mass of closely packed, relatively large cells whose cytoplasm stains an orange red, and whose nuclei are large and dark blue. Cilia are never present. At the periphery there are usually encountered a few detached single cancer cells. They have an abundant amount of blue green to gray, ill-defined, peripherally frayed cytoplasm and relatively large, round, oval, or slightly irregular deeply stained nuclei. These cells are quite well differentiated and so do not appear as "wild" as do the cells of the more anaplastic tumors to be described presently. Occasionally when there is abundant pearl formation in the original tumor one finds naked pearls within the bronchial secretions (Figs. 642 and 643). They are similar to those seen in ordinary packed cells with deep staining, elongated, pyknotic nuclei, and bluish green to gray cytoplasm.

When the tumor is less well differentiated, in adenomatous formation or a combination of the two, single cancer cells are found in the secretions (Figs. 644, 645, 646, and 647). As would be expected they vary tremendously in size, shape, and staining qualities. They are invariably considerably larger than normal cells (sometimes of giant proportions) and assume anything but the regular configurations described. Their borders are almost always ill defined, frayed and fuzzy. The cytoplasm stains bluish green, blue, or gray, and although absolutely increased it is relatively decreased and sometimes almost entirely imperceptible. The nuclear-cytoplasmic ratio is thus always increased over the normal. While theoretically some of the cells should be vacuolated, this appearance has not yet been encountered. The nuclei are single or multiple and usually are extremely bizarre. Whereas they may be round or oval they ordinarily form irregular, coiled, folded, hexagonal or dumbbell shaped configurations. Some of the larger and more regular appearing nuclei show a very sharp, deeply stained, peripheral membrane which enclose lightly stained somewhat "washed out" and clumped nucleoplasm. Other nuclei are solid and

Fig. 649.—Smear of tumor from the same case illustrated in Fig. 648 showing numerous anaplastic cancer cells. They contain practically no cytoplasm and deeply stained irregularly shaped nuclei. Note the presence of one or more nucleoli within a single nucleus. Papanicolaou stain ×400. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

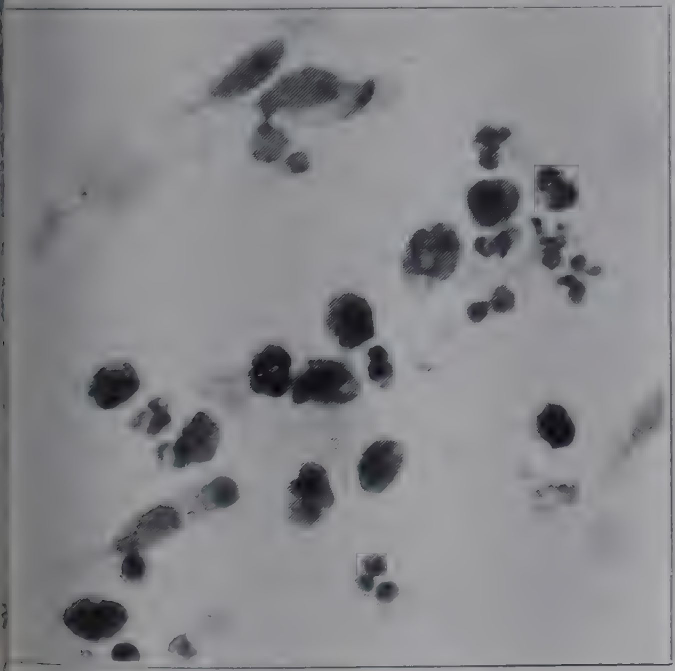

Fig. 650.

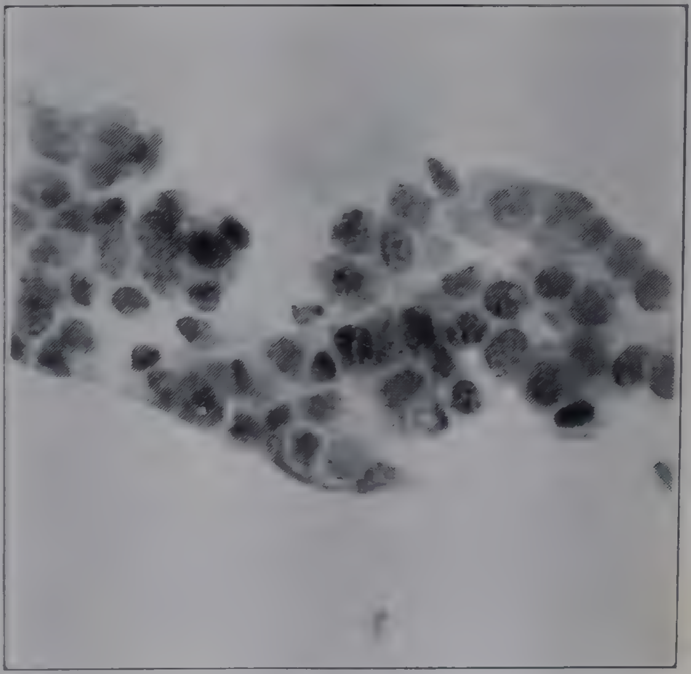

Fig. 651.

Fig. 650.—Smear of bronchial secretions obtained from the same case illustrated in Fig. 648. There are ten cancer cells identical with those shown in Fig. 649. There are present also a few polymorphonuclear leukocytes, one normal columnar epithelial cell with cilia, and two partly degenerated columnar epithelial cells in the lower portion of the photomicrograph. Papanicolaou stain ×400. (Courtesy of Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.

Fig. 651.—Smear of bronchial secretions removed endoscopically from a case of pulmonary tuberculosis showing a group of noncancerous intermediary cells as compared with cancer cells seen in Fig. 649. They are loosely united and contain large evenly stained nuclei and a relatively small amount of cytoplasm that stains bluish green. Papanicolaou stain ×400. (Courtesy Drs. P. A. Herbut and L. H. Clerf, and the Journal of the American Medical Association.)

so hyperchromatic that the internal structure is not discernible. Nucleoli are not always demonstrable but, when present, they are easily recognizable as round or slightly oval, sharply circumscribed bodies stained either lighter or heavier than the surrounding nucleoplasm. Often as many as four can be seen within a single nucleus.

As compared with the foregoing cells, neoplastic cells derived from the so-called "oat cell" carcinoma are relatively small (Figs. 648, 649, and 650). They are round, oval, or slightly irregular, contain a scanty amount of blue to green cytoplasm, and possess round, oval, or somewhat irregular, sharply defined, deeply stained single nuclei. They are best identified by their size and by the fact that although the cells are similar there are definite variations in the shape of the nuclei from cell to cell.

In 30 consecutive cases of primary pulmonary carcinoma, bronchial secretions were stained by the Papanicolaou technic and studied. Cancer cells were demonstrated in 22 cases, or 73 per cent. Cancer cells were present in the secretions from 7 cases in which bronchoscopic findings were negative. In only 1 of 5 cases in which cancer cells were present were neoplastic cells found. This is not a substitute for any other method of making a diagnosis of bronchogenic carcinoma but it is an adjunct to the means already employed. It is particularly useful in cases in which the tumor is located at the periphery of the lung or in the upper lobe.

BIOPSY TECHNICS FOR INTERTHORACIC CONDITIONS

In addition to bronchoscopic and esophagoscopic biopsies, bronchial washings, cytologic examinations of sputum for pulmonary carcinoma, there is also recommended the following: (1) resection of the deep cervical fat pad and nodes; (2) mediastinal biopsy at open thoracotomy; and (3) lung biopsy through an open thoracotomy. Resection of deep cervical fat pad and continued nodes is the simplest of the three procedures, and is the best withstood by even poor risk patients. It can be performed under local anesthesia.

CYTOLOGIC DIAGNOSIS OF GASTRIC MALIGNANCY

Ever since the advent of the Papanicolaou cytologic methods, the diagnosis of gastric cancer has been hampered because cancer cells are acted upon adversely by the gastric juice and so altered that diagnosis is difficult if not impossible in most cases. Early reviews on this subject show that about one-third of the cases of gastric cancer were diagnosed by routine aspirated specimens. Tomenius[1] reported an elaborate procedure for securing better preservation of gastric cells. Papanicolaou and Cooper,[2] Hollander, Hess, and Sober,[3] Ulfelder, Graham, and Meigs,[4] Richardson, Queen, and Bishop,[5] and Botsford and Tucker[6] have reported various technics for improving the collection of gastric aspirates for diagnosis of cancer. All reports show that the clinical application has been limited by frequently missed diagnoses.

[6] J. A. M. A. 142: 975, 1950.

Seybolt, Papanicolaou, and Cooper[7] revealed that about one-third of the cases of gastric cancer were diagnosed by the routine aspirated specimen and that these results could be improved by means of careful gastric lavage. It was thought that mechanical irritation of the gastric mucosa might produce better diagnostic material. For this purpose an inflatable abrasive balloon has been devised and tested.

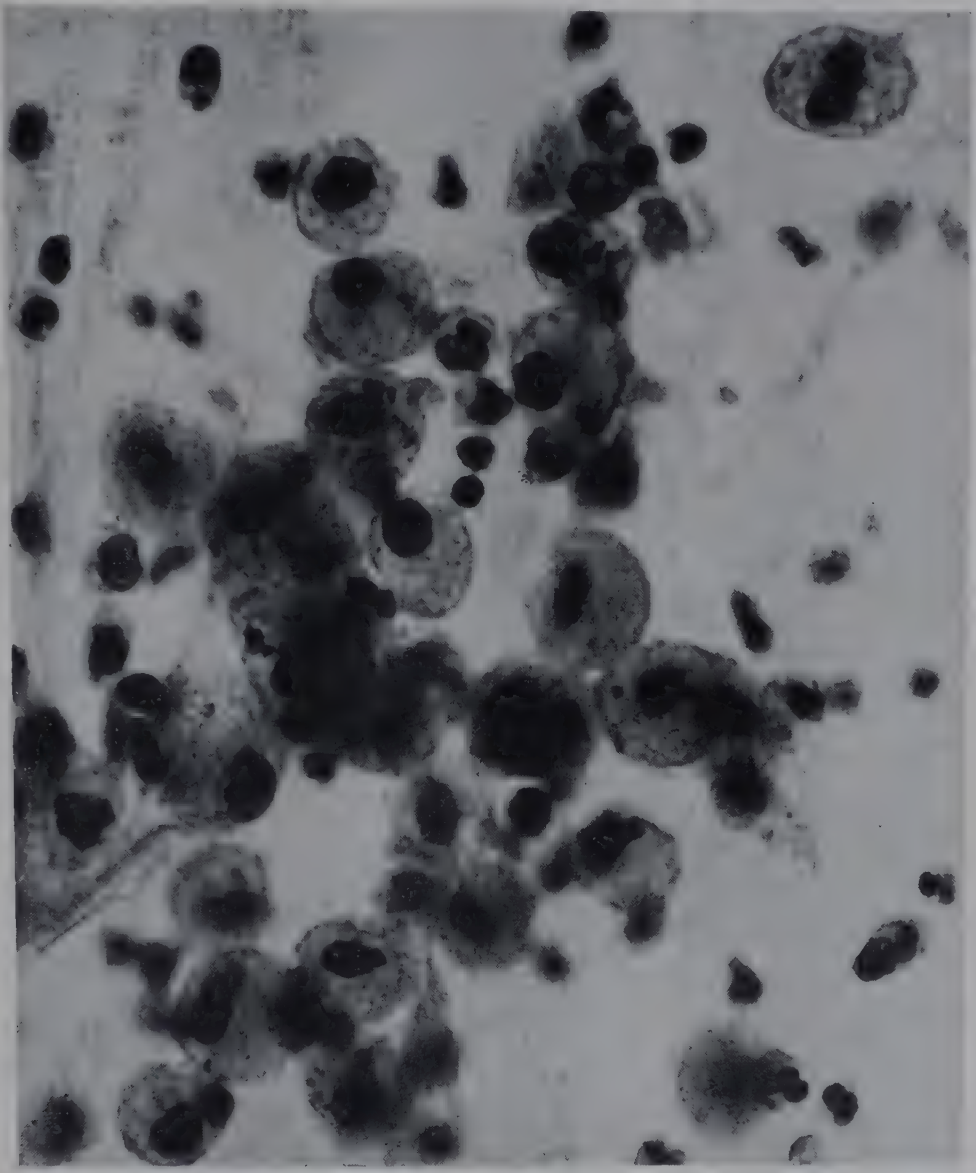

Fig. 652.—Bronchial washings showing large cancer cells. (×680.) Case 156632, Gradwohl collections.

Panico, Papanicolaou, and Cooper[8] described an apparatus for obtaining gastric secretions after mechanical irritation of the mucosa. A later paper by Cooper and Papanicolaou[9] reported further results with this method. With the two papers just cited, abrasive balloon technic has been described with the results which are tabulated. During the first year of trial with the balloon device, the studies were confined to patients in whom the pathology was known. This procedure was carried out in these known cases to learn at the outset which portion of the material obtained by using the balloon was likeliest to obtain well-preserved groups of cells. It was necessary to learn which was the best material, that aspirated while the balloon was in the stomach, that on the balloon after it was removed, or that which remained in the stomach after the balloon was withdrawn. Many extensive comparative studies were made in each patient. It was found that the best cell groups were found on the balloon itself. Material on the balloon often showed gross particles of tissue which could be smeared separately. The remaining material was washed off the balloon in Ringer's solution.

[7] Cytology in the Diagnosis of Gastric Cancer, Cancer **4**: 286, 1951.
[8] J. A. M. A. **143**: 1308, 1950.
[9] J. A. M. A. **151**: 10, 1953.

The apparatus (Fig. 653) for the test consists of a standard 16 French double-lumen tube 100 cm. long, with markings at 45, 60, and 75 cm. One lumen, designated the *aspirator,* is connected proximally to a syringe and distally to a patent, silver-plated bucket. The other lumen, designated the *agitator,* is connected proximally to an inflating bulb and distally to an inflatable balloon. The balloon is made of a condom open at both ends. To the external surface are tied by single slipped bowknots approximately 250 pieces of untreated braided silk, arranged in a regular pattern about 3 mm. apart and cut to leave ends about 2 mm. long. Ends of the balloon are fixed to the tube by silk ties about 8 cm. apart. When the balloon is uninflated it collapses on the sides of the tube; when it is inflated with 175 c.c. of air it measures 10 by 5 cm.*

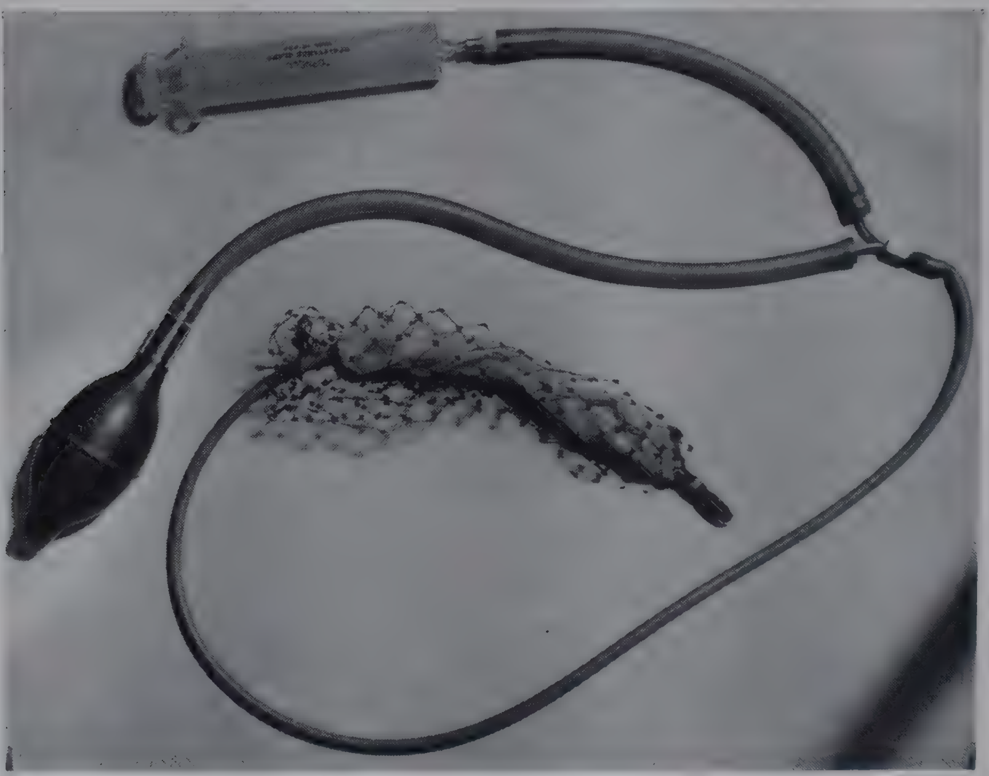

Fig. 653.—The inflatable gastric balloon apparatus of William A. Cooper, Frederick G. Panico, and George N. Papanicolaou.

The test is made in the morning, all food and fluid being withheld for the previous eight hours. If the patient has gastric retention or has had barium the day before, this may not be adequate preparation. If the stomach is found to have retained food particles, any quantity of fluid, or barium, the test should be abandoned for that day and the stomach further prepared. A day of liquid diet followed by a thorough lavage the night before will be adequate in all cases except those with marked gastric retention. In such cases, several days of a liquid diet followed by nightly lavages or continuous aspiration the night before may be necessary to clear the stomach of all retained debris. This is emphasized because the most essential factor in obtaining good specimens is a clean dry stomach.

All dentures are removed, the patient's mouth is rinsed, and the patient is instructed to expectorate all saliva. The deflated balloon is wet in Ringer's solution and passed orally, with small sips of the same solution taken through a drinking tube. Most patients swallow the balloon easily. If any great difficulty is encountered, the gag reflex may be suppressed by a little 2% solution of tetracaine (Pontocaine) hydrochloride spray.

---

*The entire apparatus can be purchased from Dr. Arthur O. Dahlberg, Walbrook Road, Scarsdale, N. Y. Full directions for using are given with the instrument.

When the tube is past the 60 cm. mark, the balloon is in the stomach.

The stomach is then aspirated until dry, and this material is saved as the fasting specimen for a gastric analysis. Histamine is then given, and three 10-minute specimens are collected for gastric analysis, using the continuous aspiration technic. After 30 minutes of aspiration, the stomach is clean and dry. The balloon is then inflated with about 150 c.c. of air, and the tube is withdrawn until the balloon is checked at the cardia. When at the cardia, the inflated balloon will not come up any further and the patient may gag. Peristaltic action then carries the balloon down to the pylorus in 5 to 10 minutes. The balloon is deflated, reinflated, and pulled back to the cardia while inflated. This process is repeated five or six times over a period of 30 minutes. While the balloon is down, the stomach is kept dry by frequent aspiration. This material is usually discarded, but it can be saved for processing in cases where the examination is being repeated, for it often contains well-preserved groups of cells. It may also be saved and processed if the material on the balloon is scanty.

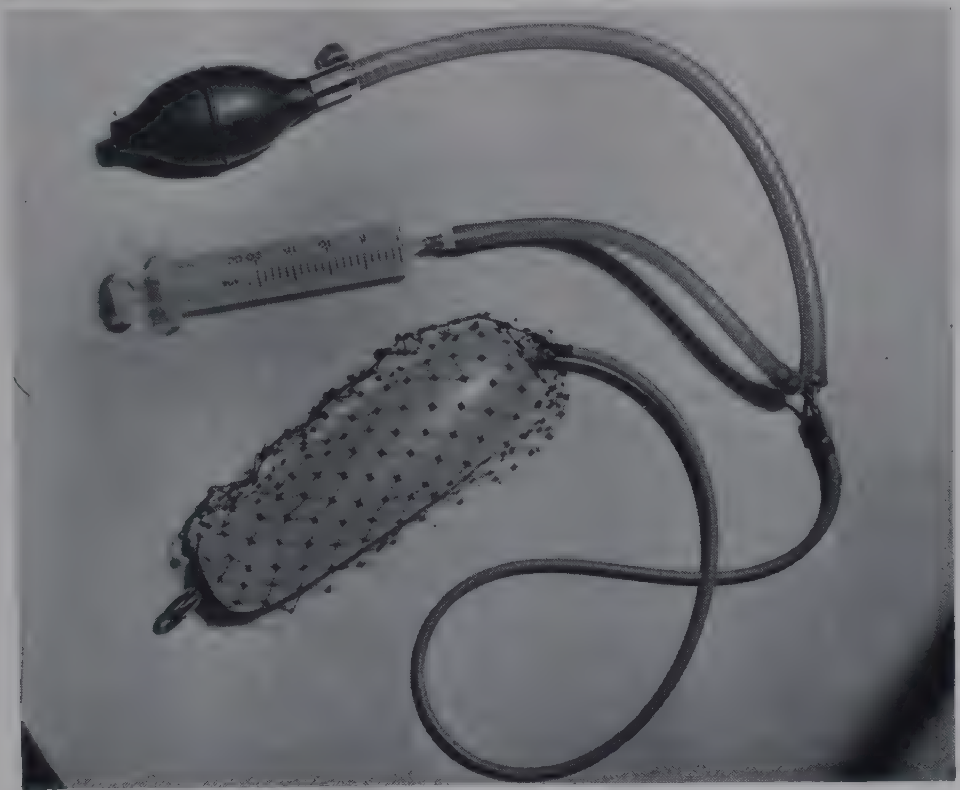

Fig. 654.—The inflatable gastric balloon apparatus, showing the balloon partially inflated.

The number of smears should be kept to a maximum of five and still there should be on these slides as much good material and as little debris as possible. If the aspirated material is saved, it should be put in 95% alcohol as it is collected.

Material when aspirated is often pink, and might contain blood. It is likely to contain fresh blood if a gastric lesion is present. If the amount of blood is in any way alarming, the test should be terminated. There have been no gastric hemorrhages or untoward reactions in over 300 clinical trials with the balloon method, although some fresh blood has been obtained in a number of cases.

The time of 30 minutes to leave the inflated balloon in the stomach has been selected arbitrarily; in some cases the time has been reduced and specimens from these patients have been perfectly adequate. In a recent case reported by Cooper, a friable papillary carcinoma yielded an excellent specimen in 10 minutes.

When the balloon has been down an hour, it is deflated and withdrawn. The balloon is then inflated again and inspected for gross particles. These particles are smeared on slides that have been prepared with albumin. In this way, the largest fragments of tumor tissue are likely to be obtained in their purest form; some of the best specimens have been obtained in this way.

The balloon is then rinsed vigorously in about 200 c.c. of a mixture of equal parts of Ringer's solution and 80% alcohol. This puts into suspension the particles clinging to the net. The solution is then centrifuged for 30 minutes at 1,500 r.p.m. and the sediment smeared on two to four slides, depending on the quantity of sediment.

Smears are then fixed and stained according to the Papanicolaou technic. Once the smears are fixed, delay is not important, but the material should not be allowed to stand around for more than an hour at any time before fixation.

The stained smears are read as class 1 or 2, which are considered negative; class 3, which is suspicious; and class 4 or 5, which are considered positive. All tests reported by these workers were done before operation.

In the last communication by Cooper and Papanicolaou, there were 7 frank errors in the 238 diagnostic problems, an over-all accuracy of 97.1 per cent. In this same series of cases, the accuracy of the x-ray examination was about 85 per cent. Therefore, this technic offers a diagnostic method with an accuracy that far exceeds that of any other method available at the present time.

Consideration must be given to this procedure as an aid in the early diagnosis of gastric cancer. As a matter of fact, about two-thirds of the patients seen are inoperable and really small gastric cancers are a rarity. But it must be remembered that three of the cancers in these series were lesions of less than 1 cm. in diameter and two had strongly positive smears. The only small lesion that was missed cytologically was a carcinoma in situ 2 mm. in diameter, which was discovered only by serial section of what appeared to be a benign ulcer. This evidence suggests that the method may be accurate in the detection of early gastric cancer. An absolute estimate will have to wait the application of the balloon smear technic to groups of patients in the presymptomatic, or at least early symptomatic, phases of the disease. This proof will not be come by easily or quickly, but as the method becomes more widely known and generally used, it is felt that some cases of gastric cancer will be discovered in their earlier phases.

As Cooper and Papanicolaou aptly state, "Earlier diagnosis cannot help but result in more cures of this disease."

Gastric Lavage With Papain-Cysteine Solution for the Diagnosis of Gastric Carcinoma

Attention has been drawn by Rosenthal and Traut[1] to the mucolytic action of papain for cell concentration in the diagnosis of gastric malignancy. They suggested the use of a buffer of approximately pH 7.3 for the purpose of neutralizing excess acid. Actually, papain is active over a wide pH range. The buffer used is that used in Ringer solution.

Buffer.—

Sodium dibasic phosphate ($Na_2HPO_4.2H_2O$)	350 gm.
(If the anhydrous form or the form with 12 molecules of water of crystallization is used, adjust the weight accordingly.)	
N/1 hydrochloric acid	400 c.c.
Distilled water	5 gallons

---

[1] Cancer 4: 1, 1951.

Papain-Cysteine Solution.—

Grind 3 level teaspoonfuls of papain in a mortar with ¾ teaspoon of cysteine hydrochloride (activator).

Stir briefly in the buffer solution and filter through a coarse filter paper. The ordinary fine filter paper becomes clogged.

Make fresh, every day.

Technic.—

Discard the fasting specimen.

Introduce one pint of papain solution through an Asepto syringe, the mouth of which is introduced into the end of an ordinary flared Levine tube.

After 10 minutes, remove from the stomach as much of the solution as can be obtained. Usually most of the solution is recovered. Rarely all is lost because of duodenal passage. This has not caused any apparent harm.

Centrifuge the lavage fluid if a large centrifuge is available; or if not available, take an aliquot after mixing.

Continue centrifugalization at moderate speeds for 5 to 10 minutes.

Discard the supernatant fluid.

Add to the sediment a drop of Gastric Mucin, Armour, and stir thoroughly. This restores adhesiveness to the cells. An alternate method is to add a pinch of Mucin to the digest just before centrifugalization.

Place a large drop of the sediment on a slide.

Spread by pressing with another slide in the same manner that cover slip blood spreads are made.

Gently pull the two slides apart and place them immediately into the fixative of equal parts of ether and 95% alcohol.

Carry out fixation and staining in the usual manner, using the Papanicolaou method.

The material should be processed preferably within one-half hour to avoid digestion of the cells.

There is a theoretical risk of provoking a hemorrhage by digestion of fibrin in the base of a gastric ulcer. Papain has a proteolytic action similar to that of pepsin. However, no undue hemorrhage has taken place in 400 examinations (Rosenthal and Traut), including approximately 40 gastric ulcers. Microscopically, blood is often seen, however. Three patients with previous massive hemorrhages (approximately two weeks previously) have been examined without provocation of hemorrhage.

CYTOLOGIC DIAGNOSIS IN UROLOGY

Foot, in his classic work, *Pathology in Surgery,** classifies tumors of the kidney as (1) papillary adenocarcinoma; (2) clear-celled carcinoma or renal cell carcinoma; (3) papillary carcinoma with granular cells; (4) malignant adenoma; (5) tubal adenocarcinoma; and finally (6) hypernephroma. Tumors of the urinary bladder are classified as papilloma, which is a transitional-celled papilloma, or an "overgrowth of the lining epithelium that takes the form of a patch of villous projections that float in the urine like clusters of seaweed"; epidermoid papilloma; carcinoma; transitional-celled carcinoma; keratinizing carcinoma; diffuse carcinoma; aniline tumors, apparently caused by long exposure to alpha- and beta-naphthylamin and benzidine; and epidermoid carcinoma.

---

*J. B. Lippincott Company, 1945.

Tumors of the prostate, as classified by Foot, are adenoma, leiomyoma, carcinoma, adenocarcinoma, of which there are several types, but they can be grouped under two headings, multiacinar form and large acinar form; myosarcoma and rhabdomyosarcoma.

The question of whether or not exfoliative cytologic methods will be helpful in the diagnosis of malignancy of the urogenital tract was taken up in a special course given by Papanicolaou and the clinical staff at Cornell University Medical School in New York in 1948. In this course, Marshall, of the Cornell University Medical School, stated that malignant cells are easily found in prostatic cases; also that this method is not useful in all clinical cases because at times biopsy of the tumor may be necessary. Papanicolaou reported on the advisability of using his method of exfoliative cytologic examination in suspected carcinoma of the prostate. Gradwohl and Hall,[1] 1948, reported their results on examination of numerous cases of known and unknown carcinoma of the prostate. These examinations were carried out by testing the urinary sediment by the Papanicolaou method. They corroborated the statements of Cahill,[2] that cytologic examination of the urine is of importance in these cases, as has been stressed by Papanicolaou. This may be of the gross urine, or may be material of ureteral specimens. The examination in which the sediment is fixed and mounted as tissue requires experience as to interpretation because of the changes occurring in the cells due to their immersion in the urine. In parenchymatous tumors, two types of cells are seen: (1) unusually large cells with mitotic changes, and (2) vacuolated cells with clear cytoplasm, rich in lipids, so characteristic of clear-celled carcinoma or hypernephroma. Cytologic studies in all urinary tumors is an essential step in the diagnosis. It is our belief that cytologic study of the urine will prove of great value in the diagnosis of renal neoplasm and for the diagnosis of cancer of the urinary tract.

Technic.—

The method used is essentially that suggested by Papanicolaou.

Obtain a specimen of urine, preferably catheterized, and mix with equal parts of 95% alcohol.

Centrifuge as soon as possible, at medium speed, for 30 minutes.

Remove the supernatant fluid.

If smears cannot be made immediately, cover the sediment with absolute alcohol, and place in a refrigerator.

To make smears, prepare a light film of Mayer's albumin fixative on slides and cover with a small amount of sediment and then spread with another slide as evenly as possible.

When it is noted that the edges are drying, while the center is still moist, fix the slide in equal parts of alcohol and ether for a minimum of one hour.

Stain exactly as described for vaginal smears (page 2174).

For the diagnosis of prostatic cancer, the recommended method is as follows: Have the patient void part of his urine, then massage the prostate. After this, have the patient void the remainder of the urine, which will contain prostatic massage fluid. Examine both specimens as indicated above, by centrifugalization and smearing the sediment over a thin film of Mayer's albumin fixative. When the film begins to dry around the edge, fix it in equal parts of alcohol and ether, and stain in the usual manner.

SOLUTIONS FOR THE PRESERVATION OF MUSEUM SPECIMENS

Kaiserling Method

The Kaiserling method gives by far the best results for ordinary pathologic and anatomic preparation where the color of the red blood cells is to be preserved. If any of the faint yellows or greens (due to bile staining or other causes) are to be kept, one of the chloral hydrate fluids, preferably Klotz, gives excellent results, with Kaiserling No. III as a permanent preservative.

Specimens must be obtained fresh from the autopsy or operation and not be allowed to soak in water for more than a few moments. Only the superfluous blood should be washed away, remembering that the one color available for preservation lies in the hemoglobin of the red blood corpuscle, and that this, therefore, must be preserved. The basis of the methods of color preservation which are to be recommended lies in the chemical change produced by the action of formaldehyde upon the hemoglobin of the red cell and its subsequent fixation as the red alkaline hematin by alcohol.

It is necessary to enlarge on the proper laying out of the specimens in the No. I solution. No cloth, metal pins, nor paper must be allowed to come in contact with them. Cotton wool to hold in shape and stretching on glass frames with cotton thread is all that is necessary. Large bodies of fresh fluids must be used. After careful comparison both abroad and at home, the following process has been found to give the best results:

Kaiserling Solution No. I.—

Potassium acetate	170 grams
Potassium nitrate	90 grams
40% Formalin[1]	1,600 c.c.
Water	8,000 c.c.

Care should be taken to use only high grade chemicals.

1. **Water white formaldehyde** must be as free from formic acid as possible. It is not necessary to buy the chemically pure grade. A white deposit, due to freezing (paraformaldehyde) is sometimes seen in the Formalin. This lessens the concentration of formaldehyde gas, and consequently the color and fixing processes are not correct. Always buy Formalin in the spring of the year and see that there is no white deposit present. Do not boil it unless you restore the amount of Formalin used in making the solution.

If the formaldehyde is found to be acid, it can be neutralized with sodium carbonate or sodium hydroxide.

To make a 2% Formalin solution:

Formalin	5 parts
Water	95 parts

4%: Use 10 parts of Formalin to 90 parts of water.
6%: Use 15 parts of Formalin to 85 parts of water.

2. **Potassium acetate.** We recommend Mallinckrodt potassium acetate.

3. **Potassium nitrate.** Merck's pure powder, U.S.P., is excellent. (It is not necessary to use c. p.)

4. **Glycerine**, water white, c. p. Do not use dynamite glycerine as it produces a change in color.

5. **Chloral hydrate.**

---

[1] Water white formaldehyde.

The length of time the specimen should remain in Kaiserling's first fixation fluid has caused a great deal of comment. It is of secondary importance to thorough hardening. The specimen should be fixed in such way that no blood will ooze out when firmly pressed between the fingers. In fact, good color results have been obtained in specimens that have stood from two to four months in the No. 1 solution. These are, of course, exceptional cases. Intestines should not be left for more than ten to twelve hours. Other specimens or organs should be left in the solution from one to five days. In all instances they must be thoroughly fixed. Formalin increases the firmness of tissue. The tissue loses its natural color and assumes an aged and grayish appearance.

Great care must be taken to wash the specimens thoroughly in running water after removal from this solution.

Kaiserling Solution No. II.—

Ninety-five per cent alcohol is used. It may be used at once without the intermediate stage of 80% alcohol recommended by Kaiserling. The specimens must be left here until the natural colors, which have disappeared under the action of the Formalin in the first solution, return, the process being watched in the same way as in the development of a photographic plate.

The strength of the alcohol should not be allowed to go below 80%. To avoid this the specimens should be transferred to a second alcohol of the original strength. The time in which the specimens remain in the alcohol varies according to the particular character of the tissue.

In this stage again the specimens must be carefully washed in water, no traces of the Formalin or alcohol used in the first and second solutions are to be carried to the final fluid. If either the alcohol or the Kaiserling or the Kaiserling No. III solution used gives off any odor of either Formalin or alcohol, it must be thrown away. This is absolutely necessary.

When specimens have been left in alcohol for too long a time, color can be restored by leaving them in equal parts of Kaiserling No. III and glycerine for twenty-four hours, allowing for the amount of glycerine already in the Kaiserling fluid.

Kaiserling Solution No. III.—

Potassium acetate	4 lb.
Glycerine	2,000 to 4,000 c.c.
Distilled water	10,000 c.c.

to which 20 c.c. carbolic acid may be added as a preservative.

In preserving veterinary or comparative anatomy specimens Kaiserling is not satisfactory: the best results have been obtained by Klotz, increasing the Formalin possibly to 6%, then placing in the alcohol, and preserving in Kaiserling III.

When specimens in Kaiserling III in open jars are used to pass around a class, care must be taken not to allow the surface to dry, or the fluid to be contaminated with molds. One infected jar may cause contaminations in many others and necessitate putting them through No. I and No. II solutions just as you would with a fresh specimen.

To Clarify Kaiserling Solutions

To get a clear Kaiserling No. III, connect a five-gallon vessel with an air compressor. Run the Kaiserling through a Berkefeld filter. This takes twenty to thirty minutes. Run water through the filter to clean it. Be sure to connect the filter with the water main.

Another method of clarifying Kaiserling No. III follows:

For 10,000 c.c. of Kaiserling No. III, 5 funnels are required. Prepare filter paper. Do not fold it. Place the five filters in a row. Use one tablespoonful of charcoal (very fine bone charcoal) for each funnelful. Put the charcoal in a jar and shake well with Kaiserling No. III. Run the solution through the funnels slowly. Refilter the first filtrate that comes through the funnels.

In making Kaiserling No. III, do not use tap water. Use distilled water; tap water contaminates the solution.

Kaiserling No. III dissolves plaster of Paris.

Klotz formerly used a little formaldehyde in Kaiserling No. III. This is not recommended as it causes an undesirable chemical reaction. He has now changed to carbolic acid. Carbolic acid makes a specimen slightly gray but prevents the growth of fungi.

Important points to remember are: There must be no odor of formaldehyde or alcohol in Kaiserling No. III. Wash out both of these materials thoroughly so that no trace of odor remains. Overharden in Kaiserling No. I rather than underharden. Always sacrifice color to permanency. Avoid infecting the jars. If infected, specimen must be treated again with Kaiserling Nos. I, II and III.

Formalin will not penetrate either liver or lungs. In order to fix and preserve color, they must either be cut into slabs or injected.

For red blood cell color preservation, place the specimen in a Novy jar and cover with Kaiserling No. I. Then saturate with carbon monoxide gas from any gas jet. To eliminate excess gas, burn off the exhaust or connect a tube to the Novy jar and extend it out of the window.

Always protect a specimen from the direct rays of the sun even after it is completed. Colors are affected by sunlight. Diffuse sunlight will not affect them. Heat will destroy color. Keep specimens in a cool place.

Never preserve a specimen in pure glycerine. A spleen preserved in pure glycerine will shrink to one-half its size.

Be careful of the concentration of alcohol in Kaiserling No. II because it will lose its strength. Keep above 80%. Use a small alcoholometer employing a small test tube (Arthur H. Thomas Company).

Frost's Sugar Solution.—

Sodium fluoride	80 gm.
Chloral hydrate	80 gm.
Potassium acetate	160 gm.
Cane sugar (Tate's cubes)	3,500 gm.
Saturated thymol water	8,000 c.c.

Sodium fluoride may be omitted. Tate's cube is not necessary. Use cane sugar. Never, under any circumstances, use beet sugar.

THE HAIR IN POLICE TECHNIC[1]

In an extensive paper presented before the Academy of Science of Havana on "The Hair of the Races in Cuba," Dr. Israel Castellaños, Director-General of the National Bureau of Identification, Havana, Cuba, pointed out that valuable researches in comparative microscopy had been made public, but very few contributions treating of the hair in police technic had been made. The most important work in this field was done in Europe.

There is an abundant bibliography of anthropologic and medicolegal studies of the hair, but there are only short references to its value in police work. This may perhaps be accounted for on the basis of Gross's exclamation, in 1904: "How seldom clothes are examined, with a view to finding some hair! And if it is found, by mere chance, how seldom is it submitted to examination by an expert!"

---

[1] Much of the material on hair in police technic and identification through the hair by both microscopic and chemical methods is abstracted by permission from the book, *Identification Problems—Criminal and Civil*, by Israel Castellaños, M.D., Director-General, National Bureau of Identification, Havana, Cuba, published by R. V. Basuino, Brooklyn, N. Y., 1939.

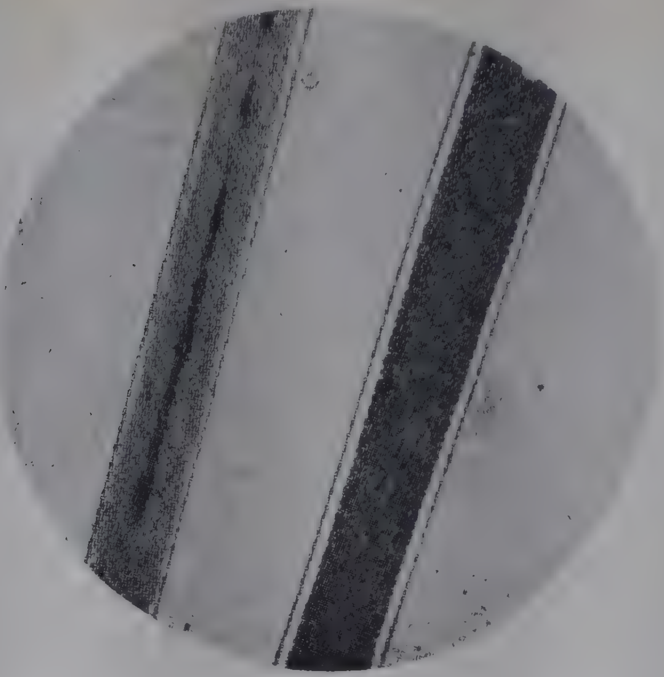

Fig. 655.—Human hair (left) and animal hair (right). These are differentiated by their three constituents—the cuticula, the cortex, and the medulla. In man, the cuticula is thin, slighted serrated, and imbricated. In animals, it is just the opposite. In man, the cortex shows small homogeneous pigment. In animals, the pigment is irregular and larger than in man. In man, the medullary channel is narrow, while in animals, it is much better developed, to such a degree that the greater part of the hair consists of the medulla. (Courtesy Dr. Israel Castellaños.)

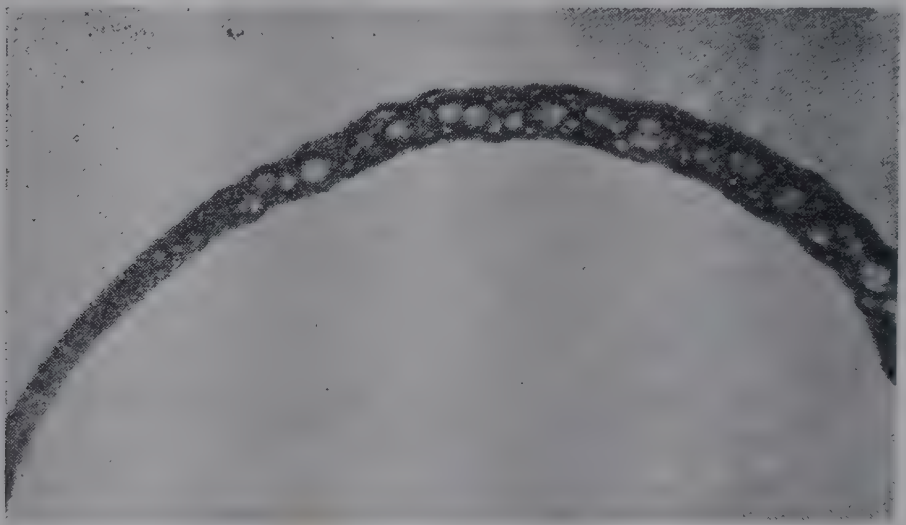

Fig. 656.—Here we see the bubbles which form inside of the hair when it has been exposed to a high temperature without burning. Hair submitted to excessive heat in a permanent wave by inexpert hairdressers has an appearance similar to this. (Courtesy Dr. Israel Castellaños.)

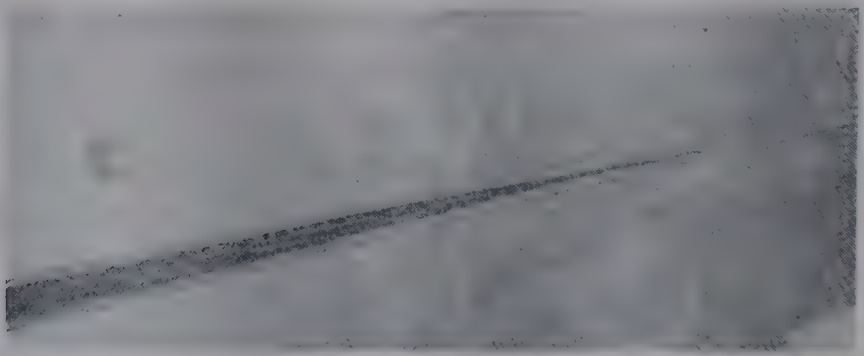

Fig. 657.—This is the point of a hair of animal origin. Note that the structural details of its central portion do not reach the distal end or free portion of the hair. (Courtesy Dr. Israel Castellaños.)

The intensive anthropologic investigations by Castellaños on the hair of Cubans, and his official position in a country where the inhabitants are accustomed to slaughter domestic animals, such as pigs, sheep, goats, etc., in the courtyards, especially on church holidays and national feasts, has shown the eminent importance of hair in police science.

Gross, the Father of Criminology, has insistently called the attention of scientific investigators and of the police to the importance of hair found at the scene of a crime. ''It is the duty of the magistrate,'' he wrote, ''to give his full attention to finding and delivering such hair immediately to experts, as a hair, in spite of its insignificance, may lead us to the discovery of the delinquent.'' (In Austria, the magistrate exercised direction over police investigation not paralleled in English-speaking countries. Dr. Gross was a magistrate.)

Criminal investigators pay considerable heed to the points made by Gross in his very valuable book. Castellaños does not accept his doctrine with respect to examination of hair, however. Gross suggested a simple procedure for establishing the position of the tip and the root of the hair. The method is efficient with respect to that object, but it requires cleaning the surface of the hair, eliminating the dust, dirt, etc., that has settled on it.

Care in Handling Hair.—Waldeyer, in his classic work, which appeared twenty years before Gross's ''Criminal Investigation'' was published, very appropriately observed: ''The dirt adhering to the hair is often more important than the hair itself.'' When a hair is found, therefore, it should never be rubbed between the fingers. Use of a magnifying lens will enable one, in most cases, to determine the direction of the tip or root of the hair.

It is of utmost importance in many cases not to touch any hair found if it can possibly be avoided. Gross recommended that the hair be placed on paper, fastened thereon by means of two glued paper strips, and the ends marked with the letters ''A'' for root, and ''B'' for point. At the same time a sketch is made and lettered accordingly, with letters corresponding to those of the specimen, so as to leave no doubt about the original position of the hair.

In countries like Cuba and America, where there is a mixed population, this may be difficult to do because all hair cannot be mounted in this fashion. Whereas the hair of most Caucasians can be mounted on paper in this manner, that of Mulattoes will seldom allow of it, and that of Negroes almost never. Hairs of these people are therefore preserved in clean white papers or in small envelopes.

Searching for Hair.—The smooth, lank hair of white persons and the straight, stiff hair of American Indians and Chinese are more likely to remain between the fingers of a victim than are those of other races. The more spiral the form of the hair, the less likely is it to stick between the fingers and be found in the hands of the victim, although his struggle with the aggressor may have been very fierce.

Because of the anatomic structure of its outer covering, hair sticks to clothes. The curlier it is, the tighter it sticks.

This brings to mind an interesting case reported by Chief Hugh D. Harper, of Colorado Springs, Colo., at the thirteenth convention of the International Association for Identification.

A white girl had been attacked by a Negro youth, and a suspect was arrested. The Negro people of Colorado Springs said that the accused man was innocent, the defendant's lawyer contending that the crime had been committed by a white man disguised as a Negro. The technical assistance of Dr. L. A. Bennet was requested. He found a long fair hair in the necktie of the youth, which he identified as having come from the raped girl. On the underclothing of the girl Dr. Bennet found pubic hair of a Negro, which he subsequently identified as having come from the arrested man. Thus the hypothesis of the defense was destroyed.

In America, where the population is composed of different racial types, knowledge of hair of various races is needed in police technic. The anatomic structure and the shape of the hair often indicate a definite ethnic type and thus facilitate police researches directed toward persons of some predetermined race. If, for example, a crime has been committed, and on the site of the crime one or more thick rigid hairs are found, it is assumed that a Chinese or an American Indian is involved. Likewise, if a kinky hair is found, some Negro must have been at the scene of the crime. Hair thus directs the investigation to persons of definite races.

One may admire beautiful atlases which form part of the most important works on hair. They do not, however, explain explicitly or precisely what ought to be done in police practice. There is no complete work on this subject.

Examination of the Hair.—It is advisable to keep the hair in bottles with ground glass stoppers in order not to lose its specific odor.

It is best to examine the hair as it is found. Pick it up with forceps and place on a slide. Cover with a cover glass. Do not touch the hair with the fingers, since this might remove any matter on the surface—dust, pollen, coal dust, etc.

Examine the hair under the microscope. Then, as Waldeyer recommends, without having cleaned the hair, add distilled water, and examine under constantly increasing magnification. One can often, in this way, discover blood, spermatozoa, pus, parasites, vegetable or metallic particles, etc., all of which can be identified. There are numerous instances where the hair is surrounded by substances which are found only on persons engaged in specialized occupations.

After having verified these preliminary observations, proceed to clean the hair with water, tissue paper, or a small brush.

Removal of Pigment.—If the hair contains much melanin, as is the case with Negroes and dark individuals, or if the medullary canals are full of air, it is difficult to observe the structural details of the hair or to determine the medullary index. To avoid this difficulty, authorities recommend removing the color from the hair by soaking it in nitric acid for several minutes if the examination is very urgent, or in oxygenated water for several hours if there is sufficient time.

In a great many cases the action of the nitric acid is protracted, and the hair under investigation is destroyed, arguments which might be brought out by either the prosecution or the defense. J. Delgado Roig, of Sevilla, Spain, has eliminated these difficulties by using oxygenated water and nitric acid; he uses a 15 per cent solution of sodium carbonate, in which he leaves slightly pigmented hair for half an hour; he leaves hair with much melanin for five hours in this solution. The hair is then mounted in Canada balsam, which is recommended by all authors. This method not only permits exact comparisons between two or more hairs, but also its identification at any later day, since the bleaching reagent does not impair or destroy the hair, even though it has been mounted for considerable time.

Cross-Section of Hair.—A portion of the hair should be cut in cross-section.

Cleanse the hair in 95 per cent alcohol for 5 to 10 minutes.

Immerse in 10 per cent sodium hydroxide solution for 5 to 10 minutes or longer depending upon how soon the hair becomes softened by the solution.

Immerse in a 20 per cent alcoholic solution of hydrochloric acid for 5 to 10 minutes.

Gonzalez suggests a convenient method of sectioning hair prepared as described. Partially incise a small segment of Formalin-fixed liver on one side, and stretch the hair out in the bed of the incision. The natural elasticity of the liver section will hold the hair in place. Then fix, harden, and embed the tissue in celloidin or paraffin. Cut it in the usual manner and mount the unstained section in balsam.

Gram Stain of Hair.—Stain with Gram stain, wash rapidly in 95 per cent alcohol, and mount in balsam without counterstain. The cuticula is outlined in violet wavy lines on the surface of the hair. If the hair is dark, it may be necessary to remove the pigment before staining, by bleaching it with a mixture of hydrogen peroxide and ammonia water.

Improved Technic for Sectioning Hairs. Method of Kirk[1]

It is often necessary and desirable to observe the hair in cross section. This is especially true when dealing with animal hairs. The transverse aspect is often highly diagnostic of a family with modifications in the genera. The usual methods of embedding lead to an angular section, which gives a distorted picture of the true contour of the fiber. Embedding in collodion is somewhat more successful, but the collodion-coated hair must ordinarily be mounted secondarily in paraffin to make it rigid. The problem of bending and distortion is therefore a serious obstacle to properly sectioned hair.

Kirk[1] described an improved method for sectioning hair. He advised a small microtome, developed by Hardy, with which a person after some experience can make a cross section in a very short period of time. The method combines embedding on a wood base with the use of a hand microtome which allows sections of 0.01 to 0.015 mm. in thickness or thicker.

Technic.—

Cut strips of balsa wood 1 cm. wide and 3 inches long from ¼ inch thick balsa planks.

On one of the centimeter-wide surfaces, apply a single layer of cellulose-acetate glue and spread out evenly to cover the wood strip completely in its central portion. Slow-drying "Comet" model airplane cement has been found to be readily available, convenient to use, and quite satisfactory as an embedding medium.

While the film of cement is still wet, lay the hairs to be sectioned on the cement parallel to the long axis of the balsa base.

As the film becomes tacky, apply a second layer of the embedding medium and spread so as to completely cover the hairs.

Label the block on the reverse side and place in a closed container, such as a small box, to dry slowly.

Observe two precautions. Do not apply more than the two necessary layers of cement because thicker films are much more difficult to cut; also do not accelerate the drying process since numerous and abnormally large bubbles are thereby formed which, if they surround the hair, tend to decrease the tenacity with which it is held. Upon drying, small bubbles are seen throughout the embedding medium. These do not ordinarily interfere with the quality of the final sections.

---

[1] J. Crim. Law, Criminol. & Police Sci. 44: 124, 1953.

Sections may be cut within one-half hour if necessary, but they are thick and wedge shaped since the embedding cement is not completely dry, which tends to make them yield in front of the cutting edge. At least 12 hours, or overnight, is recommended as a satisfactory drying time.

Before embedding, clean and dry the hair, by washing thoroughly in acetone or alcohol-ether mixture and allowing it to dry on filter paper for a short while. This process takes only a few minutes.

If a number of hairs of a known source are to be embedded on the same block, they may be oriented while drying, with all proximal or distal extremities in the same direction. This procedure facilitates handling the specimen while affixing it to the block.

When thoroughly dry, place the wood strip carrying the embedded hair in the specimen clamp of a table model hand microtome (American Optical Model 900). Adjust the microtome until the portion of the hair that is desired for sectioning is even with the blade holder guides. A razor blade holder, designed for the instrument, is always used with a fresh sharp blade. Make the cut with a short slicing motion, through the embedding layers and hair, *but only as far as the underlying wood base.* Make the next cut in the same fashion, after advancing the block the amount desired. As many cuts may be made successively as required.

If another portion of the hair must be sectioned, adjust the block to the region of interest and repeat the cutting process. As the fiber is always in view through the cellulose-acetate layer, it is convenient to obtain sections close to the ends, in the center, or in any other area of the hair. The severed but unsectioned parts of the hair remain attached to the uncut block in their original relative position and may be recovered by dissolving away the lacquer with acetone. The block has suffered little damage and may be resurfaced with sandpaper and used repeatedly.

Using a pair of fine-tipped forceps, lift the hair sections, set in a slide of cellulose-acetate 0.5 to 1.0 mm. deep and 1 cm. wide, from the block and place in a small evaporating dish. Dissolve the lacquer with 1 or 2 c.c. of acetone. When the acetone evaporates, the resolidified cellulose acetate will be seen to have migrated up the sides of the dish, leaving the clean, free sections in the bottom.

Observe under a stereoscopic binocular microscope and transfer to a previously albuminized slide by touching each with the tip of a sharpened dissecting needle, to which they cling, then depositing them on the slide.

Inspect the slide briefly under the stereoscopic binocular microscope. Any sections standing on edge can be gently teased into their transverse plane with a needle.

A slightly faster procedure is to separate the lacquer slices and mount them on a slide. However, the lacquer slice surrounding the hair sections somewhat interferes with definition of the contour of the hair.

Apply a permanent mounting medium and cover slip. Clarite "X" dissolved in xylol is excellent. This medium infiltrates the hair and clears it very well for observation.

This technic has been useful in our hands. One difficulty we have had in getting the mounted hair in the proper position was due to the fact that we did not get all the lacquer off the hair before mounting it.* By using two or three washings with removal of the acetone each time, the lacquer is all removed.

Points in Investigation.—During the struggle which usually precedes the death of one or the other antagonists, it often happens that the hair or beard is grasped. Therefore, we must look for hair in the hands of the victim and on the clothes of the aggressor. If the victim died by strangulation, one must search not only the fingers but also the areas under the fingernails of the victim and the suspect. In cases of rape, the underclothing is examined. Most published cases refer to such findings.

---

*Kirk, Paul L., Professor of Criminalistics, School of Criminology, University of California, Berkeley, Calif. Personal communication.

A review of the cases of death by shooting shows that the literature gives little information concerning investigation of hair in these cases. Investigators often do not look for hair or examine it in cases which appear to be suicides or homicides. They rely too much in certain instances on the necropsy findings. Forensic study of wounds and collection of data by the police should coincide, since police technic and forensic technic complement each other.

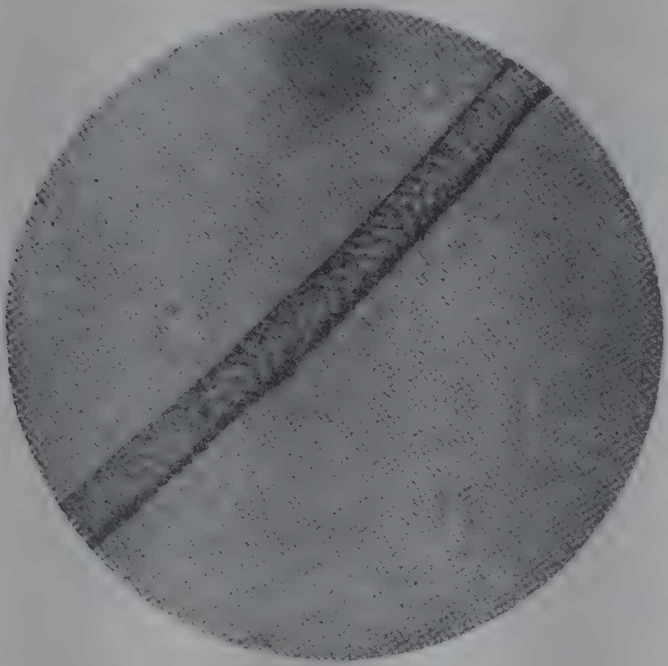

Fig. 658.—This is the hair of a sheep. The cuticular scales are discernible in no other type of hair. Note the absence of medullary channel and structural regularity of the cortex. (Courtesy Dr. Israel Castellaños.)

As an example of the part played by hair investigation, Castellaños cites the following case:

A woman, a foreigner, was found dead in a bathtub, in a state of advanced putrefaction. There were three large wounds on her head. It was alleged that she had died an accidental death, having slipped and fallen while bathing, and that her skull was fractured when it struck the faucets of the tub. Public interest in the case was great; some agreed with the accident hypothesis, while others insisted that this was a criminal death. Some days after the corpse had been found, Dr. Castellaños' bureau was called upon to make an investigation.

A thorough search was made and in the tub and on the walls of the bathroom, at approximately the height of the corpse, police recovered an abundance of hair. This was compared with that of the dead body and found to be identical.

The roots were examined; they presented evidence, without a doubt, of having been violently torn out of the scalp. Some of the shafts were bruised; others had been cut with a rather blunt instrument. The hair thus changed the situation, and led the police from the hypothesis of suicide to the certainty of homicide. To complete the demonstration, Castellaños proved that there was blood in the bathtub and that this blood had flowed from the victim; there was blood on the floor of the bathroom which had been washed; and, finally, on the basin, blood was found which the perpetrator of the crime had washed from his hands. When dressing before making his escape, he had left some gray hair between the teeth of a comb, which the Cuban Bureau is still holding. The medical examiner reported that a murder had been committed, and the police confirmed this thesis.

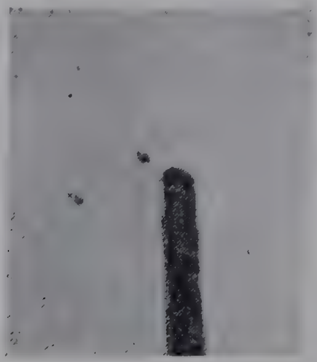

Fig. 659.—Round end of a hair shaft. This form appears on hairs which have been in continual contact with clothing. (Courtesy Dr. Israel Castellaños.)

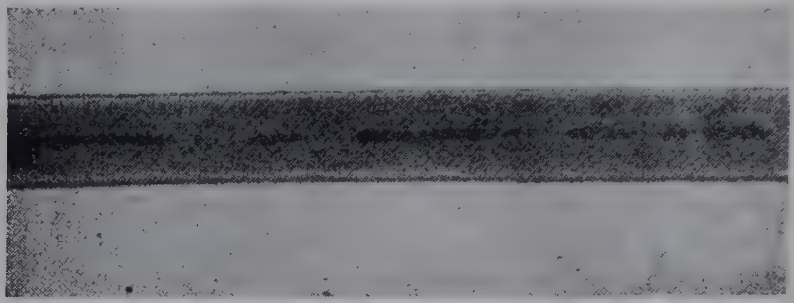

Fig. 660.—This is a shaft in which we can clearly observe the three constituents of hair—cuticula, cortex, and medulla. Note the lack of continuity of the medullary channel. (Courtesy Dr. Israel Castellaños.)

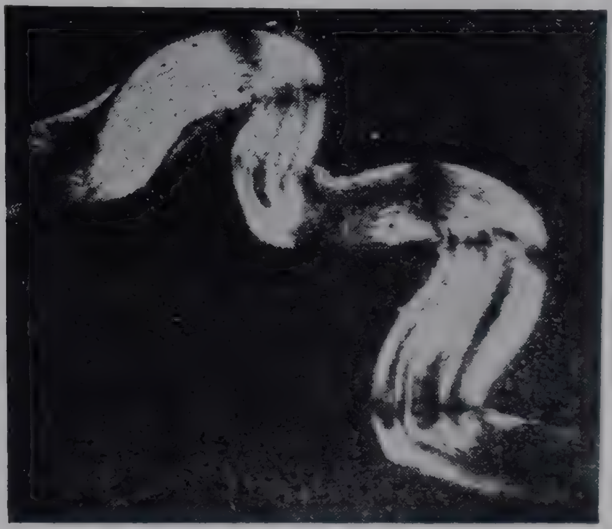

Fig. 661.—Photomicrograph showing the microscopic appearance of curled hair. (Courtesy Dr. Israel Castellaños.)

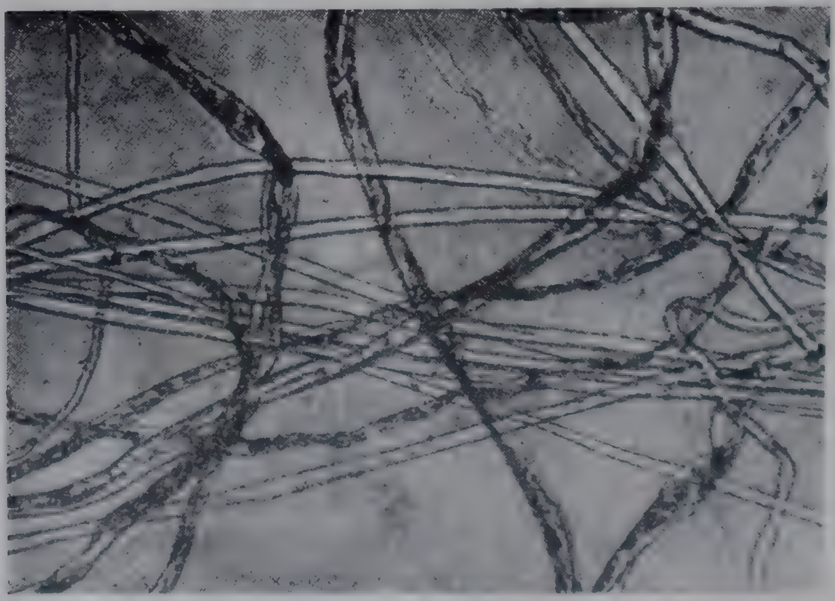

Fig. 662.—Cotton and silk fibers. Note the different microscopic appearance of each. (Courtesy Dr. Israel Castellaños.)

There are a great many homicides and murders by shooting which give the appearance of suicides. On the other hand, some cases of suicide present the appearance of murder. In these cases the study of the hair often helps to solve such medicolegal problems.

Effect of Firearm Wounds on Hair.—The first investigator to study the effect of firearm wounds on hair was Minakow. Daake, confirming the tests of Minakow, showed that the microscopic examination of hair is decisive in determinating the distance at which the shot was fired.

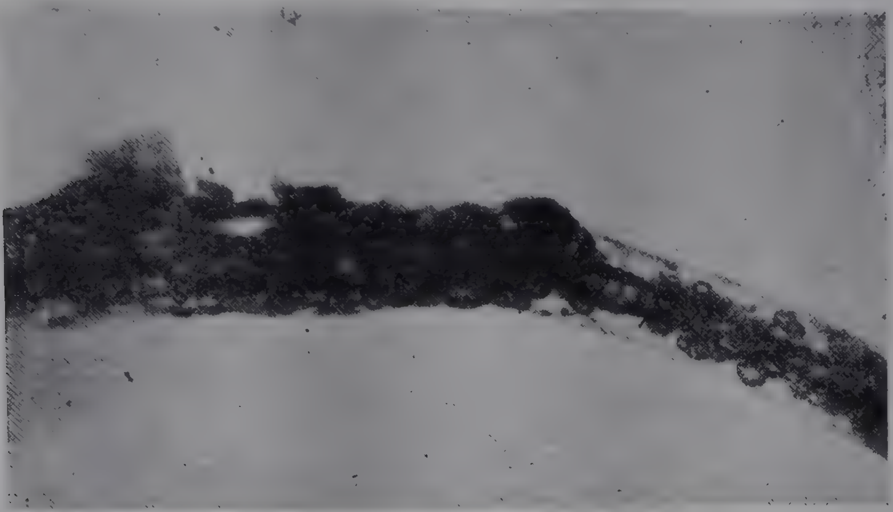

Fig. 663.—Appearance of the hair from a person who committed suicide by shooting himself. The hair is burned by a point-blank shot with black powder. Note the presence of bubbles produced by the heat in the mass of the medulla, and the residue left by the shot on the outside of the hair. (Courtesy Dr. Israel Castellaños.)

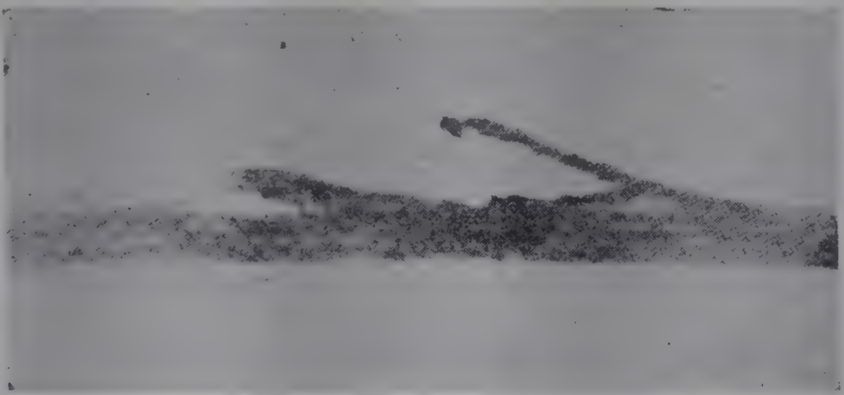

Fig. 664.—In this case the shot was fired from a short distance and smokeless powder was used. The cortex has been broken and raised by the unburned grains of powder, which always escape from the barrel of pistols or revolvers. Note that the outside of the hair also shows residue from the shot. (Courtesy Dr. Israel Castellaños.)

If the shot is fired from a very short distance, the hair of the victim is burnt. Microscopically the hair shows countless bubbles inside, but no change can be detected by the naked eye. Changes are greater after black powder has been fired than when smokeless powder is used. Schwalbe has performed magnificent researches in connection with this problem.

Temperature at Which Hair Burns.—It is very important to know the temperature at which hair burns. Piedelievre and Zebouni, using electric stoves, showed that at 100° C. hair shortens and loses weight; at 150° it presents gaseous bubbles in its medulla; and at 300° it is carbonized. These data are useful for determining to what temperature the body of the victim has been exposed. As an example, one case is cited.

In a village of the province of Santa Clara, Cuba, there lived a widow with her idiot daughter. The mother married a baker, and moved with her daughter into the baker's shop. The stepfather forced the idiot to carry logs for the oven, and in many ways was cruel to her. One day he beat her until she was almost dead. The poor idiot's cries were pitiful. After that incident she disappeared. The mother announced that she had left her home, but the neighbors were inclined to doubt her story and were suspicious that the baker had murdered her. An examination of the baker's quarters was ordered. Police searched the oven and found there countless carbonized hairs. Upon further examination and under questioning, the baker was proved to have murdered the girl and to have tried to destroy the evidence of his crime by burning the body in the oven.

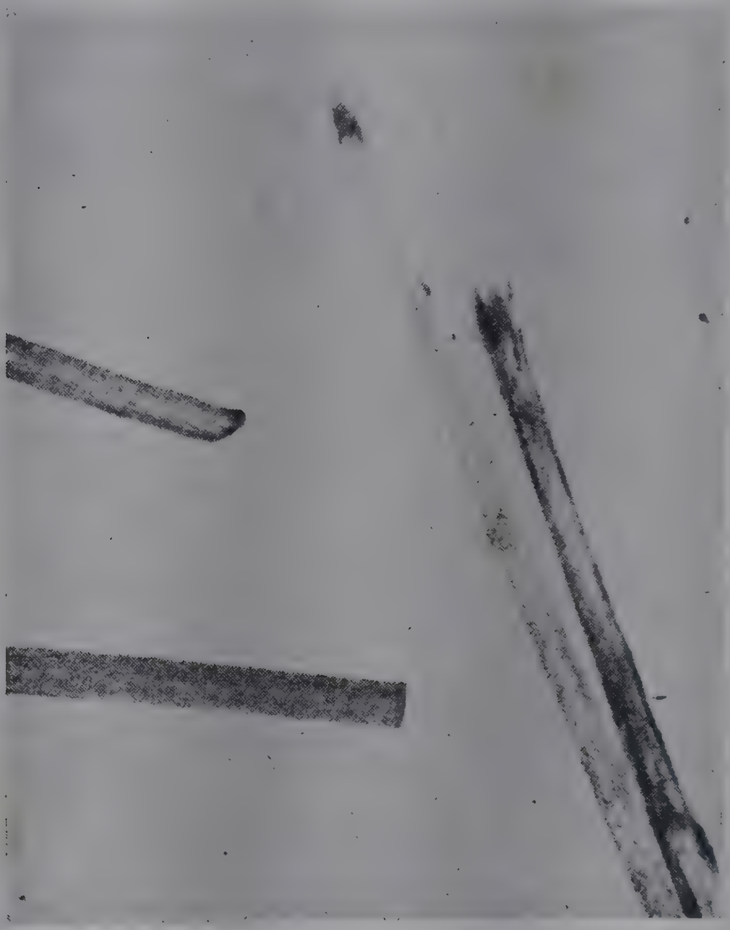

Fig. 665.—The point ending in a sharp angle and the one below, perfectly flat, with clean edges, were recently cut with the sharp scissors of a hairdresser. These hairs came from a woman. The lighter points, lying vertically, which are from less pigmented hair of another woman, are split, indicating the use of tweezers. The irregular or spread ends show that it has been a long time since the hair was cut. (Courtesy Dr. Israel Castellaños.)

Importance of Examining Hair.—All authors dwell at length on the different features of human and animal hair; the specific signs of hair cut with sharp instruments, of bruised hair, of hair torn out by violence, of hair which has fallen out spontaneously, in the course of its renewal; the details indicating the region or part of the body from which the hair comes; the data permitting deductions as to whether it belongs to a man or to a woman; the age of the person from whom it came; and the changes due to dyeing, curling, or combing it. These are but part of the program of identification. One must remember that hair, like bloodstains, reconstructs the crime in many cases, by confirming the correct and scientific findings of the autopsy, as in the case just cited. It may help to differentiate homicides from accidents; it helps to distinguish suicides and murders by proving the distance at which shots were fired; it offers definite proof in some cases of sodomy, as Kutter and Sonnenschein have shown; and it may determine the race of the victim or aggressor in even the most complex and difficult cases. For these reasons, a search for hair must be made in all criminal cases; it must be properly recovered and perfectly preserved, so that examination of such hair will give the best possible scientific results.

Hair should be searched for not only in some types of crimes of personal violence, as rape, strangulation, etc., where it obviously is likely to be found, but also in every crime, from robbery to murder, from infanticide to rape, from suicide to sodomy.

Microscopic Examination of Hair.—The importance of the microscopic examination of hair in criminal investigation has been described by many authors. Rolffs, in 1840, referred to the problem given the experts by a number of black hairs, obtained in 1832, in connection with a homicide. Orfila, in 1835, Ollivier, in 1838, Shuermeyer, in 1846, Falk, in 1856, Lender, in 1863, Kutter, in 1865, and many others thereafter have published cases and insisted on the necessity of studying the hair in order scientifically to decide a multitude of legal cases. In the introduction to the work of Glaister it is pointed out that, since 1851, British judges have considered hair to be valuable circumstantial evidence in criminal cases.

Hair is a distinctive specialized anatomic structure. It consists of a shaft, a point, and a root. That part of the hair which is not embedded in the skin is called the **shaft.** The shaft terminates in a free end called a **point.** The part which is inserted in the skin is called the **root.** The root swells into a more or less ovoid form called the **bulb.** The bulb contains an indentation, very much like the bottom of a bottle, in which is contained the **papilla,** a projection of the skin, which is the organ which produces the hair. Each of these parts—the shaft, the point, and the bulb—offers important details. We may compare a hair with a fine pin, in which the head is the bulb, the body is the shaft, and the sharp extremity is the point.

The shaft is composed of the **medulla,** the innermost core of the hair; the **cortex,** the intermediate layer which surrounds the medulla, and which is the thickest and most distinctive part of the shaft; and the **cuticula,** around the cortex. The medulla looks like an irregular cylinder and contains air spaces and some scattered cells of various sizes and shapes. The medulla often disappears toward the distal end of the shaft. The very fine type of human hair might not contain a medulla. The cortex is composed of elongated, spindle-shaped, longitudinal, horny plates attached closely to each other. They contain pigment granules. The cuticula is composed of non-nucleated overlapping polygonal cells, the free edges of which are directed toward the distal end of the hair.

Age of the Individual From Whom Derived.—Oesterlen gives the following average diameters of hair of different age groups:

12 days	24 microns
6 months	37 microns
18 months	38 microns
15 years	53 microns
Adults	70 microns

Lanugo hairs on the fetus are very fine, have no medulla, and are almost colorless. The average diameter of the hair increases with age as can be seen in Oesterlen's table. The hairs of infants and children are usually finer than those of adults, they usually have no medullary cavity until after puberty, and contain less pigment than do adult hairs. Gray and white hairs appear in middle life. This is due to loss of pigment from the shaft. Gray hair without pigment is usually translucent or may even be transparent. The diameter of the hair in the aged is less as a rule than that of younger adults.

It was formerly thought that the morphology of the medulla of human hair depended on the age of the individual, but E. M. Wynkoop showed that this is in proportion to the diameter of the shaft of the hair and is not due to age.

The hair of young people has a lower pigment content and a smaller diameter than that of adults. In elderly people the hair tends to become scarcer and finer and the bulb degenerates. The shaft also shows signs of degeneration.

Race.—Scalp hair is usually examined to study race. The color of the hair of the Caucasian race varies from light to dark. The shaft may be fairly straight or wavy and curly with varying caliber throughout the length. The shaft is ovoid. Medulla is central in straight hairs or slightly excentric in curly hair. In dark individuals of the Caucasian race the cortex contains much pigment and is dark brown. In fair individuals the hairs are lighter brown, or they may be reddish or blond.

American Indians, Chinese and other Asiatics usually have long straight coarse black hair with deeply pigmented large shaft. Cross sections show cylindrical or triangular shafts with the medulla centrally situated.

Hair of Negroes is usually kinky and black, the caliber varying greatly along the entire length of the hair. A large amount of pigment is to be found in the cortex. The hair in cross-section is ovoid and narrow or may be almost flat. The medullary canal is excentrically placed.

Sex.—It was formerly possible in many cases to identify hair from female subjects by the length of the hair, but since women cut their hair frequently today and also shave the armpits and legs, the length and shape of the point are of much less value than formerly for differentiating hair. The best rule, as indicated by Glaister, is that a woman's hair generally shows a more delicate structure and a much finer granulation of pigment than that of a man. A study of the cross-sections shows that the sexual difference in the weight of hair is due to the difference which exists in the area of cross-section and the difference in the amount of pigment. M. Bernstein and S. Robertson, of Chicago, showed that male hair is heavier than female hair.

Region From Which the Hair Is Derived.—To determine the region from which the hair is derived, consideration is given to the length, the diameter, the shape of the point, the material which covers the surface, and the shape of the cross-section of the hair. Hairs from the beard are usually larger and curlier than those from the scalp. They usually show the effects of shaving, although if undisturbed will taper to a point. Hairs from eyebrows, eyelids, nose, and ears are as thick as the hair from the scalp but are much shorter, and taper rapidly to a point. Medullary cavities are consistently present. Hairs from the axilla and pubic regions are fairly long and uneven with excentrically placed medullary canals. The hair has a tendency to curl. Hairs on the trunk and extremities vary in thickness and have less pigment than other hairs. There is a fine medullary cavity, although this may be absent.

The mere presence of certain substances indicates the region from which the hair came. A hair covered with fatty matter unquestionably came from the armpit; a curly hair, with crystals and vaginal secretion, can come only from the genital region of a female, etc.

Glaister summarized the bases of diagnosis as follows: (1) the total length of the hairs, (2) their texture and contour, (3) the character of both ends, (4) the general thickness, (5) whether sweat, vaginal secretion, seminal fluid, fecal material, food, nasal secretion, or wax adheres to them, (6) the exact character of the cross sections.

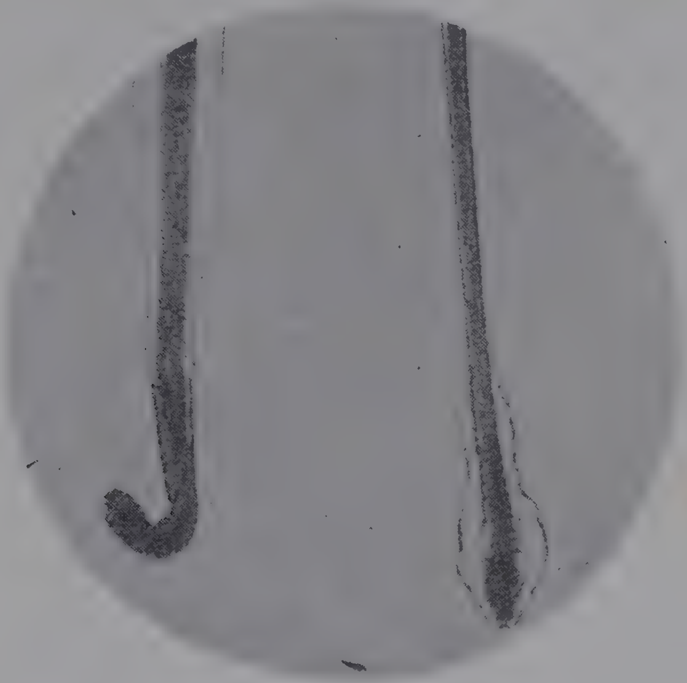

Fig. 666.—Root portion of hairs which have been torn out. Note the typical appearance of the bulb. The one at the right carried part of the follicle sheath. (Courtesy Dr. Israel Castellaños.)

Miscellaneous Facts.—Hair which has been recently cut shows the cut end more or less clean, according to the sharpness of the instrument used. At times hair is found in caps or hats with both ends cut, one cut being recent and the other much older. In all cases where the cut is recent, the edges are clean, neat, and form more or less acute angles. After three days the point of the cut hair begins to become rounded, convex, because of the continuous rubbing of substances against it.

Pincus estimated that an individual of 20 years loses 70 hairs of his head daily; this figure decreases until the age of 50 years, when only 22 hairs are lost each day. Hair which falls out of itself shows a full bulb, replete, as it has reached full growth. On the other hand, those which have the bulb hollow or excavated, because they have not attained full growth, show that they were pulled out. When the pull has been very violent, the root is found to have particles or cells of the surrounding skin clinging to it. In some cases hair which has been pulled out is found to have numerous cells of the skin adherent to the root, and the shaft is more or less noticeably bruised. This always occurs when the victim was attacked with a heavy, blunt, and crushing instrument.

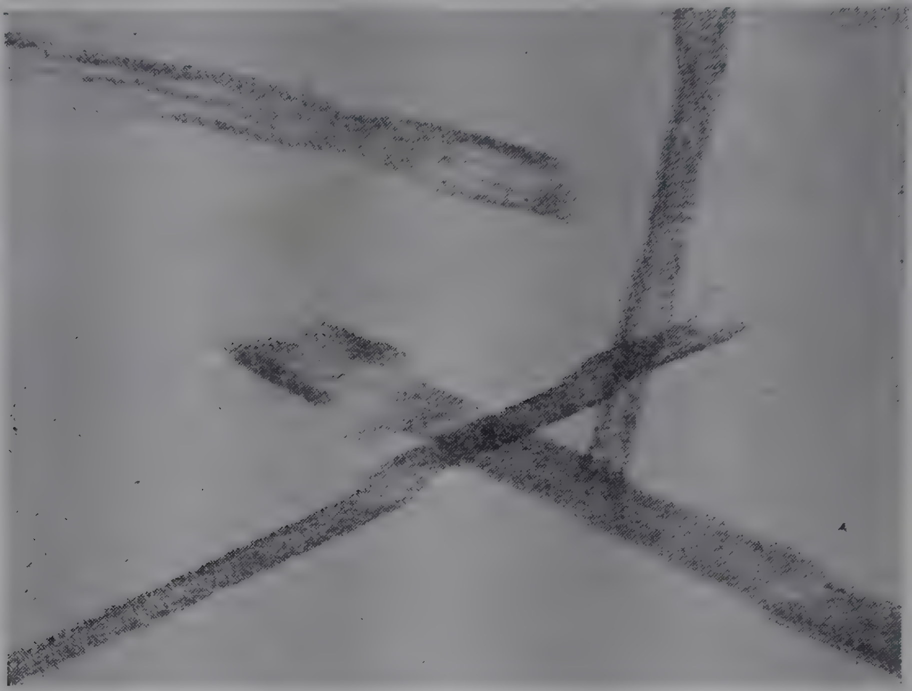

Fig. 667.—Microscopic appearance of several hairs which have been struck with an instrument or weapon without a cutting edge. It can be seen how part of the hair shaft is bruised. (Courtesy Dr. Israel Castellaños.)

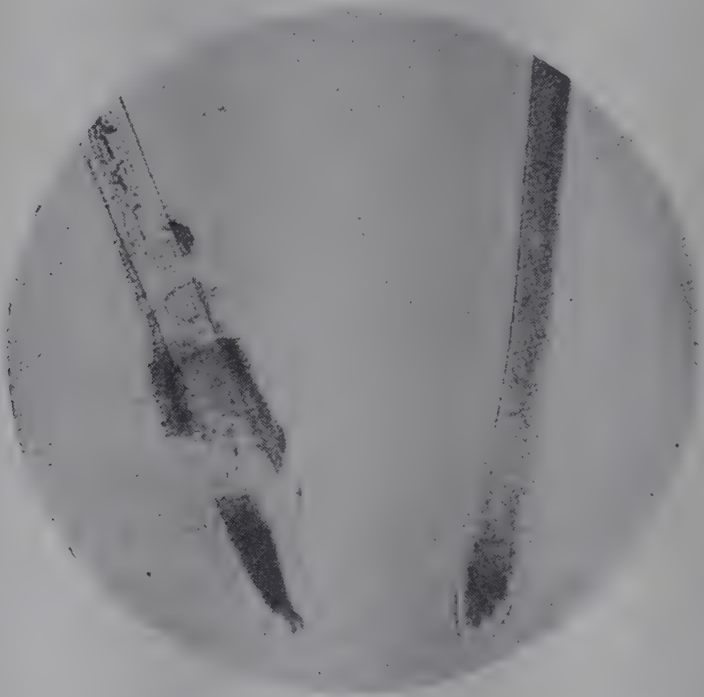

Fig. 668.—Root portions of two hairs. The one at left was torn out and the one on the right fell spontaneously. Note the typical appearance of the terminal portion in this fallen hair. (Courtesy Dr. Israel Castellaños.)

Bleaching or Dyeing the Hair.—Bleaching of the hair is more difficult to determine than the fact that the hair has been dyed. Dyes are easily discovered, because they leave on the periphery of the hair a homogeneous or irregular layer which can be seen perfectly under the microscope. Tests for determining the dye used are based more on chemical analysis than on microscopic examination.

Dyes of a metallic salt base, bismuth, silver, or lead, or those having a base of organic substances, such as vegetable dyes, can be determined by chemical analysis.

Many criminals do not hesitate to make use of surgical means to disfigure themselves and thus evade the action of the police; they may also use wigs for that purpose. It is necessary, therefore, to be able to distinguish between hair which has recently fallen out and false hair.

Examination.—If, in the hands of the victim, one finds hairs which the victim pulled from the head or beard of his aggressor during a struggle, note must be made of the position of the hairs in the victim's hand. For greater exactitude, as Gross suggested, a drawing is made of the hand to fix that position exactly.

It is often possible to tell the root at a glance, by the enlargement of the bulb, which is always visible with an ordinary magnifying glass. It is then unnecessary to take steps to decide where the point lies and where the root is.

The material adhering to the surface of the hair should not be dislodged, since, as Waldeyer stated, "often the dirt adhering to the hair is more important than the hair itself." For this reason, any hair which may be found must be neither rubbed nor cleaned.

The hair from the victim should be placed in bottles labeled "victim," and any hair from a suspected aggressor should be placed in bottles labeled "suspect."

When no hair is found in the hands of a dead body, and none is found at the scene of the crime or in the place where the victim was found, search should be made of articles of personal use, such as towels, combs, etc. Hair commonly adheres to clothing, not only to caps and hats, but also to stockings. It can frequently be found in the nap of towels, and it may be the hair of the victim or of the aggressor. It is rare not to find hair in the teeth of combs. Such hair may be from the deceased when he last used the comb, or it may have come from the aggressor if he combed his hair before leaving the scene.

Hair may also be found on sheets and pillow cases. It consists of hair which has fallen out while the victim was resting or sleeping in the bed, or hair which has been pulled out violently in the struggle which preceded death.

Hair comes out not only because of the periodic renewal to which it is subject, but also because of a tug given by an individual in defending himself or by the aggressor in an attack. The hair falls unnoticed and remains at the scene of the crime as a silent witness to the tragedy and as circumstantial evidence of the crime. If the investigator searches for it with a magnifying glass, he will find that it contains a varied number of substances, according to the nature of the crime: blood from a mortal wound, black or smokeless powder from a fatal shot, semen, etc.

Finding a hair, according to Glaister, makes it necessary to answer these questions:

1. Is the hair that of a human being?
2. If it is human hair, is it the hair of a male or a female subject?
3. What is the approximate age of the individual from whom the hair has been derived?

4. From what part of the body has the hair been derived?
5. Has the hair been dyed or is it of natural color?
6. Has the hair fallen out, been pulled out, or cut?
7. If it has been cut, was a sharp or a blunt instrument used?

Lambert and Balthazard suggest the following program:

1. Is the hair that of a human being or of an animal?
2. From what part of the body does the hair come?
3. Is the hair from a male or female individual?
4. What is the age of the individual from whom the hair came?

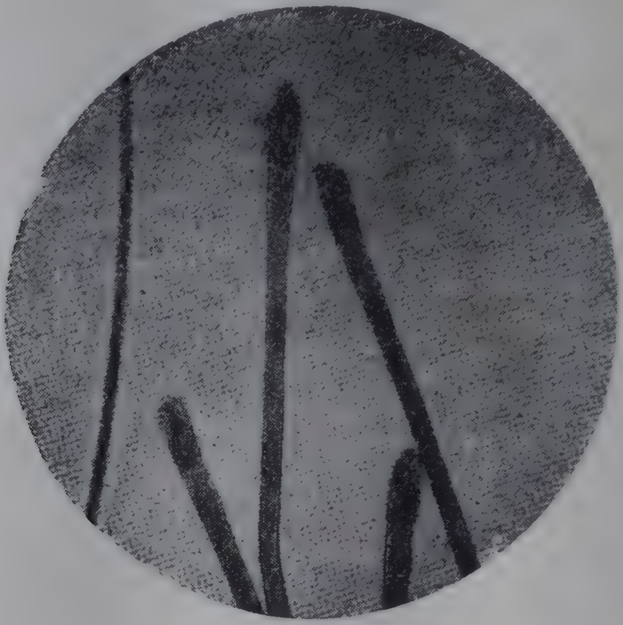

Fig. 669.—These hairs show that in fallen hairs the root sheath is missing. In cases of falling hair, part of this sheath always remains embedded. (Courtesy Dr. Israel Castellaños.)

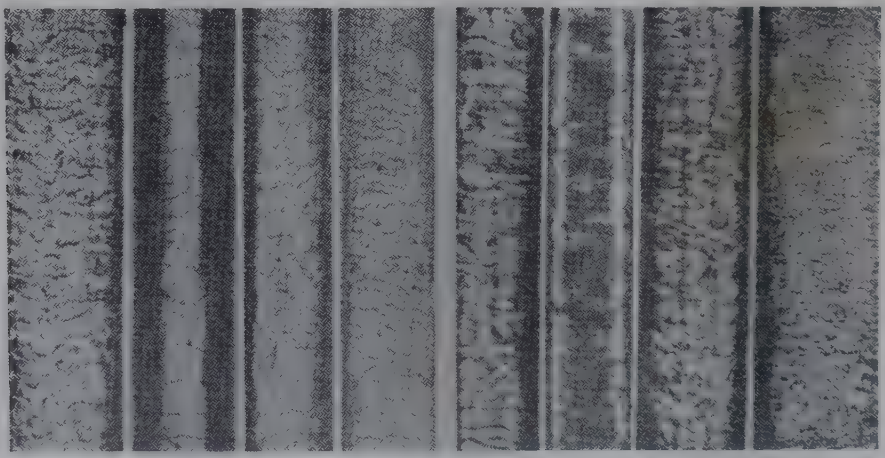

Fig. 670.—Hair characteristics. Left to right, hair of Negro, Mulatto, white man, white woman, dog, cat, horse, and pig. (Courtesy Dr. Israel Castellaños.)

5. Was the hair cut, and at what time?
6. Was the hair pulled out, or did it fall out accidentally?
7. Is the hair dyed, and if so, by what process?
8. Did the hair under examination come from a living person?
9. The identification of the hair.

Castellaños' questionnaire is longer, because he makes additional examinations to determine:

a. The trade of the individual from whom it came.
b. The distance at which the fatal shot was fired in cases of gunshot deaths.
c. The kind of powder used in the fatal shot in such cases.
d. The poisoning of the subject from which it came.

Human and Animal Hair.—Most authors begin the investigation by determining whether the hair found is from a human subject or from a lower animal. At present there is no one known identifying specific characteristic of human hair, just as there is no illness which can be diagnosed by a single symptom; but the hair of no one animal combines the various anatomic characteristics found in the hair of man. Table 215 gives the characteristics of human and animal hairs. See Figs. 655, 657, 658, 670.

TABLE 215.—CHARACTERISTICS OF HAIRS COMPARED

A. Medullary (Center) Channel

I. MAN

a. Aerial net with fine granules
b. Invisible
c. Medullary cells not previously dissociated
d. Value of medullary index (relation of diameter of the medulla to shaft diameter) inferior to 0′ 30
e. Downy hair without medulla

II. ANIMAL

a. Aerial content of vesicles more or less voluminous
b. Medullary cells very apparent
c. Value of medullary index over 0′ 50
d. Medulla in steps in the downy hair

B. Cortical (Outer) Substance

I. MAN

a. Constitutes a thick muff
b. Pigment in very small homogeneous granulations

II. ANIMAL

a. Constitutes a very thin tube
b. Pigment in irregular granulations, always larger than those of man

C. Cuticula

I. MAN

Thin scales, lightly serrated (saw-toothed), strongly imbricated (tile-like)

II. ANIMAL

Thick scales, less imbricated than in man, markedly serrated.

Microscopic Comparison of Hair.—It is after having settled all the points discussed above that the investigator undertakes what may be properly called the identification of the hair, that is to say, the individualization thereof, or, in other words, the determination of whether the hair found comes from a definite suspect or from a given individual.

Measurements are taken of the length of the hairs under comparison and their average diameter, and the maximum measurements are noted. If the different data coincide and the pigmentation of the hair is identical, as determined by the Fischer chromatic scale, one has reason to believe that the origin is the same. To make the examination definitive, minutely study the individual signs or characteristics of the hair. Observe the peculiarities of the *medullary canal* and the *point*. The coincidence of wear or degree of rubbing of the free point of the hair, with the coincidence of the length and the coincidence of the diameter, consolidate the identifying diagnosis. The coincidence of arrangement, abundance, and coloring of the pigmentary granulations make identification or individualization of the hair certain.

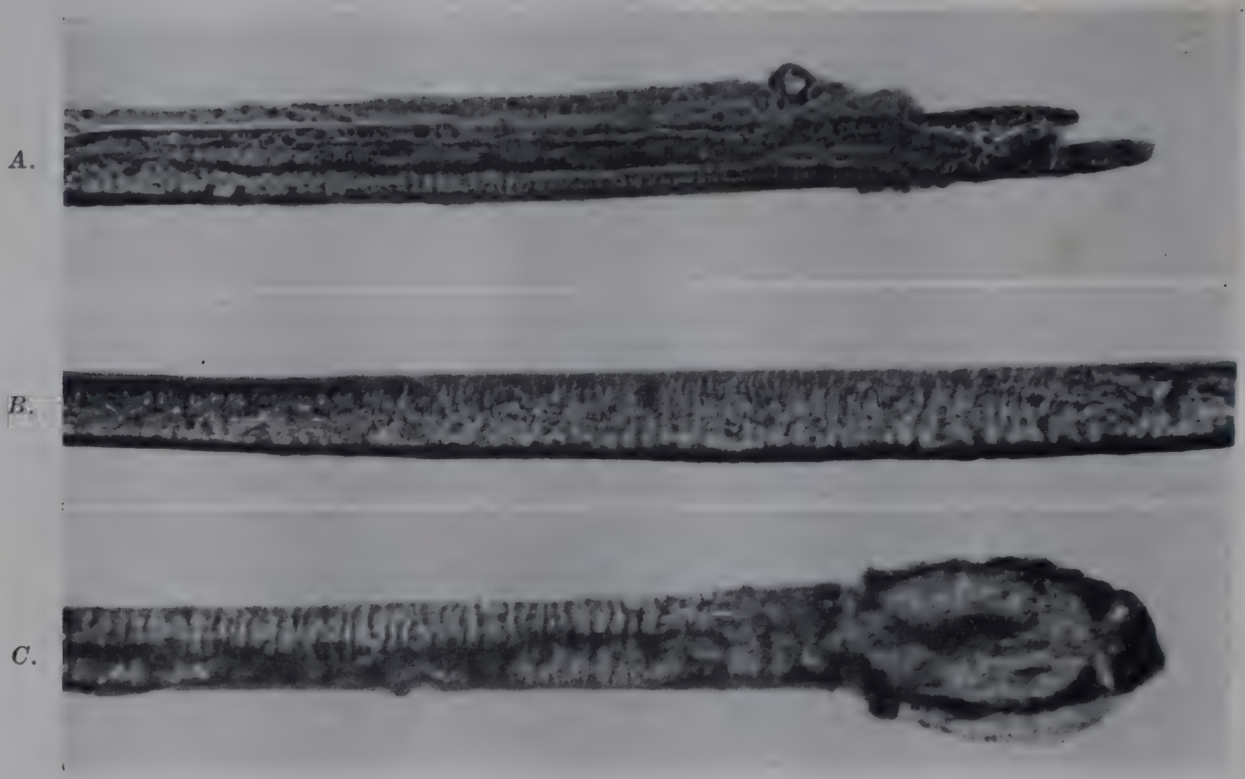

Fig. 671.—Exhibit A, Case 1. *A*, Photomicrograph of the severed end of the hair found in the slit of a screen door. *B*, Photomicrograph of the middle portion of the same hair. *C*, Photomicrograph of the root of the same hair. (Courtesy Dr. Israel Castellaños.)

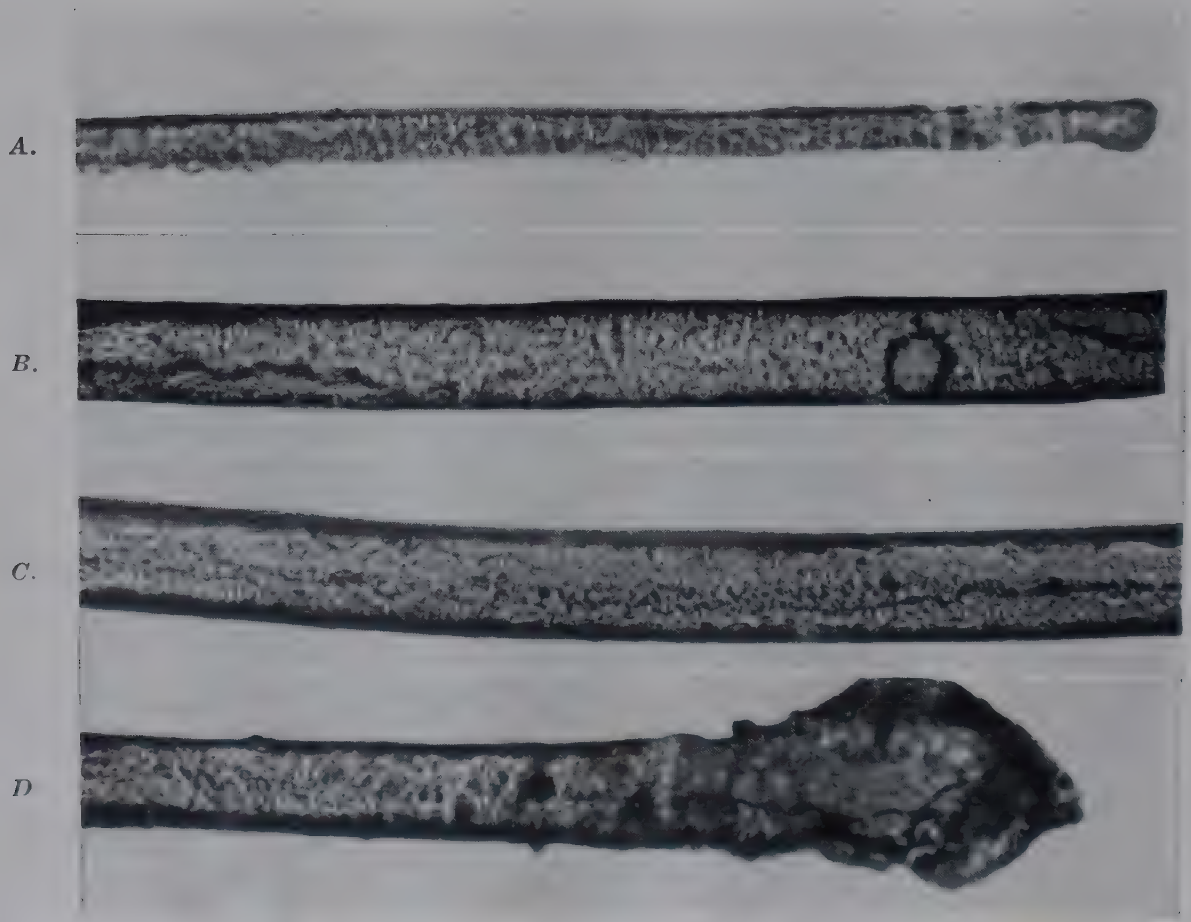

Fig. 672.—Photomicrographs of one of the hairs taken from the left arm of suspect B, Case 1. *A*, End portion of the hair. *B*, Portion near the middle of the same hair. *C*, Portion beyond the middle of the same hair. *D*, Root of the same hair. (Courtesy Dr. Israel Castellaños.)

In addition to these details, purely anatomic, there are many others which contribute to make identification of the hair more eloquent; such as racial characteristics, the existence of identical vegetable substances, metal particles, pathologic changes, parasites, etc.

The presence of foreign particles, such as coal, pollen, etc., may prove to be indications of the trade in which the individual was engaged.

Finally, it has been shown that with adequate chemical methods, presence of arsenic in the hair can be shown when the individual has been poisoned with arsenicals.

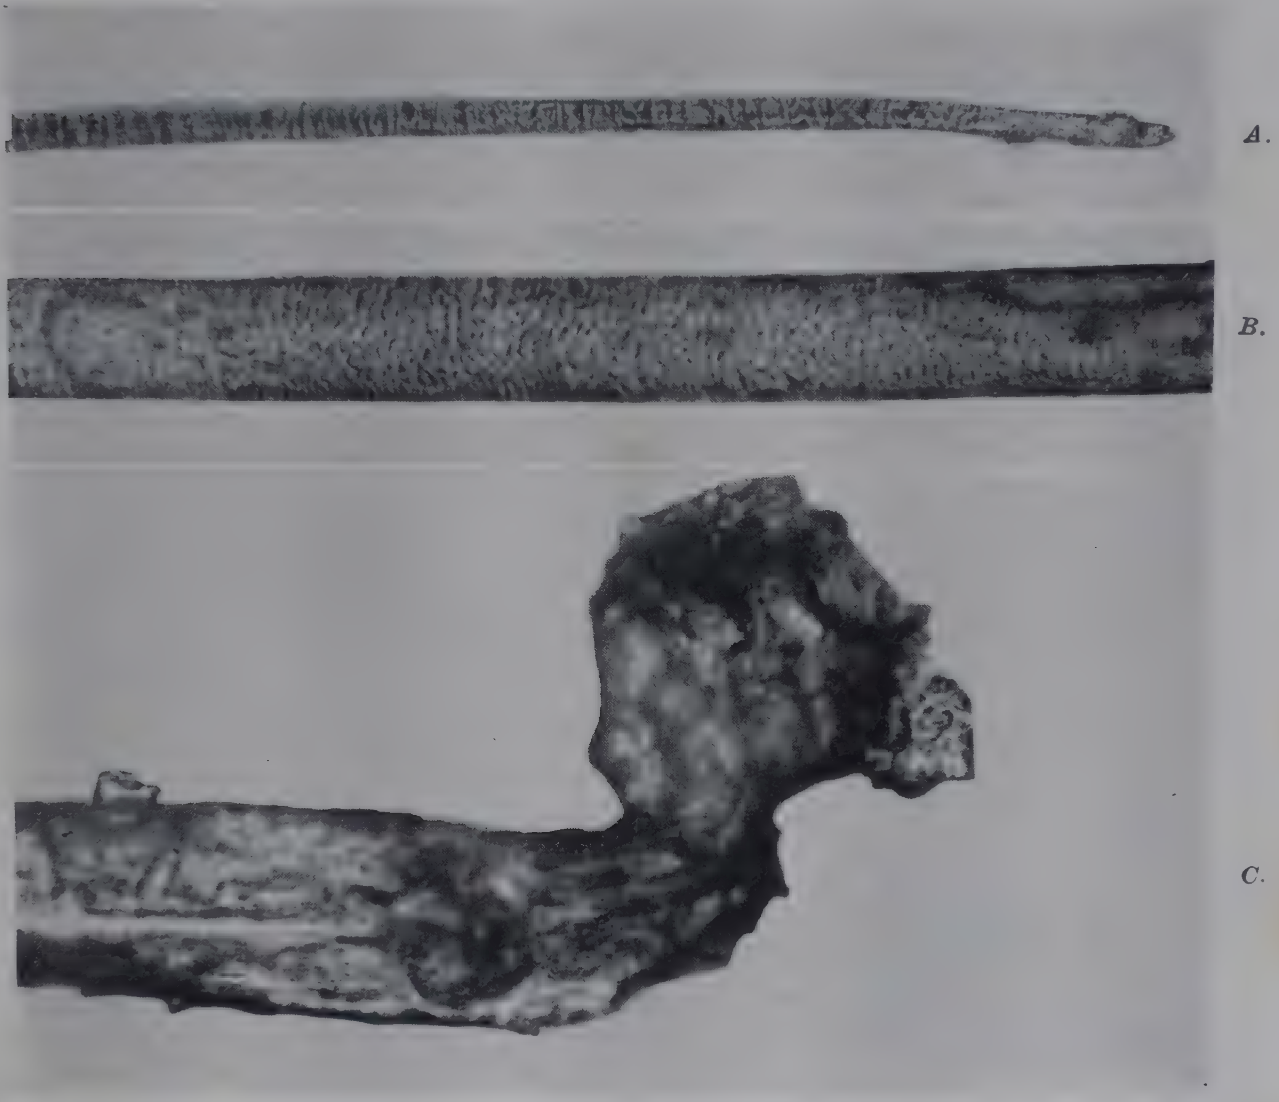

Fig. 673.—Photomicrographs of one of the hairs taken from the left arm of suspect C, Case 1. *A*, End of the hair. *B*, Middle portion of the same hair. *C*, Root of the same hair. (Courtesy Dr. Israel Castellaños.)

It may be concluded that microscopic, chemical, and bacteriologic study of hair offers a fertile field of criminal investigation. From Castellaños' experience of over fifteen years he has found, on numerous occasions, that when the usual investigation had failed and the criminal seemed about to be freed, he was able, from a few hairs which he had obtained in some cases weeks after the tragedy, to identify the persons involved in the crime and to deliver the guilty to justice.

In a personal communication, May, 1947, Dr. Castellaños furnished the author with records taken from his own files of cases in which the identification of hair contributed an important part to a medicolegal procedure.

Case 1.—In Louisiana, the screen door of a camp hut was found broken. Investigators found a hair caught in the broken screen wires and, using the necessary precautions, took it for examination. Specimens of hair were also taken from suspected persons, those near the camp hut during the night. These were submitted for comparison.

The hair taken from the slit in the screen door was labeled ''Exhibit A'' (see Fig. 671 *A, B, C*). Those from the two suspects were labeled, respectively, ''Exhibit B'' and ''Exhibit C.'' Examination of Exhibit ''A'' established:

1. That said hair is human hair.
2. That it came, not from the head, but from an extremity.
3. The color of the hair is light blond.
4. The free end of this hair appeared to have been cut transversely by an edge which was rather thick and not extremely sharp. If the hair had been cut by a very sharp edge, the free end would show a straight, clean cut instead of the jagged cut as seen in Fig. 671, *A*.
5. Examination of the full length of this hair revealed that the stem was not injured or compressed, since all of its elements were intact. The regularity of the hair and the integrity of the cuticula can be seen in Fig. 671, *B*. The diameter varied from 22 to 56 microns.
6. That the root of this hair presented all of the characteristics found in hairs which have been pulled out, as is seen in Fig. 671, *C*.

Examination of Exhibits ''B'' and ''C'' showed:

1. That these are also human hairs taken from the extremities.
2. That Exhibit ''B'' comprised nine hairs the length of which ranged from 8 to 28 millimeters.
3. That Exhibit ''C'' comprised five hairs the length of which ranged from 11 to 27 millimeters.
4. That the diameter of the hairs in Exhibit ''B'' varied from 14 to 66 microns.
5. That the diameter of the hairs of Exhibit ''C'' varied from 12 to 134 microns.
6. That the hairs taken from Exhibit ''B'' were light like those of Exhibit ''A,'' while the hairs taken from Exhibit ''C'' were darker or pigmented.
7. That the similarity of color of the hairs of Exhibits ''A'' and ''B'' was clearly visible, and microscopic comparison proved that the tone or chromatism of both exhibits was identical.
8. That while the disparity between Exhibits ''A'' and ''C'' was clearly visible to the naked eye, microscopic comparison proved the chromatic discordance between these exhibits.
9. That through macroscopic and microscopic examination, and the micrometric measurements taken of the nine hairs sent as Exhibit ''B,'' their anatomic structure, characteristics of cuticula and outer covering, the nature of the medullary structure, the tone and arrangement of pigmentation, proved that they were identical to those of Exhibit ''A.''
10. That through all of the aforementioned anatomic details it was proved that the five hairs sent as Exhibit ''C'' were completely different from these of Exhibit ''A.''
11. That all the scientific observations made proved that all the macroscopic, microscopic, anatomic, metric, and chromatic characteristics found in Exhibit ''B'' are also found in Exhibit ''A,'' while the contrary is true of Exhibit ''C.''
12. That all these data coincided to establish the fact that the hairs taken from the left arm of Suspect No. 1 were exactly the same as those taken from the hair found in the slit in a screen door in the rear entrance to a camp hut. Fig. 674 shows that the hair of Exhibit ''A'' coincides exactly with that of Exhibit ''B'' as registered by examination with the Spencer comparison microscope.

CASE 2.—A man was struck and killed by a motor vehicle. A passenger bus had been seen in the vicinity at about the time the man was killed. The driver of this bus was questioned by the police. He stated, under questioning, that he had felt a slight jar at about the place where the body had been found. It was quite dark. He had stopped his bus, looked around and, finding nothing wrong, had driven on.

An examination of the bottom of the bus revealed the presence of one strand of hair and a small fragment of what appeared to be human tissue.

Later a quantity of hair was taken from the dead man's head for comparison.

Castellaños received two specimens marked, respectively, ''Victim'' and ''Questioned.'' The envelope marked ''Questioned'' contained the tiny fragment seen in Fig. 675.

This tiny fragment, when placed upon slides, showed two objects, the details of which may be noted in Fig. 676, *A* and *B*.

The dirt was removed from the small organic fragment by washing it in saline solution which does not alter the anatomic structure or the color. The cleansed fragment was then prepared for microscopic examination, which revealed that the fragment was connective tissue, as seen in Fig. 677. The preliminary microscopic examination revealed that the material clinging to the small fragment was hair and not fiber.

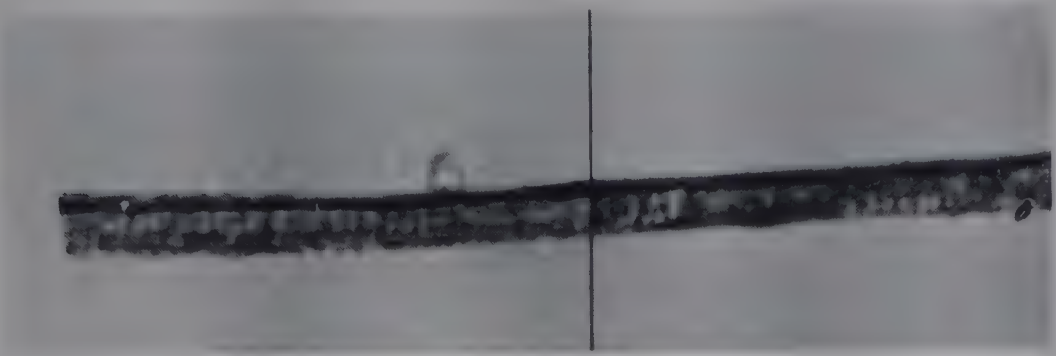

Fig. 674.—Photomicrographs of Exhibit "A" and "B," Case 1, as seen under the Spencer comparison microscope. (Courtesy Dr. Israel Castellaños.)

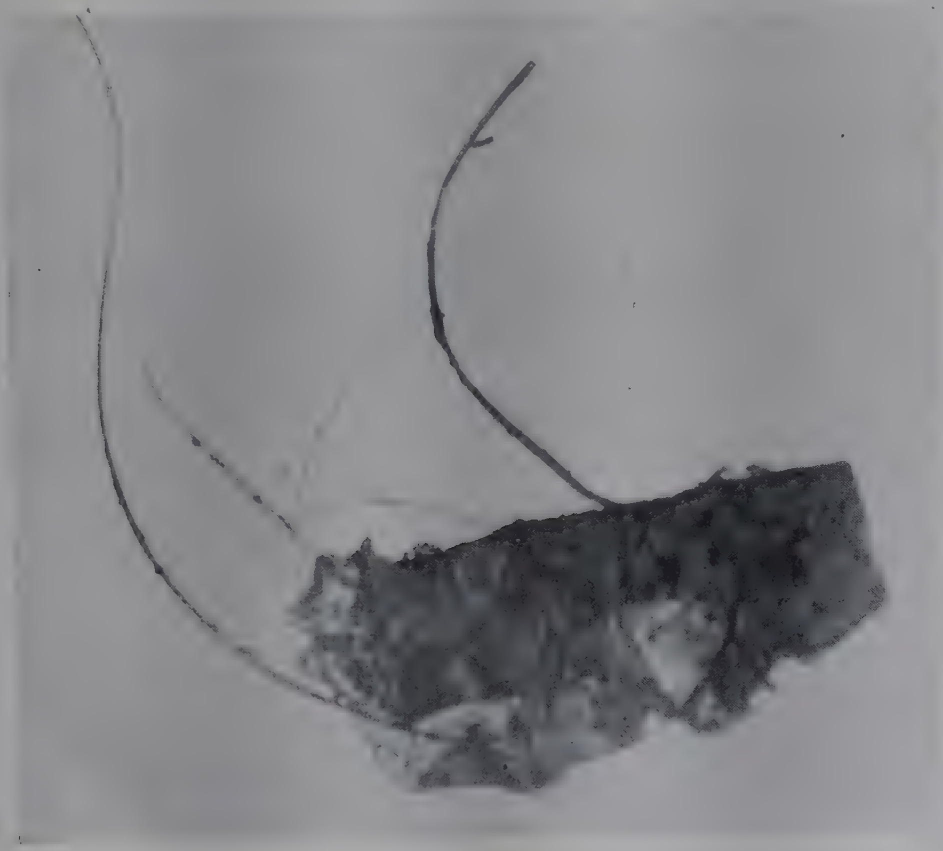

Fig. 675.—Tiny fragment contained in envelope marked "Questioned," Case 2. (Courtesy Dr. Israel Castellaños.)

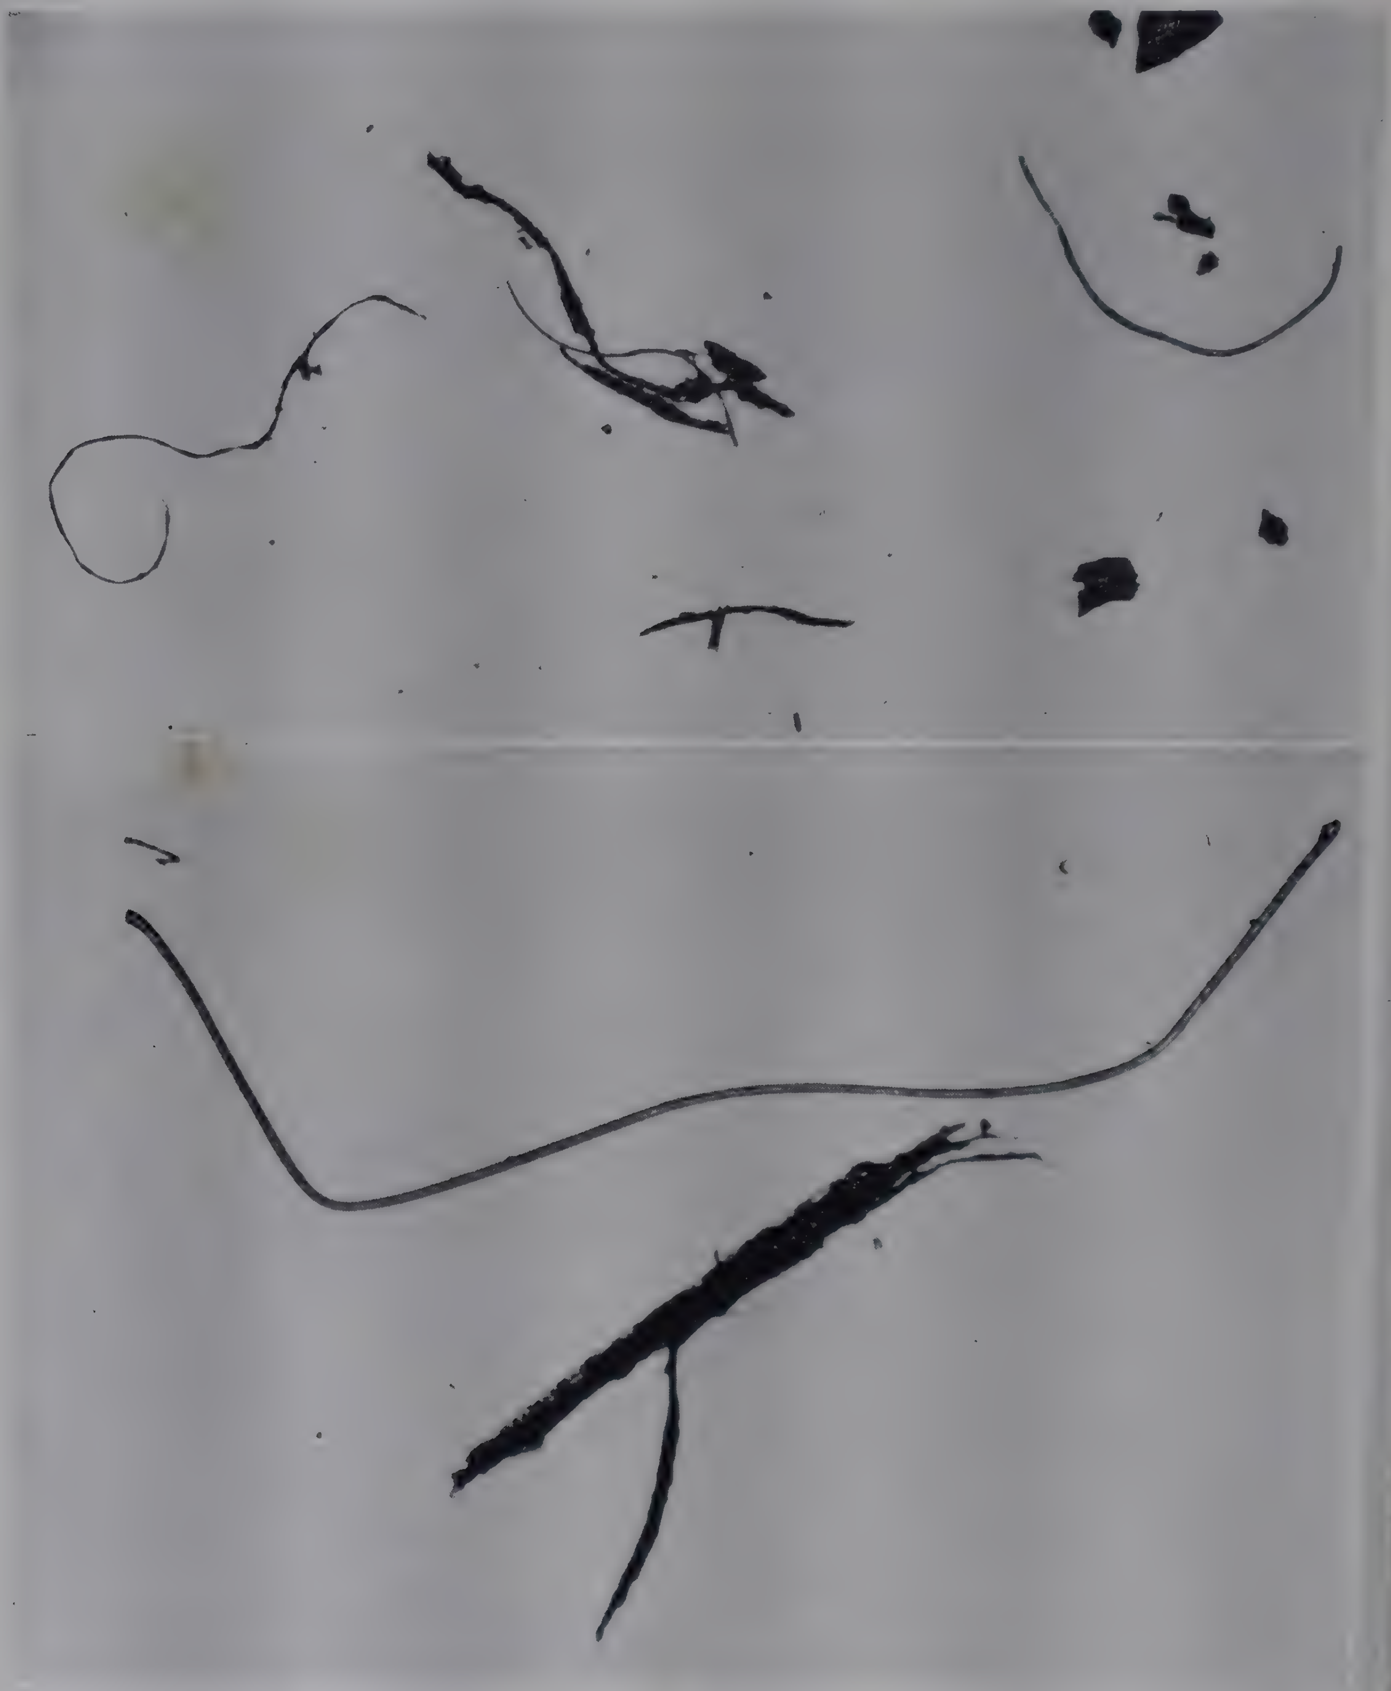
As can be seen in Fig. 676, *A* and *B*, the hairs which were clinging to the fragment were dirty. Before they could be submitted to complete anatomical examination, they were thoroughly cleansed in saline solutions. Saline solutions make not the slightest alteration in the structure or coloring of hair. These hairs, removed from the connective tissue, were 1 to 2 cm. long and were arched.

The hairs terminated sharply or in a point. The stem or body of the hairs was bruised, crushed, or broken. Fig. 678 shows a crushed portion on the right-hand side. There are portions or fragments, however, in which the structure is normal, as seen in Figs. 679 and 680, *A* and *B*.

The hairs removed from the small piece of connective tissue were examined under natural and transmitted light and classified according to the Bertillon chromatic classification as "light brown."



A.

B.

Fig. 676.—*A* and *B*. Contents of envelope marked "Questioned," same as Fig. 675. (Courtesy Dr. Israel Castellaños.)

The cuticula of these hairs, especially in the stem or body, was definitely imbricated. The end, which is the portion opposite to the root, was disintegrated; parts were lacking so that the cortex was exposed. Such disintegration shows that these hairs had been altered mechanically by repeated friction and crushing. The stem of one of the hairs showed a green-stick fracture, in which the body of the hair is split open. The medulla was disunited in some regions and in others it was not visible but showed a granular airlike network.

The examination of the diameters of the shortest hair, approximately one centimeter long, showed: maximum diameter, 98 microns; minimum diameter, 17 microns; average diameter, 56.1 microns; medullary index, 0.25.

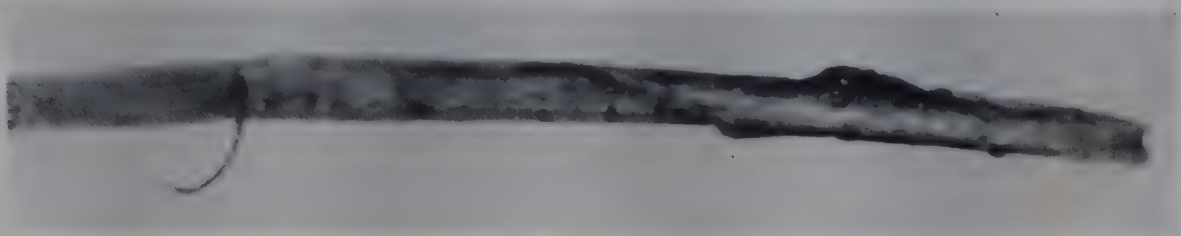


Fig. 677.—Enlargement of fragment (Fig. 676), which reveals it as connective tissue. (Courtesy Dr. Israel Castellaños.)

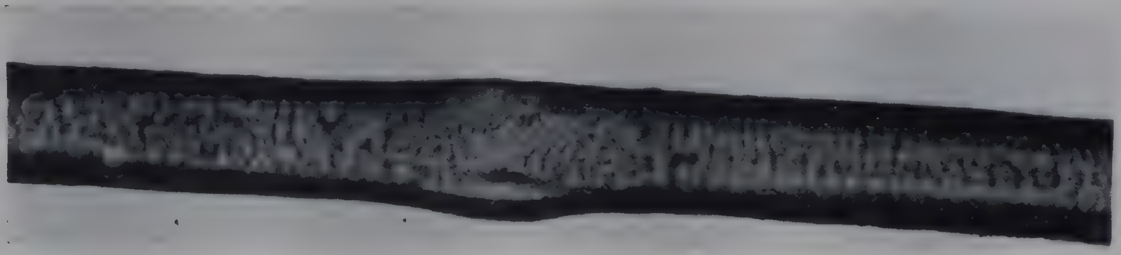

Fig. 678.—Body of hair showing crushed portion on the right-hand side. Case 2. (Courtesy Dr. Israel Castellaños.)

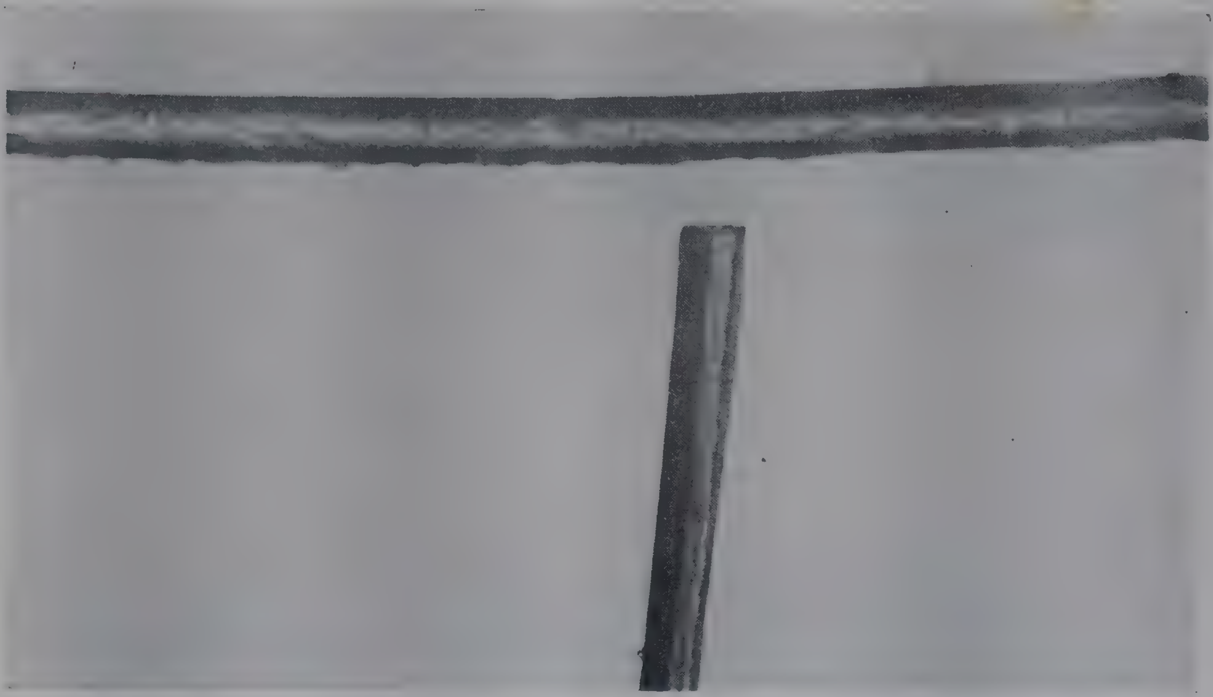

Fig. 679.—Portions of fragments revealing normal hair structure. Case 2. (Courtesy Dr. Israel Castellaños.)

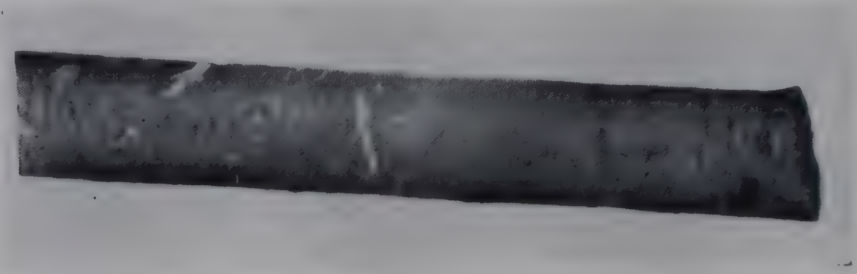
Measurements of diameters of the longest hair, approximately two centimeters long, showed: maximum diameter, 98 microns; average diameter, 56.1 microns; medullary index, 0.25.

The hairs of the "Victim" were light brown according to the Bertillon chromatic scale. Since all of these hairs had been cut, none of them showed the root. These hairs had a definitely imbricated cuticula. On some it was torn, as seen in Fig. 680, *A*, but there were large portions in which the hair was perfectly normal.

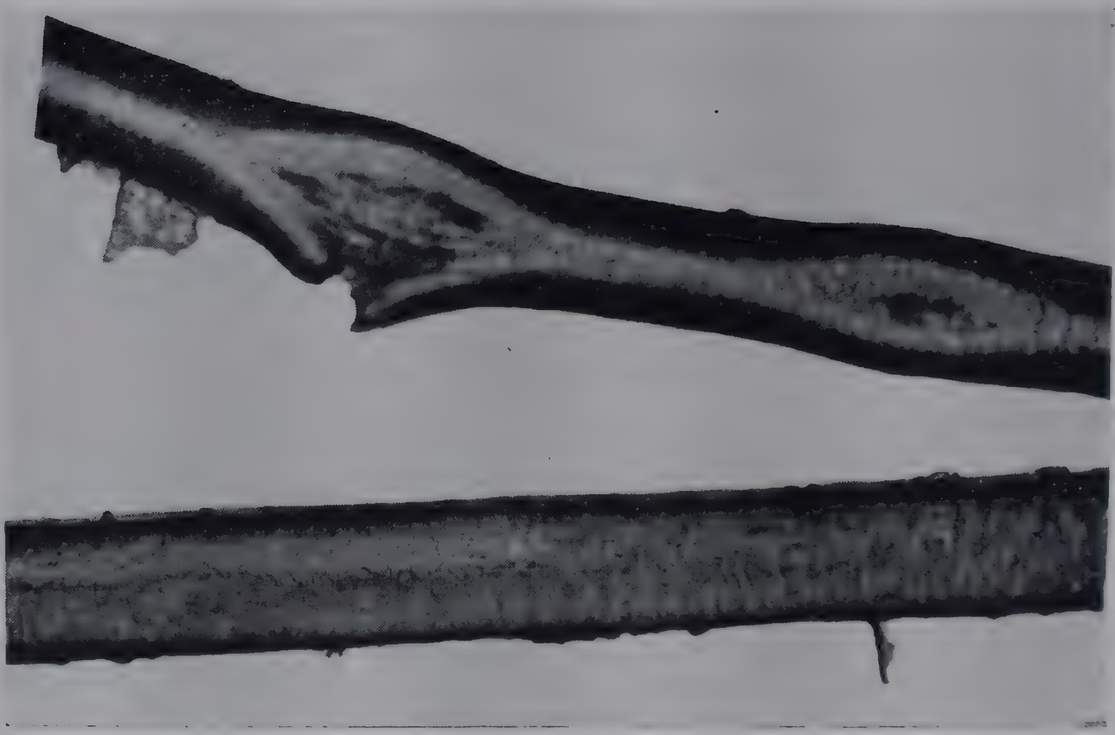
As seen in Figs. 680, *B* and 681, some of the hairs were crushed and broken, thus showing enormous mechanical action. There are large portions, however, in which normal anatomical structure can be observed.

Diameters of the hair coming from the "Victim" were: maximum, 73 microns; minimum, 17 microns; average diameter, 41.5 microns; medullary index 0.23.

The medulla of these hairs was disunited in some regions and invisible in others



A.



B.

Fig. 680.—*A*, Hair showing torn cuticula. *B*, Hair showing green-stick fracture of the stem. Case 2. (Courtesy Dr. Israel Castellaños.)

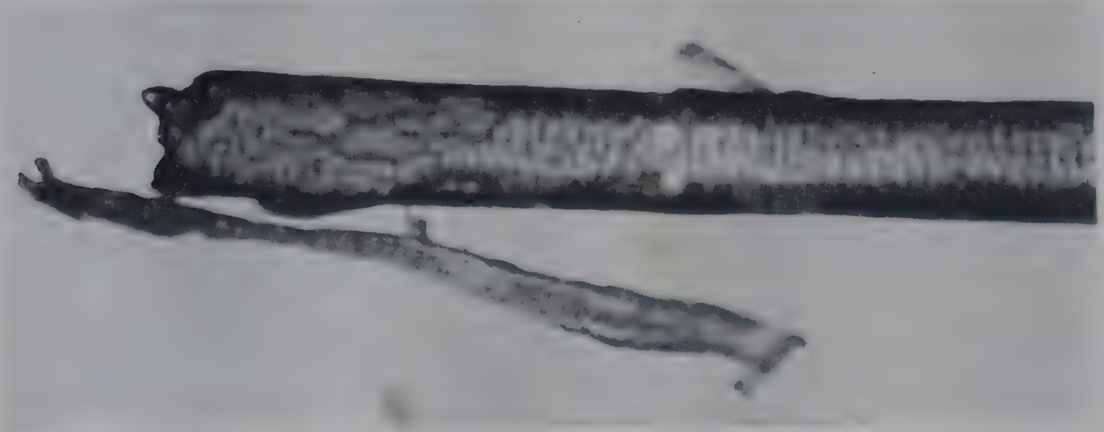


Fig. 681.—Hair which has been crushed and broken, showing mechanical action. (Courtesy Dr. Israel Castellaños.)

In comparing the results of the examinations of hairs marked "Questioned" and "Victim," there can be noted a marked resemblance in the type of the cuticula cells (definitely imbricated) and the pigmentation or coloring. Furthermore, the lesions in the hairs of the "Questioned" are similar to those in the hairs from the "Victim."

Diameters are not the same in the two specimens, but such discrepancies are found when the hairs come from different regions of the body. If hairs from different regions are compared, measurements are of secondary value. Anatomical characteristics, color, pigmentation, the morphologic type of hair, etc., are the decisive factors in making the diagnosis. In Case 2 all details are alike except the measurements.

The fragment of connective tissue was too small to be submitted to all the biological tests. There was not enough to test it serologically to determine whether it was of human or animal origin. It was found with human hairs clinging strongly to it, and the histologic examination does not deny that it is of human origin, so that it can be assumed to be human hair.

Investigations of hairs are always slow but such investigations are extremely important.

CHAPTER XV

TOXICOLOGIC TECHNIC[1]

A complete scientific investigation into the cause of death is a most important civic function and community responsibility. For this investigation, there should be properly trained personnel and well-equipped laboratories.

A toxicologic laboratory as an integral unit of an organization devoted to this subject aids materially in determining the nature and cause of death in many otherwise unsolved cases; helps place the responsibility for industrial poisoning; and aids in ruling out the possibility of foul play in supposedly apparent cases of drowning, carbon monoxide poisoning, and the like.

To illustrate these various possibilities, a few case histories are cited briefly.

(a) A young husband returned home unexpectedly one week-end to find that his wife had been unfaithful to him. Since this was not the first offense, he informed his wife that he intended to leave her and sue for divorce. Hotel accommodations were difficult to find; his wife thus had little trouble in persuading him to remain at home. She succeeded in convincing him that they should have one last celebration before he brought suit for divorce. They made the rounds of the taverns, returning to their home in a somewhat inebriated condition. Shortly after returning to his home, the young man died. Although it was not the primary cause of death, alcoholic intoxication appeared to be present. Autopsy and chemical analysis revealed the presence of large quantities of chloral hydrate. The wife was confronted with this startling information and later confessed that she had poisoned her husband. She gave as her reason his constant determination to obtain a divorce.

(b) An elderly couple were found dead in their hotel room. Autopsy revealed very little that might point to the cause of death, and chemical analysis of the organs was ordered. This analysis failed to reveal anything other than faint traces of cyanide. With this clue, a special examination was made of the lung tissues. Cyanide was revealed in large quantities. The hotel management was confronted with this information. They admitted, under questioning, that the room directly below this couple had been fumigated with cyanide gas, but that the management had failed to order the other apartments vacated, as required by law. They had, by their negligence, contributed directly to the death of these two elderly people.[2]

(c) A young woman was found dead in bed. She was lying in a natural position. All the gas jets in her home were opened. A cursory examination might have suggested carbon monoxide suicide. However, a skilled examiner noted that there were certain peculiarities about the case, and a toxicologic analysis was requested. Examination revealed no evidences of carbon monoxide or other poisons. The husband was questioned and later admitted that he had forced his wife's head onto the pillow and had killed her by asphyxiation. He had then placed her on her back, turned on all the gas jets, and left home for work.[2]

These few cases are cited as an example of the importance of toxicologic examination in death from unknown causes, and to point out the responsibility which the community must assume in the pursuit of justice. These crimes might have remained undetected had no toxicologic investigation been made.

---

[1] This chapter has been revised under the direction of Sidney Kaye, formerly Toxicologist to the Research Laboratory of the St. Louis Police Department; at present Toxicologist, Office of Chief Medical Examiner, Commonwealth of Virginia.

[2] A. O. Gettler: Why the Coroner System Has Broken Down, National Municipal Review 13: 10, Oct., 1924.

To date only a few communities in the United States have a medical examiner system to make routine thorough investigations into the cause of death. Such systems are to be found in New York City, Boston, Newark, Nassau County, Cleveland, Los Angeles, Cincinnati, and the States of Maryland, Virginia, Connecticut, and Vermont.

Investigations do not always reveal results favorable to the prosecution as is illustrated in the following case:

A young man was admitted to a hospital suffering from injuries sustained in an automobile accident. Since he was in a serious condition, blood transfusions were indicated and he was given a number of transfusions. Several days later the patient died, and an autopsy was performed. This revealed evidences of nephritis, and a toxicologic analysis was requested. None of the common poisons were found except a faint trace of mercury in the kidneys. All tests for mercury gave specific reactions. These findings were disconcerting because the young man had at first shown signs of recovery, he had the will to live, and had no known enemies; nor did there appear to be any source of error in medication. A thorough investigation of the treatment administered to the patient was ordered. This revealed that the patient had been given two blood plasma transfusions, both containing Merthiolate as a preservative. Merthiolate is sodium ethyl mercuri-thiosalicylate. The presence of Merthiolate in the plasma immediately solved the mystery of the origin of the mercury.

GLOSSARY

Toxicology is the science of poisons and their properties; isolation, purification, identification, and quantitative determination from biologic material; the lethal or fatal dose; the action upon living tissue; and the proper treatment necessary to counteract this action.

A **poison** is any substance which, without acting mechanically, causes a disturbance of body functions, injury, disease, or death, when introduced into a living organism and when absorbed in sufficient amount.

A **potent poison** is usually defined as any substance which is likely to destroy human life or seriously injure health when applied in quantities of less than 5 c.c. or 5 grams.

Minimum lethal dose is the smallest quantity of a poison which, when actually absorbed into the system, has been proved to be fatal.

GENERAL FACTS CONCERNING TOXICOLOGIC ANALYSIS

Toxicologic analysis of biological material must be performed by experts. It should be undertaken only by those with specialized training and experience, since the life and liberty of others may depend upon the results of these investigations. Rough qualitative testing, sometimes attempted by those with little or no experience in forensic chemistry, is most unwise, for at best it consumes irreplaceable material and at worst it may lead to miscarriage of justice.

Qualitative testing of poisons must always be performed with the same care and accuracy used in all micro-quantitative procedures.

Before making an analysis, a careful study of the complete history of the case should be made. This history should include first appearance of symptoms before death; symptoms occurring after taking last food or drink; nature and intensity of such symptoms, whether there was vomiting, deep sleep, tingling of skin, throat, convulsions or twitching of the muscles, delirium, dyspnea, contraction or dilatation of pupils, visual or auditory effects, if any.

Patient's symptoms and other clues may be of great help to the toxicologist in ruling out large groups of poisons which, in view of the history, would not likely be present. Close cooperation with the physician who last saw the patient, and with the pathologist who performed the autopsy and examined the tissues, is solicited.

SYMPTOMS SHOWN BEFORE DEATH

Many diseases cause symptoms which are similar to those caused by poisons. Differentiation between clinical symptoms and symptoms due to poisons is often difficult unless a very careful study is made. It must be kept in mind that unusual symptoms may be produced by a variety of poisons, just as unusual symptoms may occur in disease. The list of Webster[1] below gives the poisons and diseases which produce similar symptoms.

Vomiting, Purging, and Abdominal Pain.—

Poisons: Heavy metal salts such as arsenic, antimony, barium, copper, mercury, zinc, corrosive acids and alkalies, halogens, aconite, cantharides, croton oil, digitalis, gelsemium, phosphorus, phenols, wood alcohol, veratrum, and muscarine

Diseases: Gastritis and enteritis, gastric and duodenal ulcer, cholera, uremia, acidosis, onset of many infectious diseases, early pregnancy, and brain tumor

Convulsions:

Poisons: Ammonium salts, aspidium, brucine, camphor, santonin, aconitine, picrotoxin, cyanides, and strychnine

Diseases: Uremia, eclampsia, tetanus, epilepsy, many acute diseases of the cerebrospinal system, especially meningitis

Coma:

Poisons: Opium, morphine, heroin, barbiturates, chloral, sulphonal, trional, paraldehyde, chloroform, ether, cyanide, carbon monoxide, carbon dioxide, atropine, nicotine, hyoscine, alcohols, phenols, scopolamine

Diseases: Uremia, eclampsia, acidosis, cerebral hemorrhage, cerebral embolism and thrombosis, brain injuries, epilepsy, and other brain diseases

General or Partial Paralysis:

Poisons: Cyanides, carbon monoxide, carbon dioxide, botulism

Diseases: Apoplexy, brain tumor, meningitis

Dilatation of the Pupils:

Poisons: Belladonna and its derivatives, hyoscyamine, stromonium, gelsemium, cocaine, nicotine

Diseases: Those causing optic atrophy, sympathetic irritation, or oculomotor paresis

Contraction of Pupil:

Poisons: Derivatives of opium, physostigmine, pilocarpine, muscarine

Diseases: Tabes and certain other diseases of the central nervous system

Slow Respiration:

Poisons: Opium derivatives, carbon monoxide, hypnotics

Diseases: Uremia, compression of brain from any cause, for example, hemorrhage

---

[1] Peterson, F., Haines, W. S., and Webster, R. W.: Legal Medicine and Toxicology, ed. 2, Philadelphia, 1923, W. B. Saunders Co., Vol 2.

Rapid Respiration:
Poisons: Atropine group, cocaine, carbon dioxide
Diseases: Acute respiratory diseases, lesions of medulla, hysteria

Delirium:
Poisons: Atropine group, cocaine, alcohols, camphor, solanine, marihuana
Diseases: Epilepsy, insanity, delerium tremens, organic brain diseases, such as meningitis, encephalitis; nephritis

Dyspnea:
Poisons: Strychnine during the convulsions, cyanide, carbon monoxide, carbon dioxide, easily volatile organic liquids
Diseases: Those of cardiac and respiratory systems, lesions of medulla and vagus

Cyanosis:
Poisons: Nitrobenzene, aniline, acetanilide, opium, chlorates, amyl nitrite
Diseases: Same as dyspnea, prolonged convulsions due to any cause, by producing cardiac embarrassment or dilatation

Many of these clues and leads may prove of great value as ante-mortem symptoms.

ADDITIONAL GENERAL CLUES AND "LEADS" ANTE-MORTEM

Color of the Urine.—

Dark green: phenol, salol, creosote, resorcinol
Red: antipyrine, trional
Brown or black: pyrogallol
Yellow: phenacetin, picric acid. Santonin changes from bright yellow to scarlet upon the addition of sodium hydroxide.

Breath, Odor.—

Phenol: phenolic
Creosote: phenolic
Ether: ethereal
Chloroform: sweetish
Cyanide: bitter almonds
Alcohol: alcoholic
Phosphorus: garlic
Chloral hydrate: pears
Nitrobenzene: shoe polish
And many others

Miscellaneous.—

Saponins: foam persists upon shaking the urine specimen
Quinine, acetanilid, salicylates: depress the heat centers and lower body temperature
Strychnine: may cause tingling of the skin; it increases sensitivity to sound
Salicylates: may cause buzzing of the ear; *quinine* may cause ringing of the ear
Pulse, in acute poisoning: may be quick and feeble due to shock

CLUES AND LEADS FOUND AT AUTOPSY*

Gastrointestinal Tract.—Inflammation, erosion, hemorrhage, ulceration, perforation:

Mineral acids, caustic alkalies, ammonia, heavy metal salts, sodium fluoride, phosphorus, halogens, oxalic acid, aconite, croton oil, cantharides, gelsemium, muscarine, phenols, veratrum, and wood alcohol

---

*Based largely on descriptions given by A. O. Gettler in his numerous articles in the literature.

Inflammation of indefinite severity, and necrosis severe.

DCP, AMS, March 1944

Odor of Gastric Contents.—Volatile substances having specific odors:

Alcohol, benzene, chloroform, cyanide, ether, nicotine, nitrobenzene, opium, phenol, Lysol

Colored Materials in Stomach.—

Grayish-white undissolved material: arsenic oxide, remnants of tablets, etc.
Green or blue coloration: copper salts and dyes added to fluoride and strychnine
Yellow: picric acid, nitric acid
Black: sulphuric acid, oxalic acid
Luminous particles (in the dark): phosphorus
Pink to violet: permanganate
Blue or brown: iodine
Bright red: Mercurochrome

Skin Discoloration.—

Icteric tint: phosphorus, arsenic, alcohol
Cherry red or pink: carbon monoxide, cyanide
Brown, chocolate color: nitrobenzene, chlorates, acetanilid
Blue lividity: carbon dioxide
Dark blue-gray: silver (chronic)
Blue: iodine
Deep brown: bromine
Yellow: nitric acid and picric acid
Bleached: phenols

Gums, discoloration, usually in chronic poisonings.—

Lead, copper, bismuth, mercury, silver

Blood, Color of.—

Chocolate color: nitrobenzene, acetanilid, chlorates
Cherry red or pink: carbon monoxide, cyanide

CLASSIFICATION OF POISONS

Classification of poisons may be made on the basis of (a) their origin, and (b) the effects produced upon the body.

Another classification of poisons is: (1) corrosives, (2) irritants, and (3) neurotics. A better classification is (1) inorganic poisons, (2) gaseous poisons, (3) alkaloidal poisons, (4) nonalkaloidal organic poisons, and (5) food poisons.

The toxicologic investigation of viscera from autopsies where poisons are suspected is a very important part of laboratory procedure. It should not be undertaken by anyone not well-qualified to do this work. It must be remembered that the results of toxicologic examinations are later to be presented in court; one must be prepared to qualify as an expert toxicologist in order that his findings be accepted by a court of justice.

This chapter is not intended to represent a complete treatise on the subject of toxicology; rather it is a working outline. For complete details the reader is referred to standard textbooks on this subject.

There are certain suggestions regarding the choice and handling of specimens for toxicologic analysis which must be considered.

SUGGESTIONS FOR HANDLING OF SPECIMENS

1. **The Quantity of Organs Required.**—The analyst is often hampered on account of lack of material. During the autopsy it is just as easy to procure large samples as small ones. Therefore the pathologist should take out gen-

erous portions of the organs when chemical analysis is to be made. In the case of the stomach, the entire organ, together with all of its contents, should be furnished. This can be accomplished by tying a ligature around the cardiac end and another around the pyloric end. The organ is then removed and placed in the proper receptacle. Portions of the intestines about two feet long of both large and small bowel should be taken. One-fourth of the liver is a proper sample. In the case of the kidneys and other organs, the entire organ should be taken.

2. **Containers.**—Fruit jars are very satisfactory, provided they are scrupulously cleaned. This means chemical and bacteriologic cleanliness. They may be chemically cleaned by washing them thoroughly in a bichromate-acid solution followed by large quantities of distilled water. This may be followed by dry heat sterilizing at 170° C. for two hours. Each organ should be placed in a separate container and should be labeled, giving the date, the place, the name of the deceased, and the name of the autopsy operator. Before each organ is chemically examined, it should be accurately weighed and the amount noted.

3. **Refrigeration.**—If possible the organs should be kept in a refrigerator since those poisons which decompose will do so much more slowly in the cold.

4. **Embalming.**—With a fresh corpse it is much better to secure the samples before the body is embalmed. Certain poisons, such as cyanides, are impossible to analyze after formaldehyde is introduced into the body. If the body has been embalmed, determine, if possible, whether the poison found was in the embalming fluid. Some embalming fluids may contain poisons. Formaldehyde interferes with the identification of methyl alcohol, alkaloids, etc., in addition to hardening the tissue and making poison extraction extremely difficult.

5. **Preservatives.**—No preservative should be added to the organs. Blood for alcohol determination is an exception. Here one adds sodium fluoride, 200 mg. for each ounce of blood.

6. **Speed in Transmission.**—Since several of the poisons are destroyed after a time, it is best to send the organs as soon as possible. However, some poisons, such as arsenic and mercury, are not affected by standing in contact with tissues and these may be found many years after burial, if they were originally present.

7. **Precautions Against Tampering With Material for Analysis.**—In analyses, reports of which may be used in court, it is absolutely necessary to show that no one but the pathologist and analyst, or some other responsible person, had access to the material. The parts should be transported from the autopsy room to the laboratory by the pathologist himself, or by some responsible person, receiving a receipt for them. The receptacles containing the specimens should be sealed and placed under lock and key pending investigation, and during the tests.

It will be of material assistance to the chemical expert to have a brief description of the results of the autopsy. Often the macroscopic findings in the body will give the toxicologist a clue as to the particular poison to be looked for.

In the case of exhumed bodies which have already undergone decomposition, it is well to remember that poisons from the coffin may contaminate the body. It is then necessary to make a chemical analysis of the material from which the coffin is made. In cases where the body has been buried for a long time, and where the coffin has undergone decay, it is also necessary to take parts of the surrounding earth for examination.

For a complete chemical analysis the following suggestions are offered for packing and transportation of viscera:

Vessel No. 1: Stomach opened up with its contents.
Vessel No. 2: Large intestine opened up with contents.
Vessel No. 3: Small intestine opened up with contents.
Vessel No. 4: Liver, kidneys, and spleen. If possible, each kidney should be put in a separate vessel.
Vessel No. 5: Urine.

Where volatile poisons are suspected:

Vessel No. 6: Brain and organs of the chest.

Where it is thought a bacteriologic food poisoning is present:

Vessel No. 7: A doubly tied-off piece of small and large intestine.
Vessel No. 8: Sample of blood.
Vessel No. 9: Gall bladder tied off.

If there is a suggestion of the kind of poisoning present:

Vessel No. 10: Large amount of blood.

In carbon monoxide poisoning, we should examine preferably blood from the heart and the sinuses of the head.

There are a number of points relative to the chemical examination of suspected material in medicolegal cases that must be constantly borne in mind. Prior to necropsy, most cases to be investigated for evidence of poisoning will fall into one of three general categories (Maldeis[1]): category I, cases in which the cause of death has already been established and the nature of the poison determined; category II, where the evidence is such that poisoning is regarded as the probable cause of death; category III, cases in which there is so little information pertaining to the cause of death that poisoning is regarded as possible rather than probable. From the standpoint of the law it is not enough to establish the fact that a certain poison was present in the body of the decedent, although such information might be considered adequate in some instances from a medical standpoint. Further, it should be remembered that the identification of the kind of poison and the demonstration that death was due to that poison is only half of the chain of evidence essential to the administration of justice. The law is equally concerned with the acquisition of evidence relating to the identity of the person or persons through whose negligent or intentional act the poisoning occurred. The idea of probable poisoning may exist prior to the performance of the necropsy and this probability may rest on the unexpected and unobserved occurrence of death together with the finding of a suicide note or the finding of a poison that had been accessible either to the decedent or to someone who might have profited by his death. In suicidal poisoning the toxicologic search may be guided by information obtained as a result of searching the premises and belongings of the decedent. In the third category, cases come to autopsy with no positive evidence relating to the cause of death but in which poisoning is regarded as a possibility. Often the problem is settled by the finding at autopsy of some disease process which constitutes an adequate explanation of death. In some cases, however, the autopsy may fail to disclose the cause of death, and search for poisoning must be made. This search varies according to the exigencies of the situation and according to the facilities of the investigator for the conduct of toxicologic studies.

---

[1] Am. J. Clin. Path. 13: 165, 1943.

In addition to the material already catalogued for routine collection, Maldeis advises the following material should also be collected: all of the bladder urine; half of each of three vertebral bodies; and about 5 grams of hair.

Emphasis must be placed upon certain factors in toxicologic cases relative to reception of the specimens from the referring person if the toxicologist is not present at the autopsy. The exact time and date of arrival should be noted and recorded. The name of the person receiving the specimen should be recorded. The number of containers and the labelling of each should be recorded. The type of container and whether each is wrapped or sealed should also be recorded. Laboratory numbers should be given to all specimens immediately. The entire material should, after its reception in the consulting laboratory, be taken to the toxicologic laboratory and promptly placed under lock and key.

During the performance of the toxicologic investigation, all visitors should be excluded from the laboratory. The toxicologist must be able to certify in court that no one had access to the material while in his custody. In a case in St. Louis, a toxicologist was placed in an embarrassing position by being unable to complete his analysis for the reason that a porter in his laboratory had washed up the final residue of his extraction and also washed up the container with the original specimen.

It is interesting to note the problems which beset a toxicologist (Wittaus).

1. Was death due to poison?
2. Is there any chance for simulation?
3. Could there be poisoning without demonstration of the poison?
4. Which poison caused the symptoms before death?
5. Are the chemical substances recovered really the causative poison?
6. When extremely small amount of the poison is found, could this poisonous substance of such small amount cause death?
7. Could this substance have caused death?
8. Was the poison taken in sufficiently large quantity to cause death?
9. Was the poisoning suicide, accident, or murder?
10. Could the poisonous substance found have been used as a medicinal agent?
11. When and how was the poison taken?

12. Was the chemical substance found really taken by the subject intra vitam? Could another origin have existed?

13. Is the meat of poisoned animals poisonous for man?

14. Can one determine whether or not death by poison occurred in burned bodies?

TABLE 217.—MATERIAL BEST SUITED FOR ANALYSIS

SPECIMEN	MINIMUM AMOUNT NEEDED	POISON FOR WHICH BEST SUITED
Urine	All available	For most types of poisoning
Stomach	All available	For examinations in which poison is alleged to have been taken by mouth within a short time of death
Intestinal contents	All available	For poisons taken by mouth within one or two days before death
Blood	Approximately 100 c.c.	Barbiturates, cyanide, methemoglobin, carbon monoxide, sulfonamides, bromides, for the drowning test, alcohol determinations
Brain	500 grams	Volatile poisons, barbiturates, alkaloids, and acute alcoholism
Liver	300 grams	Heavy metals, barbiturates, fluorides, oxalate, sulphonal
Kidney	One kidney	Metals, especially mercury, sulfonamides
Bone	200 grams	Lead, arsenic, radium (especially chronic), and other radio-active substances
Lung	One lung	For inhaled poisons as proof of entry
Hair and fingernails	10 grams	Chronic arsenic poisoning
Muscle	200 grams	In most acute poisoning and when internal organs are badly putrified

ANTIDOTES[1]

An antidote is any agent which will remove or prevent the absorption of a poison. There are three types of antidotes: mechanical, chemical, and physiologic.

Mechanical antidote: Removes a poison or prevents its absorption

Chemical antidote: Acts chemically to form a nontoxic compound

Poisons are rendered nontoxic by formation of an insoluble compound, formation of a soluble nontoxic compound, or by oxidizing the poison

Physiologic: One whose action on the body is opposite to that of the poison

Symptoms of Poisons

Absorbed poisons quickly pass from the blood stream into the tissues of the various organs. The poison interferes with the normal functions of the organs and causes abnormal or pathologic symptoms. Poison is indicated if an individual suffers intense pain, becomes delirious, sinks into a stupor, has convulsions, or vomits freely, etc., after taking a drug or food, provided the symptoms are not caused by disease. Symptoms may vary with the amount of poison taken and absorbed, and with the length of time it remains in the body. Most poisons exhibit three stages of poisoning. Treatment varies with the degree or stage of poisoning.

---

[1] Compiled from the literature.

First Degree Poisoning

First degree poisoning is of brief duration. If the patient is observed in this stage, much of the poison is still in the stomach, and mechanical and chemical antidotes are employed.

Second Degree Poisoning

Second degree poisoning is the period in which marked symptoms are produced. These symptoms indicate the true nature of the poisoning. Physiologic antidotes are first administered in small and cautious amounts to counteract the original poison. Mechanical and chemical antidotes follow, to remove any residual poison still in the stomach.

Third Degree Poisoning

Third degree poisoning is the stage during which the poison produces the full effect upon the body. The vital organs are depressed, often to the point where function ceases and death follows. Physiologic antidotes and measures are used.

EMERGENCY TREATMENT FOR POISONING[1]

General Rules

1. Immediate action is necessary.

2. Call a physician.

3. Proceed at once to induce vomiting repeatedly except in those cases where poisoning is due to *strong acids* or to *strong alkalies.* The most commonly used *emetic* is that prepared by stirring one teaspoonful of powdered mustard in sufficient warm water to make a creamy paste. If mustard is not available a solution of 0.006 gram of potassium antimony tartrate (tartar emetic) in 25 c.c. of water can be administered; or warm salt water or even ordinary soap suds may be used; or zinc sulphate, 30 to 60 grains, in water.

4. Where the specific antidote is not indicated or where the nature of the poison is not known, administer the universal antidote described below.

5. In cases of poisoning by corrosive substances, the treatments described above may be followed by demulcent drinks to soothe the injured tissues. A convenient *demulcent* is made by dissolving 3 to 5 grams of dried egg albumin in a glass of cold water. The white of an egg or a glass of milk, or both, also are good demulcents. If none of these are available, administer a tablespoonful of mineral oil, or olive oil. Cream, flour, oatmeal gruel, or barley gruel are also fair demulcents.

6. Stimulate, if indicated, with appropriate agents; e.g., cardiac stimulation, respiratory stimulation; combat shock or collapse.

7. As a general rule, the patient should be given a purgative.

---

[1] Laboratory Emergency Chart, Fisher Scientific Co., and other sources.

Universal Antidote

Pulverized charcoal	2 parts
Magnesium oxide	1 part
Tannic acid	1 part

Keep dry until ready to use. Dose: one heaping teaspoonful in a small glass of warm water.

TREATMENT FOR SPECIFIC POISONS

(Swallowed, unless otherwise specified)

Acetone.—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer universal antidote.
3. Keep patient awake. Administer strong coffee, etc.

Acetylene.—

See ''Carbon Monoxide Treatment.''

Acids, Mineral.—

1. Do **NOT** induce vomiting. Do **NOT** use stomach pump!
2. Administer magnesium oxide, milk of magnesia, or lime water immediately. Repeat the dose at short intervals. Administer milk or white of egg, or 5 grams of egg albumin in cold water, or other demulcants. Do **NOT** give carbonates.
3. After the acid appears to be neutralized, administer a tablespoonful of mineral oil until 4 doses, 15 minutes apart, have been given.
4. Combat collapse and shock by stimulation.

Alcohols, Methyl, Amyl, Etc.—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer milk or white of egg, or 5 grams of egg albumin in cold water.
3. Combat collapse: Keep patient warm, give strong coffee, aromatic spirits of ammonia, or digitalis or strychnine.
4. If patient is not breathing, or if he is breathing with difficulty, apply artificial respiration at once. AFTER TREATMENT: Plenty of fresh air, ½ gram sodium bicarbonate in water every 2 or 3 hours, cathartic.

Aldehydes (Formaldehyde, etc.).—

1. Artificial respiration, if necessary.
2. When patient is conscious, administer repeated doses of 1 to 2 c.c. of 1 per cent ammonium hydroxide solution. Follow by alkaline mineral water or 5 per cent solution of sodium bicarbonate.
3. Administer white of an egg, milk, or barley water, or 5 grams of egg albumin in cold water.
4. Combat collapse: Keep patient warm, give strong coffee, aromatic spirits of ammonia.

Alkalies, Caustic.—

1. Do **NOT** induce vomiting, and do **NOT** use stomach pump.
2. Administer 5 per cent acetic acid or vinegar or lemon or grapefruit juice until alkali appears to be neutralized.
3. Administer white of egg, milk, or 5 grams of egg albumin in cold water, or other demulcents.

Ammonia Gas.—

See ''Corrosive Gases.''

Aniline and Derivatives.—

1. Artificial respiration, if necessary.
2. When patient is conscious, induce vomiting. See ''Poisoning, General Rules.''
3. Administer 5 per cent solution of acetic acid.
4. Combat collapse: Strychnine, atropine, or digitalis by hypodermic injection as a stimulant.

Antimony Compounds.—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer strong tea or 2 grams of tannic acid in a glass of warm water.
3. Administer milk or white of an egg or 5 grams of egg albumin in cold water, or other demulcents.
4. British anti-lewisite (BAL) intramuscularly.

Arsenic Compounds (White Arsenic, Arsenates, Arsenites).—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer a solution of 4 grams of sodium thiosulphate in 450 c.c. of water.
3. Administer a tablespoonful of milk of magnesia or a glass of milk or the white of an egg or 5 grams of egg albumin in cold water.
4. Combat collapse: Strychnine, atropine, or digitalis as a stimulant by hypodermic injection.
5. Follow treatment with one ounce of castor oil.
6. British anti-lewisite (BAL) intramuscularly.

Barbital Group (Amytal, Pentothal, Seconal, Nembutal, Phenobarbital, etc.).—

1. Irrigate stomach with tannic acid solution followed by water.
2. Give stimulants, strychnine hypodermically; or benzedrine sulphate ⅔ grain intravenously, then ⅓ grain every hour; the physician must keep careful watch over the patient.
3. High colonic irrigation. Diuretics, catheterization of bladder, and artificial respiration with oxygen when necessary.

Barium Compounds.—

1. Induce vomiting. Mustard emetics or gastric lavage followed by dose of Epsom salts.
2. Administer a solution of 4 grams of sodium thiosulphate in 450 c.c. of water.
3. Administer milk, white of an egg, or 5 grams of egg albumin in cold water.
4. Stimulant by hypodermic if necessary.

Bromine Solutions.—

1. Induce vomiting by emetics.
2. Administer a solution of starch and 5 per cent sodium bicarbonate.
3. Administer milk or white of egg or 5 grams of egg albumin in cold water, or other demulcents.
4. Morphine hypodermically for pain.

Bromine Gas.—

See ''Corrosive Gases.''

Carbolic Acid (Phenol).—

1. Administer *immediately* 4 ounces of ethyl alcohol in 4 ounces of water, or one-half pint of whisky or gin.
2. Induce vomiting. See ''Poisoning, General Rules.''
3. Administer milk, or 5 grams of egg albumin in cold water, or mineral oil.
4. Morphine by hypodermic injection for pain. Stimulants if necessary.

Cantharides.—

1. Emetic or stomach tube, followed by demulcents.
2. Drink plenty of water.
3. External heat application.
4. Morphine ¼ grain by hypodermic injection to relieve pain

Carbon Monoxide, Carbon Dioxide. Acetylene, Ethylene, Hydrogen Sulphide, Illuminating Gas, Nitrous Oxide, Phosgene.—

If Inhaled.—

1. Remove patient to fresh warm air immediately.

2. Apply artificial respiration, if necessary, for 4 hours, during which time administer oxygen if available.

3. Keep patient warm, using blankets, jars of warm water against the body, etc. Stimulants.

Chloral Hydrate (''Knock-Out Drops'').—

1. Emetic. Or irrigate stomach with large amounts of warm water.

2. Give strong coffee or caffeine orally, or strychnine sulphate 1/60 to 1/20 grain by hypodermic injection as stimulants.

3. Keep body warm.

Chlorinated Hydrocarbons.—

1. Irrigate stomach.
2. Saline cathartic.
3. Artificial respiration if necessary.
4. Calcium gluconate, intravenous or intramuscular.

Chlorine Solution.—

1. Administer 2 c.c. of ammonium hydroxide in 100 c.c. of water.
2. Induce vomiting. See ''Poisoning, General Rules.''
3. Administer milk or white of egg or 5 grams of egg albumin in cold water.
4. Administer 4 grams of sodium thiosulphate in 450 c.c. water.
5. Stimulants if necessary.

Chlorine Gas. —

See ''Corrosive Gases.''

Chromium Compounds.—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer milk or white of egg or 5 grams of egg albumin in cold water.
3. Stimulants if necessary, morphine by hypodermic injection, for pain.

Copper Compounds.—

1. Induce vomiting. See ''Poisoning, General Rules.''
2. Administer 100 c.c. of 10 per cent monobasic sodium phosphate solution.
3. Stimulants if necessary, morphine for pain, by hypodermic injection.

Corrosive Gases.—

Ammonia, Bromine, Chlorine, Hydrochloric Acid, Hydrofluoric Acid, Nitric Acid.

If Inhaled.—

1. Remove patient to fresh warm air immediately.

2. Apply artificial respiration, if necessary, for 4 hours.

3. If patient is conscious, permit the inhalation of vapors of dilute acetic acid if ammonia is active agent; inhalation of vapors of dilute ammonium hydroxide is helpful if bromine, chlorine, hydrochloric acid, or nitric acid fumes are the active agents.

4. Stimulants if necessary, hypodermic injections of morphine for pain.

Cyanides. SPEED IS ESSENTIAL.—

(a) If Swallowed.—

1. Artificial respiration, if patient is unconscious or breathing with difficulty.

2. Induce vomiting. See ''Poisoning, General Rules.''

3. Administer 250 c.c. of water containing 10 c.c. of 3 per cent hydrogen peroxide, or 250 c.c. of freshly prepared solution containing 5 per cent ferrous sulphate and 5 per cent sodium bicarbonate. Inhalation of vapors of *amyl nitrite*.

4. Combat collapse.

5. Inject intravenously *p*-aminopropiophenone followed by intravenous injection of sodium thiosulphate. Equally effective is sodium nitrite followed by sodium thiosulphate, both given intravenously. These antidoes are available in ampule form from many biological houses.

(b) If Inhaled.—

See "Carbon Monoxide Treatment."

Digitalis.—

1. Tannic acid solution, 60 grains to pint of water, and irrigate stomach or administer emetics.
2. Recumbent position for several days.
3. Artificial respiration if necessary.
4. External heat.

Ergot.—

1. Suspension of powdered charcoal in water, then irrigate stomach.
2. Give purgatives: calomel or castor oil.
3. Stimulants: hot strong coffee, caffeine with sodium benzoate (hypodermic). Amyl nitrite by inhalation.

Ethylene.—

See "Carbon Monoxide Treatment."

Fluorides.—

1. Induce vomiting.
2. Administer milk or white of egg or 5 grams of egg albumin in cold water or lime water, then irrigate stomach.
3. 20 c.c. calcium gluconate solution intravenously.
4. Combat collapse: stimulants, artificial respiration if necessary.

Fluoracetate, Monosodium (1080).—

1. Keep patient quiet.
2. Induce vomiting with emetics.
3. Induce purging with cathartics.
4. Sedation for short time.
5. Complete rest (for cardiac symptoms).

Formaldehyde.—

See "Aldehydes."

Hydrochloric Acid Gas.—

See "Corrosive Gases."

Hydrogen Sulphide Gas.—

See "Carbon Monoxide Treatment."

Illuminating Gas.—

See "Carbon Monoxide Treatment."

Iodine.—

1. Administer thin paste of soluble starch in water, or milk, or egg albumin.
2. Induce vomiting. See "Poisoning, General Rules."
3. Combat collapse with stimulants: black coffee, aromatic spirits of ammonia. Morphine by injection for pain.

Lead Compounds.—

1. Induce vomiting. See "Poisoning, General Rules."
2. Administer 4 grams of sodium thiosulphate in 450 c.c. water or 10 per cent magnesium sulphate solution.
3. Administer milk or white of egg or 5 grams of egg albumin in cold water, or other demulcents.
4. Combat collapse by stimulation by hypodermics.

Methanol.—

See "Alcohols, Methyl, Amyl, etc."

Mercury Compounds.—

1. Induce vomiting. See "Poisoning, General Rules."
2. Administer milk or white of egg or 5 grams of egg albumin in cold water.
3. Administer 4 grams of sodium thiosulphate in 450 c.c. of water.

4. Combat collapse: external heat, morphine for pain.
5. British anti-lewisite (BAL) intramuscularly.

Nitrobenzene and Compounds.—

1. Artificial respiration, if necessary.
2. Induce vomiting, with emetics.
3. Administer 100 c.c. of 3 per cent solution of acetic acid, followed by large quantities of water.
4. Combat collapse, with stimulants.

Nitric Acid Fumes.—

See "Corrosive Gases."

Oxalic Acid and Oxalates.—

1. Induce vomiting, using mustard emetic.
2. Administer milk, magnesium oxide paste, or 5 grams of egg albumin in cold water.
3. Combat collapse by administering black coffee, caffeine with sodium benzoate.

Permanganates.—

1. Induce vomiting. See "Poisoning, General Rules."
2. Administer milk or white of egg or 5 grams of egg albumin in cold water, or other demulcents.
3. Administer 5 c.c. of 3 per cent hydrogen peroxide in 100 c.c. of water slightly acidified with acetic acid.
4. Combat collapse by stimulation.

Petroleum Products (Kerosene, Benzine, Gasoline).—

1. Induce vomiting with emetics.
2. Symptomatic stimulation.
3. Artificial respiration if indicated.

Phenol.—

See "Carbolic Acid."

Phosgene.—

See "Carbon Monoxide Treatment."

Phosphorus and Compounds.—

1. Induce vomiting, with emetics.
2. Administer 2 grams of copper sulphate in 100 c.c. water.
3. Administer large quantities of water and 5 to 10 c.c. of oxidized turpentine (turpentine which has had long exposure to the air). Do **NOT** give milk or white of egg.
4. Administer 15 grams of magnesium sulphate in 100 c.c. water.
5. Morphine hypodermically for pain.

Pyridine and Compounds.—

1. Induce vomiting, with emetics.
2. Administer 2 grams of tannic acid in 50 c.c. of water, or universal antidote (above).
3. Combat collapse by artificial respiration and stimulants as indicated.

Silver Compounds.—

1. Induce vomiting, with emetics.
2. Administer 100 c.c. of 25 per cent sodium chloride solution.
3. Administer milk or white of egg or 5 grams of egg albumin in cold water, or other demulcents.

Sulfonamides.—

1. Thoroughly irrigate the stomach.
2. Follow by cathartic, intake of large quantities of water, and catheter drainage.

Tin Compounds.—

1. Induce vomiting, with emetics.
2. Administer 4 ounces of milk of magnesia or mineral oil.
3. Stimulants if indicated.

Zinc Compounds.—

1. Induce vomiting. See "Poisoning, General Rules."
2. Administer large quantities of 5 per cent sodium bicarbonate solution.
3. Administer milk or white of egg or 5 grams of egg albumin in cold water.
4. Combat collapse with stimulants.

TOXICOLOGIC METHODS

Actual testing for poisons presents no great difficulty if the poison is present in moderate amounts, but considerable skill and experience are required to separate poisons from extraneous materials and to purify them before specific tests are applied for their identification.

It is impractical to describe all of the different separation methods used to isolate poisons since they vary with the nature of the material from which they are extracted, and with the poison. Nor is it the intent of this chapter to cover thoroughly all phases of the many poisons. Only those poisons most commonly encountered have been selected for discussion.

For practical purposes, the general scheme of Stas-Otto[1] is used for isolation of many of the common poisons. These are divided into several groups. Isolation may be performed serially in many cases.

Group I. *Volatile Distillation:* Alcohols, cyanides, phosphorus, ether, chloral hydrate, chloroform, phenols, acetone, aldehydes, camphor, aniline, toluene, benzene and derivatives, carbon disulphide, pyridine, methyl bromide, etc.

Group II. *Acid-Ether Extraction:* Barbiturates and derivatives, salicylates, acetamides, oxalic acid, benzoic acid, caffeine, cantharides, acetanilid, phenacetin, picrotoxin, antipyrine, sulphonal group, etc.

Group III. *Alkaline-Ether Extraction:* Alkaloids such as strychnine, morphine, quinine, atropine, cocaine, codeine, brucine, aconitine, emetine, nicotine, yohimbine, pilocarpine, etc.

Group IV. *Heavy Metals:* Arsenic, mercury, antimony, bismuth, selenium, lead, cadmium, zinc, thallium, etc.

Group V. *Poisonous Gases:* Carbon monoxide, hydrogen cyanide, hydrogen sulphide, oxides of nitrogen, etc.

Group VI. *Special Methods.*

These groups are usually adequate for isolation of many of the common poisons. It must be remembered, however, that even some of these require special treatment (aniline, phosphorus, ether, chloroform, morphine, cyanides), while others (fluorides, carbon monoxide, halogens, toxalbumins, benzedrine) require specific procedures.

THE ISOLATION AND IDENTIFICATION OF POISONS

The first step in the identification of poisons is separation into characteristic groups. When the group to which the poison belongs is known, special tests are carried out for the actual identification of specific substances within the group. Classification of these poisons in groups is given above.

---

[1] Stas: Bull. de L'Académie de Médicine de Belgique 6: 304, 1851, Brussels. Otto: Detection of Poisons, p. 160.

GROUP I. ISOLATION OF VOLATILE POISONS

Volatile poisons must first be separated from body tissues or fluids by steam distillation. Set up the apparatus as shown in Fig. 682. Place a definite weight of finely ground material in a Florence flask of appropriate size and add two or three times its volume of distilled water. Acidify with several c.c. of saturated solution of tartaric acid and add a little mineral oil to reduce any foam which may develop. Connect the flask to the steam distillation apparatus, start the distillation, and collect an exact volume of distillate in a small container packed with ice.

Now test the distillate for the presence of various volatile poisons. Unless otherwise specified, 10 to 20 c.c. of distillate usually suffice for each test.

Several procedures used in distillation for identifying certain poisons vary slightly from this method. These procedures are described in the specific method of testing for these volatile poisons.

Alcohol is discussed first since it is the most common volatile poison.

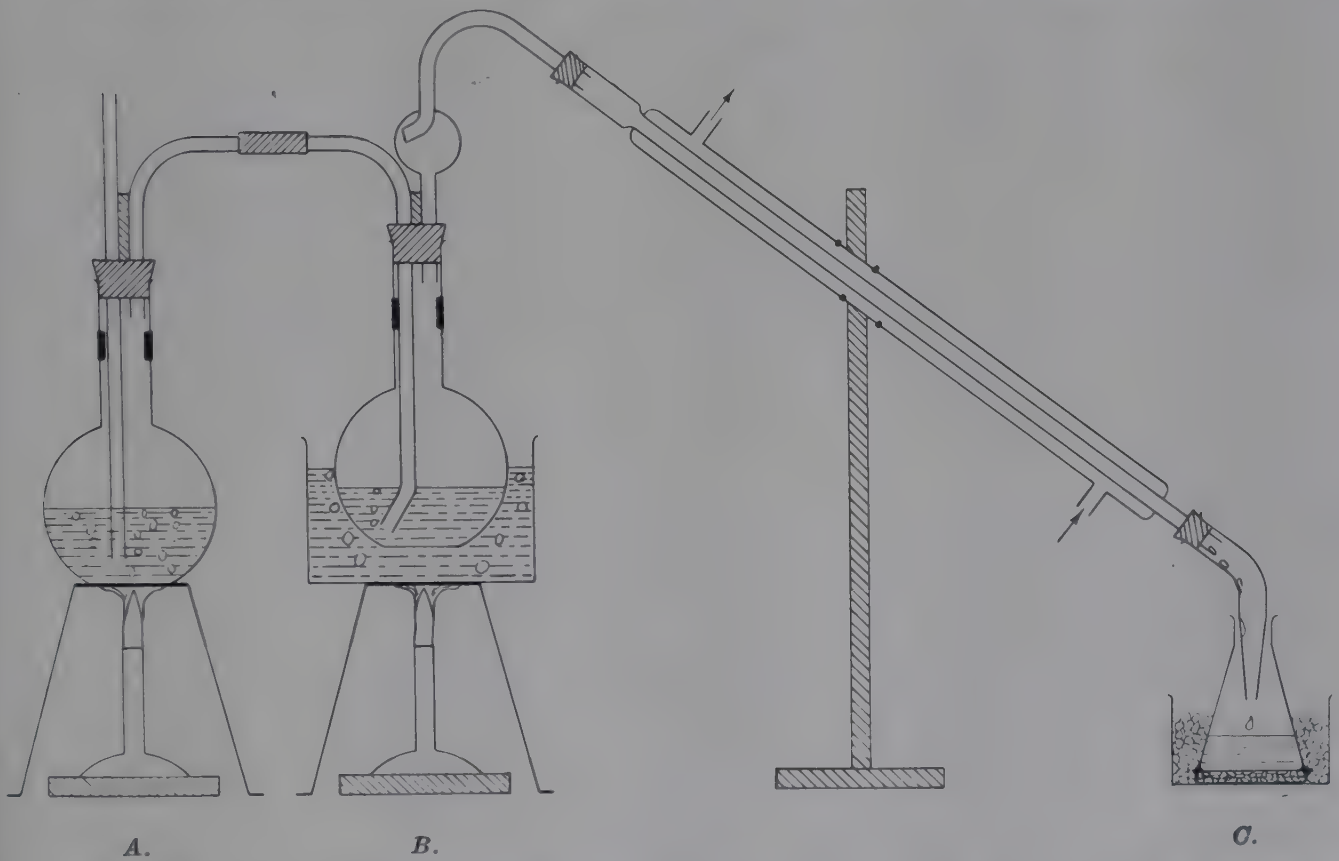

Fig. 682.—Steam distillation apparatus: *A*, distilled water; *B*, specimen in the Florence flask placed in a container partially filled with tap water; *C*, distillate caught in flask submerged in cracked ice.

THE QUANTITATIVE DETECTION OF ETHYL ALCOHOL IN HUMAN TISSUES

A number of methods have been described in the literature for the detection of ethyl alcohol in the human tissues. The first method, described by Subbotin,[1] was based on the oxidation of the alcohol to acetic acid and titration of the latter. Strassman[2] used another method, namely, a colorimetric comparison of solutions of alcohol of definite strengths, using Bodlander's principle of the change of the dichromate from orange to green. Benedict and Norris[1] completely oxidized all the alcohol by an excess but measured amount of a standard solution of dichromate-sulphuric acid. They then reduced the chromic acid that was left by an excess but known amount of a standard solution of ferrous ammonium sulphate. Next they titrated the solution of ferrous ammonium sulphate that was in excess by a standard solution of potassium permanganate until a pink end point was obtained. Another method which depends on the oxidation of the alcohol to acetaldehyde and then ascertaining the amount of the latter colorimetrically by reduced fuchsin has been described.

---

[1] Ztschr. f. biol. Chem. 7: 361, 1871.

[2] Pfuger's Arch. f. d. ges. Physiol. 49: 315, 1891.

A fourth method depends on the formation and estimation of iodine derivatives of the ethyl alcohol. A fifth method depends on physical properties; for instance, Sidersky recommended the determination of alcohol by the increased miscibility of ether and water in the presence of alcohol.

DETERMINATION OF ALCOHOL IN BODY TISSUES OR BLOOD

Method of Choice

Method of Sidney Kaye and Abraham Stolman

To determine the presence or absence of alcohol in body tissues, select brain or liver for the tests. If alcohol is found in these tissues, one is able to draw certain conclusions as to the degree of intoxication present. Many methods for determination of alcohol in tissue have been described in the literature. The method recommended by the United States Army, if slightly modified, has proved very satisfactory. Recovery yields with this method are good. The method is simple, and requires no special equipment. It can be completed in very little time.

Principle.—

A steam distillate is collected from a unit weight of brain. A modified Nicloux reaction is performed upon a small aliquot of distillate. By adhering closely to the technic, accuracy of recovery will reach 95 per cent.

Various brain-distillate ratios were attempted experimentally. It was found that by distilling 200 grams of brain and collecting 400 c.c. of distillate maximum recovery of alcohol resulted. It was also found that an ice pack surrounding the distillate during steam distillation is essential if loss of alcohol is to be prevented. Eight c.c. of distillate were found to be ideal for the modified Nicloux procedure.

The **Nicloux procedure** is based on the reduction of potassium dichromate by alcohol. The resultant change in color is compared with permanent color standards representing various concentrations of alcohol.

Since the colors of artificial standards are not quite true in all cases, actual conditions of the test are simulated by using an alcohol-free distillate to which are added standard quantities of alcohol. The Nicloux reaction is then made on these standards.

With the Nicloux reaction, objectionable foaming is produced during aspiration. This may be sucked up into the color reaction tube. If an empty safety tube is interposed between the distillate and the color reagent during suction, this objectionable feature of the reaction will be eliminated. Instead of interposing the empty tube, 0.5 c.c. of castor oil with 0.5 c.c. of oil of petrolatum may be added to the tube containing the test to prevent foaming.

Interference in the reaction by other reducing substances, such as methyl alcohol, acetone, and others, is possible, but these reducing substances may be detected by other qualitative tests on the original distillate. Gettler's procedure is particularly good for the detection of methyl alcohol. Adding Scott-Wilson reagent will inhibit possible interference by acetone in the reaction.

---

[1] J. Am. Chem. Soc. 20: 293, 1898.

Reagents.—

Saturated Solution of Tartaric Acid.—

Dissolve 20 grams of tartaric acid in 100 c.c. of distilled water.

Anstie's Reagent.—

Dissolve 3.70 grams of potassium dichromate in 150 c.c. distilled water.

Add 280.0 c.c. of concentrated sulphuric acid.

Dilute to 500 c.c. with distilled water.

Allow to stand 24 hours before using.

Scott-Wilson Reagent.—

Dissolve 5 gm. mercuric cyanide, c.p., in 300 c.c. distilled water.

Dissolve 90 gm. sodium hydroxide, c.p., in 300 c.c. distilled water.

Dissolve 1.5 gm. silver nitrate, c.p., in 200 c.c. distilled water.

When the sodium hydroxide solution is cool, add it to the mercuric cyanide solution.

Mix thoroughly. Then add the silver nitrate solution and again mix thoroughly.

If the solution becomes cloudy, or a precepitate forms on standing, filter.

Note: This solution is poisonous. *Do not pipette!*

Stock Alcohol Solution (2%).—

Place 50 c.c. of distilled water in a 100 c.c. volumetric flask.

Add 2.53 c.c. of absolute alcohol (200 proof), using an accurate pipette, and holding the pipette near the surface of the water.

Dilute to 100 c.c. with distilled water.

Standard Alcohol Solutions (Permanent Standards).—

Have on hand alcohol-free tissue distillate.

Arrange a series of 8 test tubes in a row and place 10 c.c. of the alcohol-free distillate in each. Then add to this the given amount of alcohol and distilled water mixture as indicated in Table 218.

TABLE 218

STOCK ALCOHOL SOLUTION	DISTILLED WATER	CORRESPONDS TO ALCOHOL IN SPECIMEN, MG. PER 100 GRAMS
0.0	1.0	negative
0.1	0.9	0.05
0.2	0.8	0.10
0.3	0.7	0.15
0.4	0.6	0.20
0.5	0.5	0.25
0.6	0.4	0.30
0.7	0.3	0.35

Carry out the Nicloux reaction as described below.

Dilute the contents of each tube to 10 c.c. with Anstie's reagent.

Transfer to clean, approximately matched ampules. These ampules may be prepared by drawing out approximately matched test tubes.

Label and store in the dark. Standards prepared in this manner and kept away from light when not in use will be stable for at least one year.

Technic.—

Mix 200 gm. finely ground brain or liver with 300 c.c. distilled water in a Florence flask which can be connected to a distillation apparatus. (See Fig. 682.)

Acidulate with several c.c. of saturated solution of tartaric acid.

Add approximately 5 c.c. of oil of petrolatum to reduce foaming.

Connect with the steam distillation apparatus. (See Fig. 682.)

The distillate is collected in an Erlenmeyer flask packed in ice.

The adapter which enters the Erlenmeyer flask is elongated so that it lies below the level of the ice pack.

The receiving vessel should be marked with a wax pencil to indicate a 400 c.c. level.

Nicloux Reaction.—

Collect 400 c.c. of distillate.

Have on hand three test tubes 25 by 200 mm., with two-holed rubber stoppers, containing outlet tubes.

Tube 1.—Place 8 c.c. of brain distillate and 2 c.c. of Scotts-Wilson reagent in tube 1.

Tube 2.—This tube remains empty.

Tube 3.—Place 9 c.c. of Anstie's reagent in tube 3.

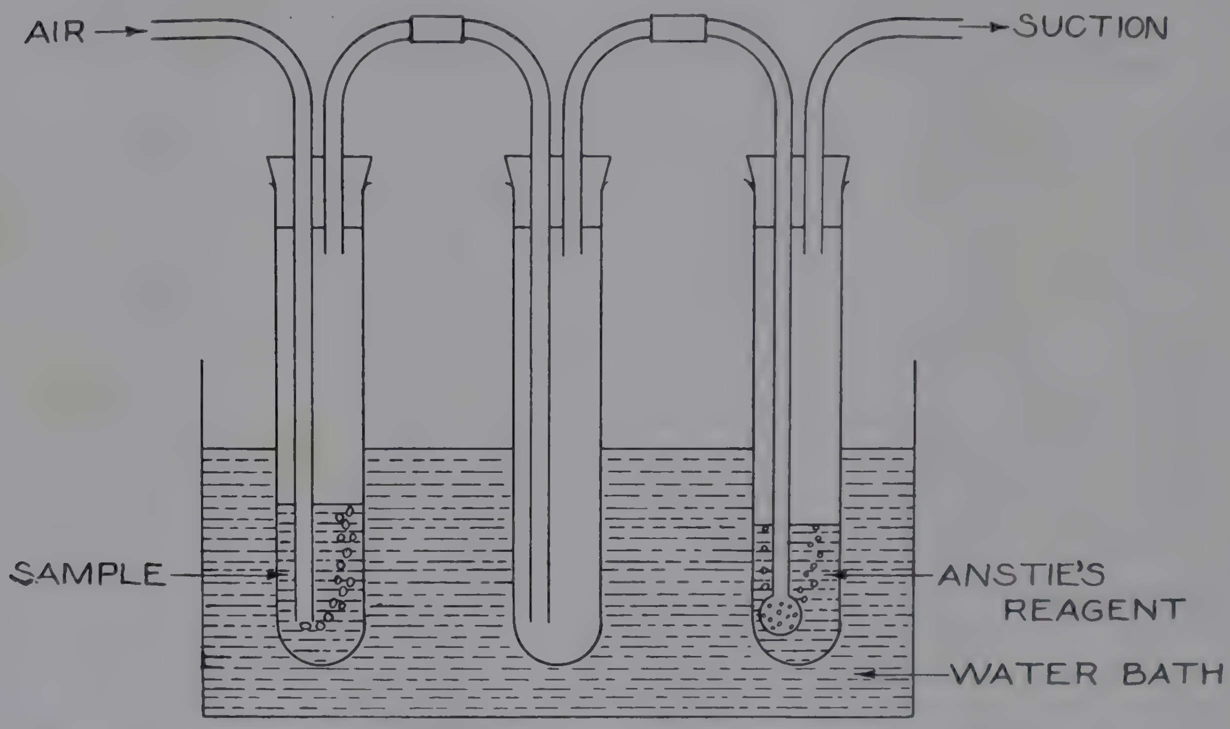

Fig. 683.—Apparatus for the Nicloux reaction. Arrange three 25 × 200 mm. tubes with two-holed rubber stoppers, and inlet and outlet tubes. The inlet tubes should extend nearly to the bottom of the tubes and the outlet tubes just below the stoppers. Connect the inlets and outlets of the three test tubes with rubber tubing in such fashion that a current of air may be aspirated through the specimen tube, then through the safety tube, into the tube of Anstie's reagent.

Stopper the three tubes.

The inlet tubing should extend nearly to the bottom of the test tubes. The outlets must be just below the stoppers.

Use rubber tubing to connect the inlet and outlet tubes.

Arrange the tubes in proper order so that a current of air may be aspirated through the specimen tube into the tube of Anstie's reagent. The second tube is to prevent foaming into the reagent. The reagent tube is placed next to the source of suction. (See Fig. 683.)

Adjust the suction so that an air current is slowly drawn from the specimen tube through the safety tube, and into the tube containing Anstie's reagent.

Immerse the tubes in a gently boiling water bath. Continue the boiling and aspiration for approximately twenty minutes.

Remove the tubes from the bath.

Cool the tube containing Anstie's reagent. Transfer the solution to a tube, similar in size and shape to the standard tubes.

Dilute to exactly 10 c.c. by adding Anstie's reagent dropwise.

Compare the color of the unknown with the color of the standards.

Report the results in milligrams of alcohol per 100 grams of tissue according to the standard tube with which the unknown matches.

Alcohol concentrations higher than 0.35 mg. per cent cannot be accurately measured with these standards since the Beer-Lampert law is not valid beyond 0.35 mg. per cent. If a concentration higher than 0.35 mg. per cent is indicated, repeat the analysis using 4 c.c. of distillate (one-half the usual quantity), and multiply the final results by 2.

Experimental.—

Various ratios of brain weight-distillate volume were tested experimentally. These experiments proved that a 1:2 ratio resulted in maximum recovery of alcohol. (Two hundred grams of brain were used to produce 400 c.c. of distillate.) Known amounts of alcohol were mixed with the alcohol-free ground brain, and analyzed for percentage recovery. Results are given in Table 219.

The results in Table 219 indicate that 100 per cent recovery of alcohol was obtained. Actually results were recorded only to the closest 0.05 mg. per cent recovery. In a few cases, the color was slightly less than the results recorded. Comparison with spectrophotometer reading revealed that even these never varied by more than 0.01 mg. to 0.02 mg. from the nearest standard report.

TABLE 219

CONCENTRATION OF ALCOHOL ADDED TO 200 GM. BRAIN	C.C. OF 2% ALCOHOL	NUMBER OF SAMPLES	ALCOHOL RECOVERED
0	0 c.c.	5	0
0.05 mg. %	5 c.c.	5	0.05 mg. %
0.10 mg. %	10 c.c.	5	0.10 mg. %
0.15 mg. %	15 c.c.	5	0.15 mg. %
0.20 mg. %	20 c.c.	5	0.20 mg. %
0.25 mg. %	25 c.c.	5	0.25 mg. %
0.30 mg. %	30 c.c.	5	0.30 mg. %
0.35 mg. %	35 c.c.	5	0.35 mg. %

Interpretation.—

Levels of 0.10 to 0.15 per cent of alcohol usually indicate that an individual is under the influence of alcohol, but not definitely intoxicated.

Levels of 0.20 to 0.25 per cent of alcohol indicate that an individual may be regarded as definitely intoxicated.

Levels of 0.30 to 0.35 per cent of alcohol indicate that the individual is quite seriously intoxicated.

Levels of 0.40 per cent of alcohol indicate that the individual is either at or quite close to the ''dead drunk'' stage. Higher concentrations indicate very serious intoxication, which may even result in death.

Determination of Alcohol in Tissues

Method of Gettler and Tiber

As soon as the tissue is removed from the body, place it in a tightly closed jar, and store in a refrigerator.

When ice cold, weigh 500 gm., quickly grind it, and place in a 2-liter flask.

Add 600 c.c. of distilled water
5 c.c. of a saturated solution of tartaric acid
and 1 c.c. of white mineral oil.

Distill with steam (Fig. 682). Use a long, well-cooled condenser.

Continue distillation until exactly 800 c.c. have been collected.

Mix the distillate thoroughly.

Place 20 gm. of potassium bichromate
and 40 c.c. of concentrated sulphuric acid
in a 500 c.c. distilling flask.

Add 300 c.c. of the distillate obtained above. Mix well.

Connect the flask to a long, well-cooled condenser by means of a Hopkins distilling head, and start the distillation.

Regulate the heat so that it will take from 45 to 50 minutes to collect exactly 250 c.c. of distillate.

Mix thoroughly.

Titrate 50 c.c. of the distillate with N/20 sodium hydroxide solution, using phenolphthalein as an indicator.

The amount of alcohol present in 1 kg. of brain tissue = (c.c. N/20 NaOH − 1.32) × 71.58. The figure 1.32 holds only for brain tissue. For other tissues, one must determine experimentally the corresponding blank.

Test to Determine Alcohol Intoxication

Considerable literature has been published regarding tests for alcohol to determine intoxication in individuals suspected of driving automobiles while intoxicated. The problem is to prove intoxication of the operator of an automobile when a driver is accused of operating while intoxicated, or for manslaughter in case death results to the victim of an automobile accident, or in a civil action for damages in which the alleged drunkenness of a defendant driver is one of the material points in issue. There are a number of tests recommended to prove intoxication, some of which are detailed in the following pages. It is evident that a knowledge of the concentration of alcohol in the blood is the best guide to prove alcoholic intoxication. Widmark, in Sweden, advocated the use of this test for blood alcohol content. He concluded that when the blood alcohol level is 200 mg. per cent or over, individuals are almost without exception intoxicated; with a value of over 160 mg. per cent and less than 200 mg. per cent, the probability of intoxication is very great. Ladd and Gibson[1] state that, on the basis of a number of European investigations, a blood alcohol level of 200 mg. per 100 gm. of blood has been recognized in Sweden and Germany as a state of intoxication. The Committee on Tests for Intoxication of the National Safety Council, 1938, recommended that blood alcohol concentrations over 0.15 per cent by weight should be conclusive evidence that a driver is under the influence of alcohol. This level is reached ordinarily by the ingestion of 6-7 ounces of whiskey. When the level is between 70 and 150 mg., the symptoms observed in the medical and physical examination should be considered. The American Medical Association's Committee on Problems of Motor Vehicle Accidents[2] made the following statement with reference to chemical tests: "Since it is impossible to diagnose drunkenness adequately—drunkenness from symptoms alone—it is important that the chemical observation of the blood, urine, saliva, and breath for alcohol be used to confirm obvious intoxication. The Committee on the Driver, of the National Safety Council, has agreed that 0.15 per cent (150 mg. per cent) of alcohol by weight in the body fluid is associated with mental and/or physical inferiority and that this figure is therefore valuable in legal cases. It must be understood, however, that much lower levels of alcohol are associated with definite impairment of judgment and particularly of self-criticism."

According to a number of European workers, there is a close agreement in the alcohol content of blood and urine after alcohol administration. Later data have shown that the urine alcohol is usually in higher concentration than blood alcohol, a ratio of about 1:1.35 having been established.

---

[1] Iowa Law Rev. **24**: No. 2, Jan., 1939.

[2] Report of Committee on Problems of Motor Vehicle Accidents of the American Medical Association, J. A. M. A. **108**: 2137, 1937.

The breath alcohol test, which was recommended by Harger and which will be described later, was first brought out by Bogen.[3] His method was much improved upon by Harger.

There is a relationship of close degree between the salivary and blood alcohol levels. So far as cerebrospinal fluid is concerned, Gettler and Tiber[4] conclude that the alcohol content of the brains of post-mortem cases can be used to prove intoxication previous to death. Gettler and Freireich,[5] whose technic is described below, claim that the alcohol content of the cerebrospinal fluid, but not of the blood, can be used for estimating the amount of alcohol in the brain of a living individual. Harger, Hulpieu, and Lamb[6] denied the claims of Gettler and Freireich and believed from their experiments from dogs that brain alcohol may at all times be predicated with reasonable accuracy from the alcohol content of the blood.

There are a number of conditions affecting the predictability from these tests; for instance, tolerance and concentration of the alcoholic level. Experiments on both fasting men and animals have shown not a lessened absorption but a more rapid absorption, reaching a slightly higher peak in habituated subjects than in nonhabituated as determined in blood alcohol curves. If alcohol is administered intravenously, the curves are almost identical for both the accustomed and the unaccustomed subjects. As Ladd and Gibson (l.c.) further point out, the effect of shock, applied or mental, or of apprehension during a waiting period or during an examination may for a short time produce a sobering effect on the intoxicated individual.

Muehlberger,[7] in reference to the variations to be expected in the relationship between blood alcohol concentrations and the physical and mental impairment of different individuals, prepared a table for the National Safety Council showing the overlapping stages of intoxication. The values were as follows:[8]

1. *Subclinical:* blood 0-120 mg. per 100 c.c., urine 0-160 mg. per 100 c.c. Normal by ordinary observation; slight change by special tests.
2. *Stimulation:* blood 90-210 mg. per 100 c.c., urine 130-290 mg. per 100 c.c. Increased inhibitions; emotional instability; slight incoordination; slowing of stimuli responses.
3. *Confusion:* blood 180-300 mg. per 100 c.c., urine 260-420 mg. per 100 c.c. Disturbance of sensation; decreased pain sense; staggering gait; slurred speech.
4. *Stupor:* blood 270-390 mg. per 100 c.c., urine 380-540 mg. per 100 c.c. Marked stimuli decrease; approaching paralysis.
5. *Coma:* blood 360-480 mg. per 100 c.c., urine 510-670 mg. per 100 c.c. Complete unconsciousness; depressed reflexes; subnormal temperature; anesthesia; impairment of circulation; stertorous breathing; possible death.

Precautions and Methods in Respect to the Blood Test.—Mason and Ladd emphasize the legal side of the method of taking the blood test. They state that care should be taken that the physician-patient relationship is not established so as to bring the test within the scope of privileged communications and observations. The doctor taking the blood specimen should avoid rendering any medical treatment at the time, as that would give rise to the privilege in some states. If necessary to give first aid treatment, some physician other than the one taking the blood specimen should give this treatment. The physician taking the test should also note the odor of alcohol on the breath, abnormalities of the gait and speech, size of the pupils, flushing of the face, and should be able to state that the patient, in his opinion, is not perceptibly, or is slightly or highly affected by alcohol. The specimen should be taken after proper disinfection of the skin. The use of alcohol, alcohol preparations, or phenol solution for sterilization of the skin might affect legally the validity of the analytical results. To avoid possibility of civil action, subject's consent should be obtained. Blood should be withdrawn in the usual manner for blood chemical test into a bottle containing sodium fluoride. Stopper the container with a clean cork and mix. Samples should be sealed and labeled in the presence of a witness, showing the name of the donor, hour and date the specimen was taken, and the signature of the physician and witness or witnesses. Specimen should be delivered personally by the physician to the chemist or qualified person who is to make the analysis. If specimens are mailed to a laboratory, they should be registered or sent by special delivery so that receipt by the analyst is verified by signature. Specimen should be identified and marked. Both blood and urine specimens should be taken.

[7] Cited from Committee on Tests for Intoxication of the National Safety Council.

[8] Ladd, Mason, and Gibson, R. B.: L. c.

Special precautions with respect to the glassware used in analysis should be carried out; that is, it should be chemically cleaned and thoroughly rinsed with pure distilled water.

Just what test is to be used depends on the individual and the experience of the analyst. The method of Gettler and Freireich and the chemical test of breath by Harger are detailed in the following pages.

Determination of Ethyl Alcohol in Blood and Spinal Fluid

(Method of A. O. Gettler and A. W. Freireich*)

Ten c.c. of spinal fluid and 1 gm. of paraffin are placed in a 100 c.c. distillation flask which is set up for steam distillation (Fig. 682). It is to be noted that the flask containing the blood or spinal fluid is not heated, but steam alone is used for the distillation. One hundred c.c. of distillate are collected. To these 100 c.c. of distillate, placed in a 200 c.c. round-bottom flask, are added 7.5 gm. of potassium dichromate and 15 c.c. of concentrated sulphuric acid. Connect the flask to a long, well-cooled condenser by means of a Hopkins distilling head. The contents are well mixed.

A medium-sized (1½ inch) Bunsen flame is applied in order that the distillation is not too rapid. It should be slow but at a constant rate and should take about 60 minutes to collect the required 80 c.c. of distillate.

After collecting 80 c.c. of distillate, it is mixed and aliquot portions are titrated with 0.05 N sodium hydroxide for acetic acid produced.

The titration is carried out by using phenolphthalein indicator. The indicator is added to the distillate, the 0.05 N sodium hydroxide is placed in a buret, and the alkali added to the distillate a drop at a time with constant stirring until the first faint permanent pink color appears. This is the end point.

The amount of sodium hydroxide (0.05 N) used is read from the buret. This is the equivalent of the 0.05 N acetic acid in the distillate.

---

*J. Biol. Chem. 92: 199, 1931.

The amount of alcohol in the spinal fluid is calculated according to the following figures:

$$\text{Per cent of alcohol} = (\text{c.c. } 0.05 \text{ N alkali used} - 0.42) \times \frac{100}{85} \times 0.0023 \times 10.$$

The figure 0.42 represents the blank control to eliminate the normal amount of titratable acid in spinal fluid.

$\frac{100}{85}$ is the factor used based on the fact that, from normal spinal fluids to which alcohol was added, only 85% of the added alcohol was recoverable by this method.

0.0023 represents the grams of alcohol equivalent to 1 c.c. of 0.05 N alkali used in the titration.

10 is the multiple used to convert to 100 c.c. of spinal fluid, because 10 c.c. of spinal fluid were used in the titration.

A small portion of this distillate is now tested for the sulphate ion to make sure that no sulphur trioxide passed into the distillate.

From the amount of acetic acid found by titration, the amount of ethyl alcohol is calculated (above).

It was found by Gettler and Freireich that nonalcoholic spinal fluid yields certain volatile substances to the distillate, which, when oxidized in accordance with their method, yield on the average for every 10 c.c. of spinal fluid an acidity of 0.78 c.c. 0.02 N, which is equivalent to 0.0071 per cent of ethyl alcohol, or 0.71 mg. of ethyl alcohol in every 10 c.c. of spinal fluid.

In order to determine whether normal blood yields any acidity, the method was carrried out by these investigators on fourteen patients who had been under observation in the hospital and had partaken of no alcohol. These experiments showed that nonalcoholic bloods yield certain volatile substances to the distillate, which, when oxidized by their method, yield for every 10 c.c. of blood an acidity of 1.33 c.c. or 0.012 per cent of ethyl alcohol. They do not claim that this is ethyl alcohol, but that it is some volatile material found in normal blood which, upon oxidation, yields titratable acidity.

These workers further examined the alcohol content of the brain in a series of cases and showed that the alcohol content of the brain can be used to prove intoxication. In order to draw conclusions, they examined the brain, blood, and spinal fluid of cadavers, and the blood and spinal fluid of living alcohol drinkers, and determined the relationship between the alcohol of the brain and that of the spinal fluid. They showed that the smaller the alcohol content of the brain, the larger is the spinal fluid:brain ratio. The larger the amount of alcohol in the brain, the nearer do the spinal fluid values approach the values in the brain, the spinal fluid: brain ratio approaching a value of 1.1. On the other hand, the spinal fluid: brain ratio in intoxicated individuals is below 1.4. They showed also that the blood: brain ratios range anywhere from 0.66 to 4.55.

From their figures, they deduced that the *spinal fluid, but not the blood,* can better be used for estimating the amount of alcohol in the brain of a living individual. The alcohol content of the brain and that of the spinal fluid run quite parallel; since the alcoholic content of the brain is an index of intoxication, *the spinal fluid can be used to prove intoxication in living individuals.*

They give the figure of 0.272 per cent or more alcohol in the spinal fluid to show that an individual is intoxicated. All figures below 0.2 per cent were non-intoxicated individuals.

Chemical Tests of Breath for Alcoholic Intoxication

The Harger Drunkometer

A rapid chemical test for intoxication employing the breath was described by Harger, Lamb, and Hulpieu.[1] The method utilizes apparatus called the Harger Drunkometer. The test gives prompt information; one can determine within a few minutes whether a person has been drinking, and if so, the approximate accumulation of alcohol in his body. The preliminary test is easily performed and does not require specialized chemical knowledge. The final test, however, which is quantitative, requires the services of a chemical expert. The test has been accepted in many states. The test for alcohol depends on a change in color, with the disappearance of the initial purple, produced by the combination of 16 N sulphuric acid and N/20 potassium permanganate solution, mixed in a glass portion of the Drunkometer into which is allowed to flow air from a balloon which has been blown up by the subject. The details of the apparatus insofar as the quantitative analysis is concerned are seen in Fig. 684.

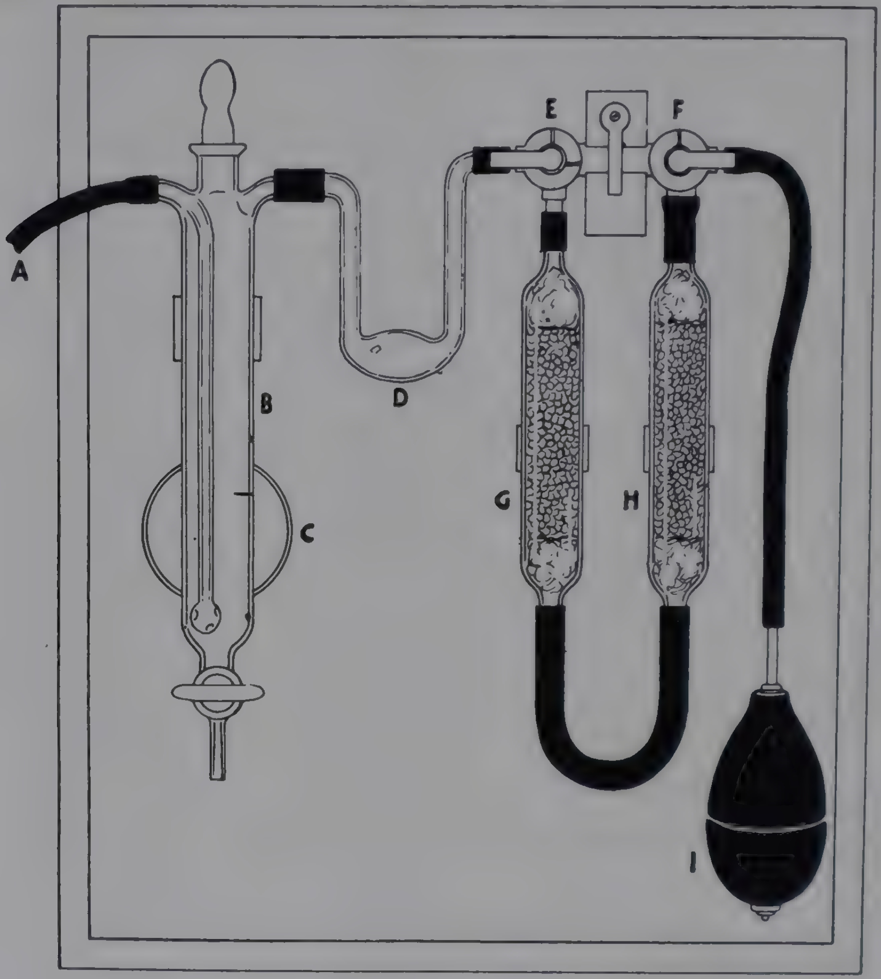

Fig. 684.—Details of the Harger Drunkometer. The reagent used is a weak solution of potassium permanganate in the presence of approximately 55 per cent sulphuric acid by weight.

The technic is as follows: (Fig. 684.) Turn valves *E* and *F* to shunt the gas past tube *G* and directly out by way of the rubber tube and bulb I. In the reaction tube *B* place 10 c.c. of solution I, then exactly 1 c.c. of solution II,* solution I being 16 N sulphuric acid and solution II, N/20 potassium permanganate solution; replace stopper and mix contents by one or two strokes of the bulb pump.

---

*This mixture deteriorates rapidly and loses its purple color; it should be used within 5 or 10 minutes of the time it is prepared.

[1] J. A. M. A. **110**: 779, 1938.

With the subject's cooperation, collect slightly more than 2 liters of breath in one of the balloons. Connect the balloon to a glass adapter the other end of which is connected to a rubber tube containing a screw clamp. Close the clamp. Release air from balloon until it fits the large 2 liter ring. Immediately connect the rubber tube of the adapter to inlet tube *A* (Fig. 684) by means of a small glass nipple, open the pinch clamp, and allow the breath to pass fairly rapidly through the apparatus. If the solution in Tube *B* is not decolorized by 2 liters of breath, the subject's blood contains less than 0.35 mg. of alcohol per c.c., if any, and he may be discharged as not having been drinking, at least to an appreciable extent.

If less than 2 liters of breath decolorizes the purple liquid, measure the quantity of breath used in the test by comparing the diameter of the balloon containing the remaining breath with the two smaller brass rings. If more than 1,000 c.c. were used, subject's blood contains less than 0.7 mg. of alcohol per c.c. and he is probably not under the influence of alcohol. If less than 1,000 c.c. of breath decolorizes the liquid, perform the quantitative test (below). The end point is the disappearance of the last trace of purple leaving a faint yellowish brown fluid.

Having determined the positive presence of alcohol in the breath by decolorization of the reagent mixture, a quantitative determination of the amount can be made by permitting the air to flow into the tube containing ascarite for the absorption of carbon dioxide. The three-way metal valves (*E* and *F*, Fig. 684) are so arranged as to leave tubes *G* and *H* out of the circuit or to send the gas stream successively through them.

Quantitative Test.—Weigh tube *H* and connect in position, the valves *E* and *F* being turned so as to include tubes *G* and *H* in the path of the gas. Use either the balloon or the pump to collect the breath, and proceed as above. When the last trace of purple has just disappeared from the fluid in tube *B*, replace tube *H* at once in its container and close the container. Send tube *H* to the laboratory for weighing. If the balloon is used, measure accurately the volume of breath passed through the apparatus by disconnecting the rubber bulb and connecting the outlet tube to a gas buret filled with water.

Calculations.—Under the above conditions, 1 c.c. of N/20 potassium permanganate is just decolorized by 0.175 mg. of ethyl alcohol. The weight of carbon dioxide absorbed by tube *H* gives the amount of alveolar air which contained 0.175 mg. alcohol. Calculate the quantity of alcohol which accompanied 190 mg. of carbon dioxide; that is, the weight of alcohol in 2 liters of alveolar air, and therefore the weight of alcohol in 1 c.c. of the subject's blood. Let x equal milligrams of alcohol in 2 liters of alveolar air and w the increase in weight of tube *H* in milligrams.

$$\frac{x}{190} = \frac{0.175}{w} \quad \text{or} \quad x = \frac{33.25}{w}$$

To calculate the milligrams of alcohol in 2 liters of alveolar air in 1 c.c. of the subject's blood, divide 33.25 by the weight of carbon dioxide contained in the sample of breath which just decolorized the purple fluid.

To check this figure, calculate the weight of alcohol in 4 liters of the sample of breath (observation of Borgen that the breath as collected usually contains about 50 per cent of alveolar air). It will require 560 c.c. of breath containing 1 mg. of alcohol in 4 liters to decolorize 1 c.c. of permanganate solution. Then 560 ÷ c.c. breath used = mg. of alcohol in 4 liters of expired air or in 1 c.c. of blood.

The ratio of alcohol to carbon dioxide in the breath may be used to measure the concentration of alcohol in the blood. The weight of the alcohol accompanying 190 mg. of carbon dioxide in the breath is very nearly equal to the weight of the alcohol in 1 c.c. of the subject's blood. Employment of the ratio of alcohol to carbon dioxide in the breath permits the test to be done without the subject's being touched. A tube is held in the breath stream and a pump draws the sample through the apparatus. As shown by Harger's test, 4 liters of expired air contained about the same amount of alcohol as 1 c.c. of the subject's blood. Because of possible fluctuations in the amount of alveolar air in such samples, it is believed that analyses of breath made on the volume basis should be checked by determining the carbon dioxide in the sample.

Fig. 685 covers 120 tests made on individuals in the City Hospital of Indianapolis, showing the correlation of breath and blood tests. This indicates very clearly that the breath test is a safe and accurate method for estimating whether or not a given motorist is capable of safely driving a car.

Certain precautions are to be borne in mind in the quantitative test. First, ascarite tube (*H*) must be kept free from moisture when it is not in use. It should be stored in a larger glass tube containing a mixture of ascarite and dehydrite and closed with a paraffin cork. If tube *H* is not in position, close the open end of the rubber tube at the bottom of tube *G* by means of a glass or metal plug to prevent entrance of moisture into tube *G*.

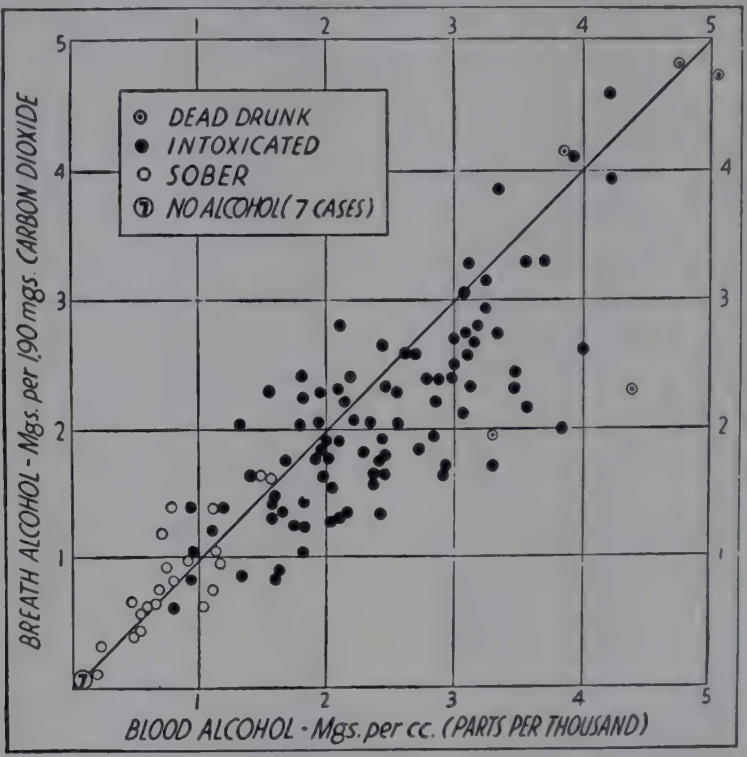

Fig. 685.—Correlation of breath alcohol and blood alcohol in tests in 120 individuals.

It is also a good idea in connection with the use of the Drunkometer to have what is known as an "artificial drunk." This is to familiarize the operator with the end point of the reaction and to demonstrate the reaction in court. For this purpose have a bottle fitted with a two-hole rubber stopper, one hole carrying a glass inlet tube extending to the bottom of the bottle, and the second a glass ell which ends just below the stopper. To obtain an "artificial drunk," place a weak (0.5%) solution of alcohol in the bottle and draw air through the solution. Use a second bottle fitted like the first for making qualitative tests for alcohol in the urine, since the urine of alcoholic subjects will serve as the fluid in the "artificial drunk."

The Intoximeter

This is another method of determination of the presence and amount of alcohol in the breath by means of an apparatus originated by Glenn C. Forrester.[1] This method has the advantage of being more easily portable and yields approximately as good results as the Harger Drunkometer.

---

[1] For further details, see book by Glenn C. Forrester, issued by Intoximeter Association, 334 Buffalo Avenue, Niagara Falls, New York, entitled *Use of Chemical Tests for Alcohol.*

This instrument is housed in a cylindrical mailing tube, 2 inches in diameter and 8 inches long. It enables a police officer to obtain an on-the-spot approximation of the level of blood alcohol by permitting the breath, which is exhaled into a rubber balloon, to pass through a mass of sintered glass particles within a capillary tube moistened with a purple oxidizing solution, and noting the time required to destroy the color. In the presence of alcohol, the color disappears, and the number of seconds, by reference to a table on the wrapper, indicates the percentage of blood alcohol. No disappearance of color means no alcohol. If this preliminary test is positive, the police officer or technician permits some of the air to pass from the balloon, while the color test is being conducted, through two tubes in series housed in the case. Tubes are sealed securely when this air has passed. The tubes are then transported to the laboratory where a chemical test is made. The weight of CO_2 is determined by direct weighing of the ascarite tube on an analytical balance. This weighing is made by the same chemist who weighed the tube before use, recorded that weight, and sealed the record and tube into the Intoximeter before issuing it to the officer.

The second tube contains perchlorate. Recommended procedure with this tube is to mix it with 40 to 60 c.c. of doubly distilled water. Twenty-four c.c. are distilled into a glass stoppered graduated flask, and the volume is made up to exactly 25 c.c. This is then well mixed and exactly 10 c.c. pipetted into a clean 25 by 150 mm. Pyrex test tube, previously charged with exactly 5 c.c. of 0.0438 N. potassium dichromate solution (1.705 grams of pure dry reagent potassium dichromate dissolved in one liter of solution) and with approximately 5 c.c. of reagent quality sulphuric acid. These two have been previously mixed and cooled by placing in a beaker of cold water. Swirl test tube with 20 c.c. of contents to mix contents thoroughly. Heat in a boiling water bath for about 15 minutes to complete the oxidation of the alcohol to acetic acid.

Cool the tube and transfer contents into a clean 500 c.c. Erlenmeyer flask and dilute to 200 c.c. total volume with distilled water. Add 2 grams of reagent quality potassium iodide and titrate the liberated iodine with sodium thiosulphate solution (0.00434 N, made by dissolving 1.1 grams of thiosulphate crystals in 1 liter of water and preserving with a few drops of chloroform).

Determine end point with 1 c.c. of starch indicator solution (preserved with a crystal of mercuric chloride).

A blank determination is run on the magnesium perchlorate of the same batch used in the preparation of the Intoximeter and distilled in the same way as in the regular analysis. This blank amounts to about 0.2 c.c. of sodium thiosulphate solution.

Colorimetric Method for Determination of Alcohol Concentration in Urine and Blood

Method No. 1

A simple method for determination of alcohol concentration in urine and blood has been described by Sheftel,[1] as follows:

Apparatus and Reagent Required.—

50 c.c. Pyrex Erlenmeyer flask.

One rubber cork in which a Monel or nichrome wire clip is inserted to keep the filter paper in place.

Filter paper strips of medium thickness, 1½ by 2 inches.

Special blue filter.*

Accurate 0.2 c.c. pipette.

Reagent.—

Solution of 0.4262 per cent of potassium dichromate in 50 per cent (by volume) sulphuric acid (1 c.c. of this reagent corresponds to 1 mg. of alcohol).

---

*Lantern blue glass filter No. 554, manufactured by MacGregor Instrument Co., of Needham, Mass.

[1] J. Lab. & Clin. Med. 23: 534, 1938.

Procedure.—

Roll one filter paper strip into a small cylinder and insert it into the clip attached to the cork. Introduce into the Erlenmeyer flask 1 c.c. of reagent. Absorb into the filter paper 0.2 c.c. of urine or blood to be examined.

The blood may be oxalated or freshly drawn from the ear lobe or the tip of the finger. Insert the cork immediately, but not tightly into the Erlenmeyer flask. Heat the neck of the flask from all sides over a Bunsen burner, and then press the cork very tightly into the neck of the flask. Place in a one liter beaker a small quantity of water, and into this put the flask. Adjust the volume of water in the beaker so that the flask does not float. Cover the beaker with a Petri dish or a watch glass. Boil the water in the beaker gently for fifteen minutes. Remove the flask from the beaker. Remove the cork gently from the flask, cool lower portion under tap, and add 4.3 c.c. of distilled water. Into a clean test tube introduce 2.5 c.c. of reagent and add to it 10 c.c. of distilled water. It will be seen from this that whereas 1 c.c. of reagent standard is diluted to 5 c.c., 1 c.c. of unknown is diluted to 5.4 c.c. Approximately 0.1 c.c. of the blood remains on the filter paper as unevaporated material.[1] The difference in the dilution is the necessary correction for absorption of light in the colorimeter by chromic sulphate. Compare in any microcolorimeter, using the blue filter and setting the unknown at 10. Calculate from the following formula:

$$\left(1 - \frac{R}{10}\right) \times 500 = \text{mg. alcohol per 100 c.c.}$$

R = Reading of the reagent-standard.

For example: R is 7.4; then $\left(1 - \frac{7.4}{10}\right) \times 500 = 130$ mg. alcohol per 100 c.c.

When the concentration of alcohol in blood or urine is high (above 250 mg. per cent), it is advisable to dilute the reagent standards by 2 or 4.

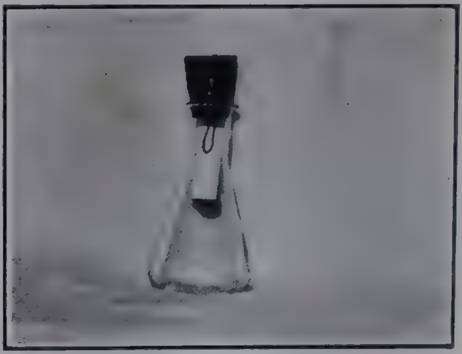

Fig. 686.—Sheftel apparatus for determination of alcohol concentration in urine and blood. (From Sheftel, A. G.: J. Lab. & Clin. Med., Feb., 1938.)

Method No. 2

The following method is in use in a number of crime laboratories.

Reagents.—

Picric Acid Solution, half-saturated.—

Dilute saturated picric acid to double its volume with distilled water.

Modified Anstie's Reagent.—

Dissolve	3.3333	gm.	of potassium dichromate, c.p.
in	250.0	c.c.	distilled water
Add	521.0	c.c.	concentrated sulphuric acid
to	200.0	c.c.	distilled water in a Pyrex flask, cooling under running water.

When cool, add the dichromate solution, slowly and with constant shaking. Dilute to 1000 c.c. with distilled water.

Apparatus.—

250 c.c. Erlenmeyer flask with glass tubing bent to connect with condenser, or 250 c.c. distilling flask. Condenser: either Liebig or Graham coiled (latter preferred).

---

[1] Abels, J. C.: Proc. Soc. Exper. Biol. & Med. 34: 346, 1936.

Rubber tubing for condenser connections.
Rubber stoppers with one hole for glass tubing connections.
Bunsen burner.
Centrifuge tube, graduated.
15 c.c. test tubes, ⅝ inch diameter.
1 set of color standards.
1 c.c. pipette.
10 c.c. pipette.

Technic.—

Pipette 10 c.c. of blood or urine into a clean, dry 250 c.c. Erlenmeyer flask.

Add 10 c.c. half-saturated picric acid solution.

Connect the flask to the condenser. **CAUTION:** Be sure that all stoppers fit tightly so that no steam can escape anywhere.

Apply heat gently. When using blood, glass beads should be used to prevent bumping.

Collect 10 c.c. of distillate in the 15 c.c. centrifuge tube. **NOTE:** If less than 10 c.c. of blood or urine is used, then the aliquot portion is collected.

To 3 c.c. of Anstie's reagent, carefully measured with a test tube*
add 1 c.c. of distillate delivered from a clean dry 1 c.c. pipette.

Place the tube in boiling water bath for 4 minutes.

Compare the color against standards and read directly. NOTE: A set of standards may be purchased from the LaMotte Chemical Company, Baltimore, Md., or may be made in the laboratory.

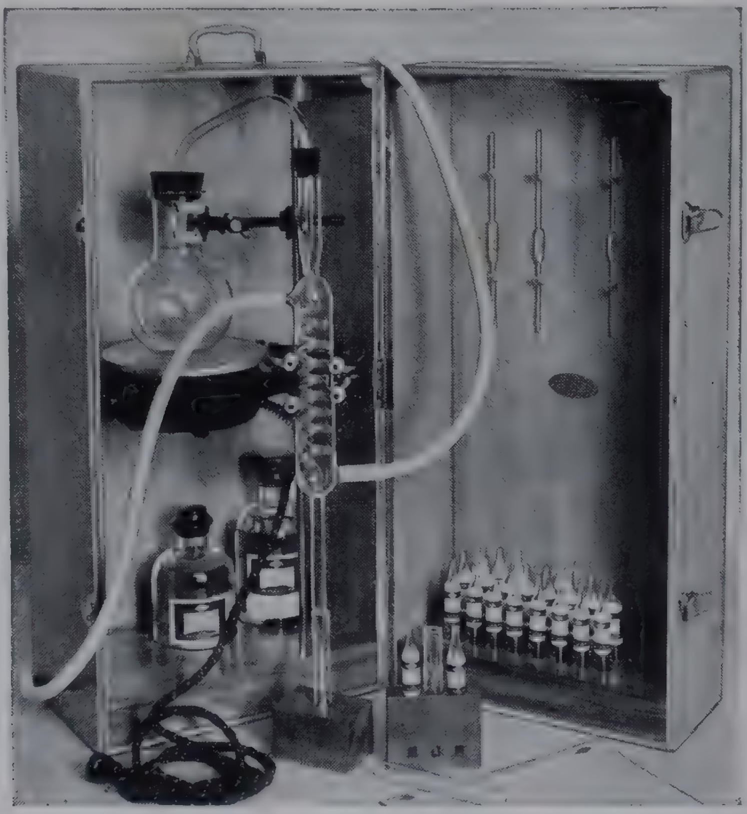

Fig. 687.—The LaMotte apparatus for determining concentration of alcohol in blood and urine. (Courtesy LaMotte Chemical Products Company, Baltimore, Md.)

LaMotte Outfit for Determining the Concentration of Alcohol in Blood and Urine[1]

This is a simple and specific test for alcohol in body fluids.

In operating the test the alcohol is distilled from a special acid mixture. The color which is developed by reaction of the distillate with standard potassium dichromate solution is compared with permanent color standards to obtain the percentage of alcohol in the fluid under examination.

---

*If the LaMotte Standards are used, the ⅝ inch test tube should be used since it is of the same bore.

[1] Heise, H. A.: Am. J. Clin. Path. 4: 182, 1934.

DETERMINATION OF METHYL ALCOHOL IN TISSUES

Gettler[1] made the subject of an investigation fifty-eight tests for methyl alcohol found in the literature. It was found by him after an analysis of over 250 liquors and over 700 human organs that some of these tests are unreliable and that foreign substances present have marked influence upon them. He therefore worked out a typical procedure which is quite reliable. His method follows:

Finely grind 500 gm. tissue, and place in a 1.5 liter distilling flask.

Add 500 c.c. water and enough sulphuric acid to make it distinctly acid.

Add a few drops of mineral oil to prevent frothing.

Distill with steam (Fig. 682). The distilling flask containing the material must be heated on a boiling water bath during steam distillation.

Collect 300 c.c.

Place the distillate in a 500 c.c. distilling flask, neutralize to phenolphthalein, if necessary, and slowly redistill, this time without steam.

Collect 100 c.c. and put into a 150 c.c. distilling flask.

Add 5 c.c. concentrated sulphuric acid and allow to cool.

Add 0.1 gm. potassium dichromate and shake to dissolve. Connect with the condenser and receiver and slowly distill until 40 c.c. are obtained. All the formaldehyde usually comes over in the first 40 c.c. unlike that in the distillation of the oxidized liquors. Use 2 c.c. of the distillate for each of the first five tests, and 30 c.c. for the sixth.

1. Fuchsin (reduced) plus sulphuric acid gradually develop a violet red color. If no sulphuric acid is added, both acetaldehyde and formaldehyde give the reaction.

2. Phenylhydrazine hydrochloride plus sodium nitroprusside plus sodium hydroxide yield a deep blue color.

3. To 3 c.c. of distillate add 5 c.c. of concentrated sulphuric acid; mix; cool. Then add a few mg. of morphine. A violet red color develops if methyl alcohol was originally present in this case.

4. To 3 c.c. of distillate add 3 c.c. of milk, then add a drop of very dilute ferric chloride and 5 c.c. of concentrated hydrochloric acid. Place the mixture in a boiling water bath. A violet color develops if methyl alcohol was originally present in the tissue examined. Although this test is unreliable when examining liquors, it is quite trustworthy and characteristic when working with tissues. This is probably due to the organism having destroyed or conjugated and excreted the interfering substance originally present in liquors.

5. To 3 c.c. of distillate add 5 or 6 drops of a saturated alcoholic solution of gallic acid and stratify some concentrated sulphuric acid underneath the mixture. A green to blue ring develops if methyl alcohol was originally present in the tissue.

6. Concentrated ammonia condenses with formaldehyde on evaporation into hexamethylenetetramine (urotropine). The latter gives characteristic crystals with mercuric chloride.

It is not necessary to obtain hexamethylenetetramine-mercuric chloride crystals to prove conclusively the presence of methyl alcohol in tissues. The reason for this is that the foreign substances found in liquors which cause false reactions are oxidized or conjugated and excreted rapidly from the organism, so that, on distillation of the brain or liver tissue, they are absent in the distillate.

---

[1] J. Biol. Chem. **43**: No. 2, June, 1920.

Rapid Method for Determination of Methyl Alcohol in the Blood and Body Fluids (Ozburn Method)

Ozburn[1] described a new test for methyl alcohol that is sensitive, specific, using stable and readily obtained reagents. It will detect as little as one microgram in one milliliter of water and easily has detected as little as two-tenths microgram of methyl alcohol in 1 c.c. of blood. Most procedures for the detection of methyl alcohol depend on its oxidation to formaldehyde and this method is no exception. The formaldehyde is usually determined by means of Schiff's reagent which is a solution of rosaniline decolorized by standard sulphurous acid in some form.* This reagent is unstable and pure quality rosaniline is difficult to obtain. Chromotropic acid and sodium bisulphite, both solids, are stable and easily procured in pure form. The advantages of these reagents over Schiff's is easy to understand. The concentrated sulphuric acid provides sufficient heat for the color reaction and vitiates the need for a water bath. The test is more specific than that with Schiff's reagent and the color produced is more stable, persisting 48 hours or more. The following substances have been tested for their possible interference in this test for methyl alcohol: ethyl alcohol, acetone, sodium formate, aspirin, Phenacetin, acetanilid, sodium barbital, sodium Amytal, phenobarbital, Nembutal, Seconal, procaine hydrochloride, cocaine hydrochloride, caffeine, atropine, quinine, Atabrine, nicotine, chloral hydrate, salicylic acid, sulfanilamide, sulfapyridine, sulfathiazole, and sulfadiazine. None give a positive test immediately, although nicotine, codeine, and quinine give a positive reaction upon standing overnight. Old solutions of cocaine, however, give a positive test, while fresh solutions do not. Methenamine (urotropin) gives an intense positive reaction, as would be expected.

Reagents.—

Sodium Bisulphite, $NaHSO_3$, reagent grade.

Chromotropic Acid, 1,8-dihydroxynaphthalene 3,6-disulphonic acid (Eastman Kodak Co., No. 1613).

Potassium Permanganate Mixture.—

Dissolve 15 gm. potassium permanganate
 and 75 c.c. of 85% phosphoric acid (H_3PO_4)
in distilled water and dilute to 500 c.c. with distilled water.

20% Trichloroacetic Acid.—

Dissolve 20 gm. of trichloroacetic acid in distilled water and dilute to 100 c.c. with distilled water.

Concentrated Sulphuric Acid, reagent grade.—

Technic.—

Place 2 c.c. of oxalated blood in a 50 c.c. Erlenmeyer flask.

Add 2 c.c. of 20 per cent trichloroacetic acid slowly with constant shaking.

Stopper the flask and shake well for 1 minute.

Pour contents into a 15 c.c. centrifuge tube and whirl for 5 minutes at 2000 r.p.m.

If the supernatant liquid is clear, carefully pipette 1 c.c. into a small test tube. If it is not clear, pour through a small No. 42 Whatman filter paper and use 1 c.c. of the filtrate.

Add 0.2 c.c. of the permanganate reagent and let stand for 1 minute, shaking gently from time to time.

---

*See page 2260.

[1] U. S. Naval Med. Bull. 46: 1170, 1946.

Add solid powdered sodium bisulphite, using just enough to decolorize the permanganate completely and also to decolorize any brown manganese dioxide that is formed. The amount of sodium bisulphite is usually about 10 mg., and the amount which will just cover the butt end of any ordinary pencil will usually suffice.

Add chromotropic acid powder and shake gently. The amount of chromotropic acid which can be lifted on the end of an ordinary safety match is sufficient.

Add 1.5 c.c. of sulphuric acid, tilting the tube and allowing the acid to flow down the sides of the tube so that it forms a separate layer underneath the solution. At this point, carefully examine the junction between the aqueous solution and the underlying sulphuric acid. If methyl alcohol is present, a purple ring will be seen at this junction.

Cautiously mix the contents of the tube by gently swirling it.

Let stand until cold.

If methyl alcohol is present, a diffuse violet color will be produced, the intensity of which will be proportional to the concentration of methyl alcohol.

Blood filtrates having no methyl alcohol give a light brown tint.

Those using the test should make preliminary determinations on several known positive and negative specimens to familiarize themselves with the procedure and the colors. Whenever possible, control positive and negative specimens should be run with each unknown.

Qualitative Test for Methyl Alcohol Using the Folin-Wu Blood Filtrate

Wright-Elvove Method Modified by Harger[1]

This is a modification of the well-known Wright-Elvove method. Harger found that the addition of a little ethyl alcohol to the fluid being tested greatly increases the sensitivity of the method when dealing with small quantities of methyl alcohol. This makes it possible to do the test directly on the Folin-Wu protein-free filtrate from blood (page 224), and thus avoid a distillation. The reagents are those described by Wright,[2] and are as follows:

Reagents.—

Potassium Permanganate.—

Dissolve 3 gm. potassium permanganate
in 100 c.c. distilled water (previously distilled over potassium permanganate) and containing 15 c.c. phosphoric acid.

By using water previously distilled from potassium permanganate solution, this reagent can be kept for a long time.

Oxalic Acid Solution.—

Dissolve 5 gm. of oxalic acid
in 100 c.c. of 50% sulphuric acid. (Dilute 50 c.c. of sulphuric acid, sp. gr. 1.84, to 100 c.c. with distilled water, adding the acid to the water in a Pyrex flask.)

Schiff's Reagent.—

Dissolve 0.2 gm. rosaniline (or equivalent weight of its salt)
in 120.0 c.c. hot distilled water.
Cool.

Dissolve 2 gm. of sodium bisulphite (metabisulphite) in 20 c.c. distilled water.

Add the rosaniline solution to the bisulphite solution, and add to the whole 2 c.c. concentrated hydrochloric acid.

Dilute the reagent to 200 c.c. with distilled water.

The reagent should become colorless or nearly so upon standing. No deterioration results if it is protected from the air. Use a very pure rosaniline base.

---

[1] Personal communication.

[2] J. Indust. & Eng. Chem. 19: 750, 1927.

Technic.—

Place 2 c.c. of Folin's protein-free filtrate (page 224) in a test tube, and add 1 drop of 95% ethyl alcohol.

Add 1 c.c. of potassium permanganate solution. Allow to stand for ten minutes, then decolorize by adding 1 c.c. of the oxalic acid solution.

Add 2 c.c. Schiff's reagent, and mix. The solution must be thoroughly mixed.

If methanol is present, a violet color develops. With traces of methanol, the color is not developed for an hour.

For approximate quantitative results, a comparison may be made with various standard solutions of methyl alcohol in water treated in the same manner. A convenient standard contains 0.2 mg. methyl alcohol dissolved in 2 c.c. water. In cases of fatal methyl alcohol poisoning as much as from 0.5 to 1.5 mg. of methyl alcohol per c.c. of blood was found by Harger.

For smaller amounts of methanol a distillate of the protein-free filtrate may be employed, distilling 2 c.c. from 20 c.c. of the protein-free filtrate.

DETERMINATION OF ALCOHOL IN LIQUORS

Per Cent by Volume and by Weight

Assemble distilling apparatus of appropriate size.

Pack the receptacle in ice. The receptacle of choice is a volumetric flask which is to be used as the standard measure of the final volume of distillate.

Preparation of Specimen

Whiskey and Gin.—

Dilute 10 c.c. of the sample to 200 c.c. with distilled water. Distill and collect 100 c.c. of the distillate. On the basis of per cent, or 100 c.c., using 10 c.c. of the sample gives a correction factor of 10 (the alcohol distills over before the water, consequently all the alcohol from the 10 c.c. sample will be in the distillate).

Wines.—

Dilute 25 c.c. of the sample to 200 c.c. with distilled water and proceed as for whiskey and gin, above. The factor for calculation is 4.

Beer.—

Dilute 100 c.c. of the sample to 200 c.c. with distilled water and proceed as for whiskey and gin. The factor for calculation is 1.

Determination of Alcohol

Obtain the density of the distillate by using either the hydrometer or the pycnometer. Use a constant temperature, preferably 20° C.

Use of Pycnometer.—Obtain the weight of the empty pycnometer (with stopper). Completely fill the pycnometer with distilled water at 20° C., insert stopper, and obtain the weight. Subtract the weight of the empty pycnometer from the weight of the pycnometer filled with water to obtain the weight of the distilled water. Now clean and dry the pycnometer, and completely fill it with the distillate. Obtain the weight. Subtract the weight of the empty pycnometer from this figure to obtain the weight of the distillate. Figure the specific gravity of the distillate by using the following formula:

$$\frac{\text{Weight of distillate}}{\text{Weight of the distilled water}} = \text{Specific gravity of the distillate.}$$

Calculation.—

Consult standard tables for conversion of specific gravity of alcohol to per cent by volume and by weight. Such tables are found in many handbooks of physics and chemistry.*

Multiply by the correction factor as given above.

Report in both per cent by volume and per cent by weight.

---

*Handbook of Chemistry and Physics, published by the Chemical Rubber Publishing Company, Cleveland, Ohio, contains these tables.

TESTING OF WHISKIES FOR IMPURITIES

Coloring

Shake together 5 c.c. of the sample and 5 c.c. of chloroform.

A clear color in the chloroform suggests artificial coloring.

The natural color will be in the chloroform.

Fusel Oil

To 10 c.c. of the sample, add 10 drops of colorless aniline and 3 drops of sulphuric acid.

A deep red color is formed if fusel oil is present.

DETECTION OF METHYL ALCOHOL IN LIQUORS[1]

Preparation.—

Place 100 c.c. of liquor in a 200 c.c. distilling flask, neutralize with sodium carbonate solution, using phenolphthalein as indicator, and slowly distill until 50 c.c. of distillate have been collected.

Oxidation.—

Add 100 c.c. of 10% sulphuric acid to distillate, using a 250 c.c. distilling flask; also add 6 gm. of potassium dichromate and let stand for 10 minutes. Connect with a condenser and receiver and very slowly distill off 30 c.c.

The distillation of these 30 c.c. should take 1 hour; the distillate then contains most of the acetaldehyde, but very little of the formaldehyde, and is to be rejected. The distillation is then continued a little faster, until 60 c.c. are obtained. This part of the distillate contains most of the formaldehyde and hardly any acetaldehyde. Some formaldehyde may still be left in the distilling flask, but the greatest portion is in these 60 c.c. and this is used for the tests.

Detection.—The tests are conducted in the following sequence:

1. To 2 c.c. of this oxidized fraction add 10 drops of a 5% solution of phenylhydrazine hydrochloride, 1 drop of 0.5% sodium nitroprusside solution, and 10 drops of 10% sodium hydroxide solution. If formaldehyde is present, a blue color is obtained which changes to green and then to yellowish red. Acetaldehyde produces a red color.

2. To 2 c.c. of the material add 2 drops of 2% phenol and carefully stratify sulphuric acid underneath. A red ring develops. Acetaldehyde gives a yellowish green, brown, or reddish brown ring.

3. To 2 c.c. of the oxidized material, add 5 c.c. of concentrated sulphuric acid, then add a few mg. of apomorphine. A reddish violet color develops.

4. Add 0.08 gm. peptone, 3 drops of 3% ferric chloride, and 2 c.c. of concentrated hydrochloric acid to 2 c.c. of the oxidized material, and heat to boiling. If the original sample contained as little as 1% of methyl alcohol, a bright violet coloration develops. Less peptone and less ferric chloride make it more sensitive.

5. To 2 c.c. of the material add 1 c.c. of concentrated sulphuric acid, cool, and add 5 c.c. of fuchsin bisulphite solution; mix and allow to stand. The presence of formaldehyde is indicated by the violet red color which gradually develops.

The *fuchsin solution* is made as follows:

Dissolve 0.5 gm. of basic fuchsin in 200 c.c. of distilled water; add an aqueous solution of sulphur dioxide, the quantity corresponding to 1 gm. of sulphur dioxide gas; allow to stand until the solution assumes an amber color (this requires about one hour). The colorless fuchsin bisulphite solution which is obtained when more than 1 gm. of sulphur dioxide is added to 0.5 gm. of fuchsin is valueless as a reagent after standing two days. A solution prepared as outlined will keep well for ten days, although it is recommended not to use a solution after seven days.

6. Place 10 c.c. of the oxidized material in a small evaporating dish, and add 10 c.c. of strong ammonia. Evaporate just to dryness on a water bath. The formaldehyde con-

---

[1] Gettler: J. Biol. Chem. 43: 2, June, 1920.

denses with the ammonia to hexamethylenetetramine. Dissolve this latter in a few drops of water. Add a drop of 5% mercuric chloride solution to a small amount of this solution, and place on a microscopic slide. Typical crystals of hexamethylenetetramine-mercuric chloride develop. The shape of these crystals varies with the concentration. It is, therefore, best to make control experiments for comparison with the suspected material.

7. Place in a test tube 3 c.c. of the oxidized distillate, 0.04 to 0.06 gm. of β-naphthol, and 3 to 5 drops of concentrated hydrochloric acid. Boil gently until the liquid becomes filled with an abundant precipitate of small white needles. Filter while hot. Wash with 1 c.c. of dilute alcohol (1:2). Boil the precipitate with 4 c.c. of dilute alcohol (1:1). (It is not necessary that all should dissolve.) Cool and filter off the precipitate. Wash with 1 c.c. of dilute alcohol (1:1). Dry on porous tile in a warm place and determine the melting point.

Methylene-di-β-naphthol, the product, forms white needles which, when the temperature in the neighborhood of the melting point is raised at the rate of 1° in fifteen seconds, begins to turn brown at 180°. It melts with decomposition to a red brown liquid at 189°-192° (uncorrected).

TOLUENE POISONING

Von Oettingen, Neal, and Donahue[1] showed that the concentration of toluene in the blood and elimination of hippuric acid in the urine were tests to determine toluene poisoning. Elimination of hippuric acid in the urine and concentration of toluene in the blood increase with the concentration of toluene in air. They found, in contrast to experience with benzene, the ratio of inorganic sulphates in the urine was not noticeably affected by exposure to toluene.

For the determination of the hippuric acid in the urine, they used Quick's method in the modification described by Kraus and Dulkins[2] in 1941.

To make this determination, acidulate the urine with acetic acid until acid to litmus and then concentrate to a volume of 150 c.c. by evaporation. To this concentrated urine, add sodium chloride, while heating and stirring, until a total of 45 gm. have been added (30 gm. per 100 c.c.). Cool to room temperature and, while stirring and scratching the sides of the beaker, add sulphuric acid of the concentration 1:1, drop by drop, until no further precipitate of hippuric acid is formed. Usually 2 to 5 or 6 c.c. of sulphuric acid are sufficient. In order to insure complete precipitation, add additional sulphuric acid to the filtrate, and in case no further precipitation occurs, allow the precipitate to stand for at least 15 minutes and then filter. Wash precipitate and beaker repeatedly with a 30% solution of sodium chloride which is free of sulphate ions, until the washings give a negative test for sulphate ions. When the washing is completed, transfer precipitate and filter to the beaker in which the original precipitation was made, add 75 to 100 c.c. of distilled water, and heat the mixture until the precipitate is dissolved. Titrate, hot, with 0.5 normal sodium hydroxide with phenolphthalein as indicator, and from the amount of sodium hydroxide used, calculate the quantity of hippuric acid. Whereas with concentrations of more than 300 mg. of hippuric acid per 150 c.c. of urine this method gives fairly accurate results, these become increasingly less exact with lower concentrations because comparatively large quantities escape the precipitation.

With this procedure, the normal hippuric acid excretion in the urine within 24 hours was determined as 403 mg. (average of 6 persons), which is somewhat lower than that frequently quoted in the literature, namely, 0.7 gm. These determinations show that the amount of hippuric acid excreted increased, roughly, with the intensity of the exposure.

In addition, the determination of toluene in blood may be utilized for appraisal of the intensity of the exposure. From the cubital vein of two of the subjects, von Oettingen and associates withdrew 5 c.c. of blood at the end of the exposure and the toluene content was determined with the method of Yant, Pearce, and Schrenk.[3] This was modified in several respects in their laboratory. Their results show that the concentration of toluene in blood increases as its concentration in air increases. In order to further prove this point, three dogs were exposed experimentally simultaneously with the human subjects to concentrations of 300 parts per million of toluene in air, and the concentration of toluene in their blood was determined at the end of the experiment. This was found in two animals to be 0.74 and 0.79 mg. per 100 c.c. of blood, and in the third, in which the sample was smaller than usual, 1.04 mg. per 100 c.c. These first two values check very well with the 0.73 mg. per 100 c.c. which was found in the human beings in the same experiment. It appears, therefore, that dogs can be well utilized for such determinations. It was found that concentrations of around 0.5 mg. per 100 c.c. of blood may already have caused definite impairment of certain nervous functions.

DETECTION OF CYANIDE IN TISSUES

The cyanide odor often suggests the presence of cyanide. However, a chemical and biological test must also be made.

Detection of Cyanide in Human Tissues.[4]—The following tests have been recommended for the detection of cyanide in gastrointestinal contents, body tissues and fluids:

1. **Copper-Guaiac Test.**—Place about 50 gm. of finely ground organ or a few centimeters of stomach contents in a 100 c.c. flask. Acidify the material with tartaric acid, and suspend above it a strip of freshly prepared copper sulphate-guaiac paper (filter paper which has been wet in turn with 10% alcoholic solution of guaiac and 0.1% aqueous copper sulphate solution), stopper the flask, warm contents a little and allow to stand about one-half hour. If a blue or green color does not develop on the paper then cyanide is definitely excluded. No further tests for cyanide need be done, because this is the most sensitive test available. If a blue color develops, cyanide may be present. Since, however, the blue color is also produced by ammonia gas, hydrogen, chloride, ozone, oxides of nitrogen, bromine, chlorine, and hydrogen peroxide, 2 or 3 of the following tests must be resorted to in order definitely to establish the presence of cyanide in the material.

For the following tests, the distillates obtained by steam distillation of the acidified organs and stomach contents are used. See page 2243.

2. **Liebig's Thiocyanate Test.**—Place 20 c.c. of the distillate and 2 c.c. of ammonium polysulphide in an evaporating dish. Evaporate to dryness on a steam bath. Treat the residue with 5 c.c. of water, slightly acidify with hydrochloric acid, warm it a little, stir thoroughly, and allow to stand several hours so that the colloidal sulphur may precipitate. Filter. Add 10% ferric chloride dropwise until a maximum color intensity is obtained. A red color indicates the presence of cyanide.

A variation of the test is: Boil an aliquot portion of the distillate with ammonium sulphide for a few minutes, concentrate to 1 c.c., acidify with hydrochloric acid, and extract several times with ether. Allow the ethereal extracts to evaporate spontaneously. Add ferric chloride solution dropwise to the residue as long as the color deepens. If a red color develops, which is soluble in ether, the presence of cyanide is established.

---

[3] Yant, W. P., Pearce, S. J., and Schrenk, H. H.: A Microcolorimetric Method for the Determination of Toluene. Washington, D. C., Bureau of Mines Reports, Investigation, 3323, 1936.

[4] Gettler, A. O. and Baine, J. O.: Am. J. M. Sc. **195**: 182, 1938.

3. **Prussian Blue Test.**—Make 20 c.c. of the distillate strongly alkaline with sodium hydroxide solution, and concentrate to about 2 c.c. Add 2 drops of 5% ferrous sulphate and 1 drop of 10% ferric chloride. Warm the mixture slightly. Add concentrated hydrochloric acid drop by drop, avoiding an excess, until the brown precipitate of iron hydroxide just dissolves. If cyanide is present, a deep blue color or precipitate of Prussian blue remains, which is insoluble in dilute hydrochloric acid.

4. **Vortman Test.**—To 5 c.c. of the distillate add a few drops of 10% potassium nitrite solution and 2 to 4 drops of 5% ferric chloride, and sufficient dilute sulphuric acid to give the mixture a bright yellow color. Heat the mixture to boiling, allow to cool, add sufficient ammonia to precipitate the excess of iron, and filter. To the filtrate add a few drops of very dilute ammonium sulphide solution. If cyanide is present, a violet color appears which gradually passes through blue, to green, and then yellow.

5. **Phenolphthalein Test.**—To 2 c.c. of the distillate add 2 or 3 drops of a colorless alkaline solution of phenolphthalein (made by boiling, under a reflux, a dilute sodium hydroxide solution of phenolphthalein with zinc dust until colorless) and a drop of very dilute (1 to 2,000) copper sulphate solution. The development of a red color indicates the presence of cyanide.

6. **Picric Acid Test.**—Make 5 c.c. of the distillate faintly alkaline with sodium hydroxide solution, and add 2 or 3 drops of saturated picric acid. On warming, a red color develops if cyanide is present in the sample.

7. **Ferrous-Uranic Test.**—Dissolve about 5 mg. of ferrous sulphate, and the same quantity of uranic nitrate in 50 c.c. of water. Place 1 c.c. in a porcelain dish and add 1 or 2 drops of the distillate to be tested. The appearance of a gray-purple color or purple precipitate indicates the presence of cyanide.

8. **Silver Test.**—Place 30 c.c. or less of the distillate in a 50 c.c. flask, and acidify with 6N nitric acid. Place a hanging drop of silver nitrate solution on a glass slide over the mouth of the flask. After 30 minutes, carefully remove the slide, add 1 drop of dilute nitric acid to the drop on the slide, and place a cover slip over it. Slightly heat the material under the cover slip by playing a very small flame across the underside of the glass slide. On cooling, long slender crystals of silver cyanide are visible under the microscope. Silver chloride crystallizes as octahedra, and can therefore easily be differentiated from silver cyanide.

Test No. 1 is used as a preliminary rapid and sensitive method of ruling out the presence of cyanide. For definitely establishing its presence, Tests 2, 3, and 8 are recommended.

Gettler and Baine Method for Cyanide

The following analytical methods for the detection of cyanide in tissues are those of Gettler and Baine.[1]

Immediately upon removal of the organs from the body, place them in a covered receptacle in the refrigerator. When ice cold, pass 125 gm. through a meat grinder previously cooled by cracked ice. These precautions are to prevent any loss of HCN by volatilization. Quickly place 100 gm. of the finely divided tissue in a 500 c.c. flask (Fig. 688, *B*), and add 300 c.c. of cold water, 2 c.c. white mineral oil, and 10 c.c. of 5% tartaric acid. Mineral oil prevents frothing during distillation; tartaric acid facilitates complete removal of the cyanide. Connect the flask to a vertical, water-cooled condenser (*C*), and join this to 3 absorption tubes (*D*), connected in series. Each absorption tube contains 10 c.c. of N/10 sodium hydroxide. Apply suction to the side-arm of the last absorption tube. Heat the water in bath (*A*) to boiling, then regulate the suction so that the content of the flask (*B*) is vigorously agitated, but slowly (about 5 drops per minute) distills into the first alkali absorption tube. Any escaping HCN is absorbed from tube D_1 in the alkali solution of D_2 and D_3. After 2 hours of distillation, shut off the suction and disconnect from the distillation flask at *E*. Transfer the 3 alkali absorption solutions quantitatively to a 100 c.c. volumetric flask, and make up to the 100 c.c. mark. If very small quantities of cyanide are suspected in the tissues, keep the final volume down to 50 c.c. by washing each tube successively with the same wash water. If the resulting solution is not perfectly clear, cool to 0° C., and then filter through a dry filter paper. Take aliquot portions for analysis.

---

[1] Am. J. M. Sc. **195**: 182, 1938.

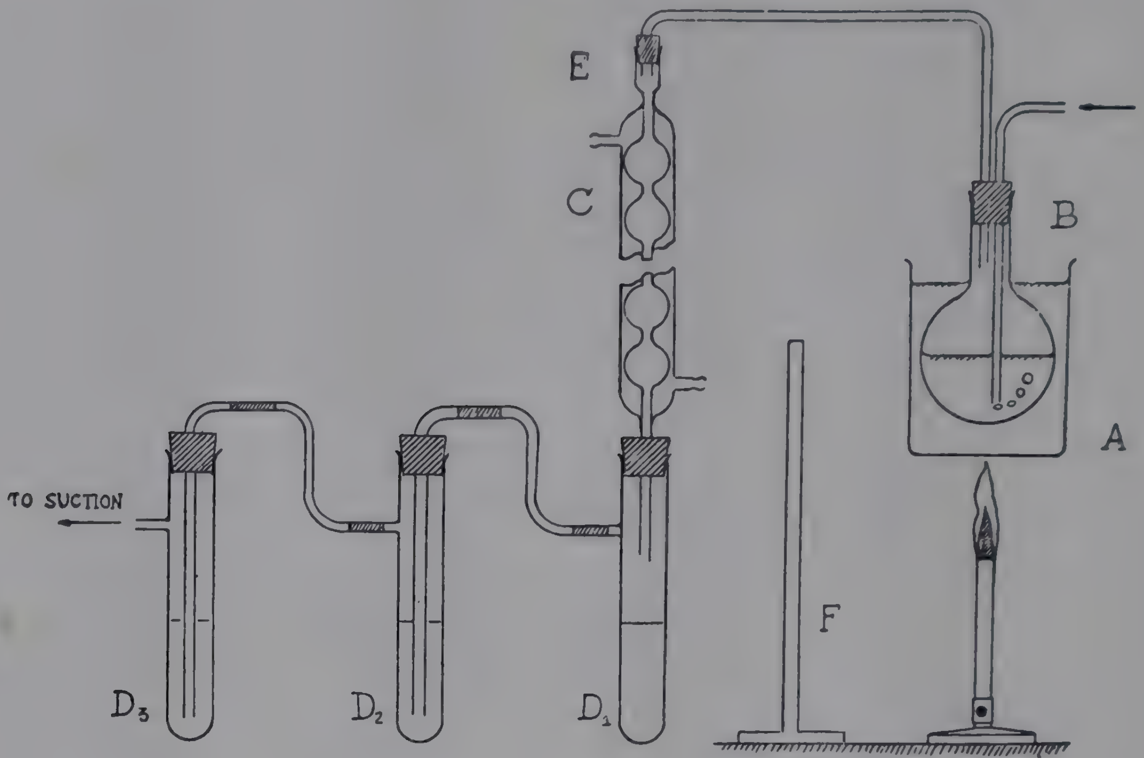

Fig. 688.—*A*, Water bath; *B*, round-bottom flask; *C*, reflux condenser; D_1, D_2, D_3, absorption tubes; *F*, asbestos screen. (Gettler and Baine: Am. J. M. Sc., 1938.)

Gettler and Baine Quantitative Determination of Cyanide

For the quantitative estimation of cyanide, Gettler and Baine tested out the various methods and found the Colorimetric Ferric Thiocyanate Method and the Volumetric Silver Nitrate Method fairly accurate. These are as follows:

9. **Colorimetric Ferric Thiocyanate Method.**—Place in a small evaporating dish an accurately measured aliquot of the alkaline absorbed distillate, containing in the neighborhood of 1 mg. of HCN (as previously determined by the picrate method), and add 10 c.c. of ammonium polysulphide.* Evaporate the mixture to dryness on the water bath. Add to the residue 30 c.c. water and N/10 hydrochloric acid until distinctly acid. Heat slightly, stir thoroughly, and allow to stand overnight to insure complete precipitation of the colloidal sulphur. Filter into a 50 c.c. volumetric flask, washing the evaporating dish and residue on filter paper with small portions of water, and adding washings to the main filtrate. Add 5 c.c. of 10% ferric chloride and enough water to bring the volume to the 50 c.c. mark, mix thoroughly, and compare the red color obtained in a colorimeter with a standard potassium thiocyanate solution (3.6 mg. potassium thiocyanate, equivalent to 1 mg. HCN, plus 5 c.c. of 10% ferric chloride made up to 50 c.c. with water). Should the HCN content in the distillate be very small (0.2 mg. or less in 10 c.c.) then reduce all working volumes and keep the final volume down to 25 c.c.

10. **Volumetric Silver Nitrate Method.**—Place 25 c.c. of the alkaline absorbed distillate containing the cyanide in a 50 c.c. Erlenmeyer flask. Add 2 c.c. concentrated ammonium hydroxide and 1 c.c. of 10% potassium iodide solution. Titrate the cyanide with 0.005/N

---

*Saturate 600 c.c. of concentrated ammonium hydroxide with H_2S, then dilute to 1 liter with concentrated ammonium hydroxide. Add an excess of powdered sulphur, and let stand, shaking occasionally, until saturated.

silver nitrate solution. The end point occurs with the formation of a bluish-white opalescent cloud of silver iodide, which is very sharp, and most easily observed against a black background.

Calculation: each c.c. of 0.005/N silver nitrate solution is equivalent to 0.266 mg. of HCN.

11. **Biological Presumptive Test for Cyanide.—**

Take up a portion of the material to be tested in a dropper with a rubber bulb.

Feed it to a guinea pig.

If the guinea pig fails to show symptoms within five minute, feed it a small amount more of the specimen.

If 15 c.c. fail to give symptoms, cyanide is not present.

If, upon feeding, the guinea pig dies with typical cyanide convulsions, within one to ten minutes, the specimen probably contains cyanide.

12. **Other Simple Chemical Tests.—**

Grind up a portion of the material to be tested.
Cover it with distilled water.
Distill the specimen over steam.
Collect several portions of the distillate.
Test as follows:

1. Mix equal parts of the distillate and yellow ammonium sulphide.
Evaporate to dryness.
Add a few drops of hydrochloric acid, c. p., and 5 c.c. of 10% ferric chloride.
A blood red color develops if cyanide is present.

2. Mix equal parts of the distillate and 10% ferric chloride and ferrous sulphate.
Add a few c.c. 10% potassium hydroxide.
A green precipitate is formed.
Add hydrochloric acid.
If cyanide is present, a Prussian blue is formed.

3. Place about 5 c.c. of the distillate in a test tube.
Add 2 c.c. 5% silver nitrate solution.
A white precipitate is formed if cyanide is present.

Is Cyanide Normally Present in Human Organs?—

Gettler and Baine failed to detect HCN in normal tissues.

What is the minimum lethal absorbed dose of cyanide? 0.5 mg. HCN per kilo of body weight.

What is the effect of putrefaction on the cyanide content of tissues? Putrefaction interferes in the colorimetric picrate method and in the silver nitrate titration. The colorimetric thiocyanate method alone gives reliable results when applied to putrefied material. Cyanide material is little changed during putrefaction.

Is cyanide produced during putrefaction of normal tissue? A small amount of cyanide is produced during putrefaction, 0.01 to 0.03 mg. of HCN per 100 gm. of tissue, but since this is only one-tenth of the lowest content ever found in organs where death was due to cyanide poisoning, putrefaction should in no way interfere in deciding a cyanide poisoning case.

Does embalming alter the cyanide content of organs? Cyanide in tissue is rapidly lost when the tissue is embalmed with formaldehyde.

MICROCHEMICAL DETERMINATION OF YELLOW PHOSPHORUS[1]

The following method for the confirmation and quantitative determination of yellow phosphorus uses a spot test color reaction which is confined to a standard area, the color intensity of which is proportional to the concentration of phosphorus present. This method is not only specific and sensitive, but also very simple. The test is based upon the formation of phosphine, which in turn easily reduces a mercuric bromide test paper, yielding a canary yellow color.

Phosphorus may exist in several forms; the best known of these are yellow and red phosphorus. Red phosphorus is considered by most authorities as nontoxic, whereas yellow phosphorus is very toxic, 0.1 gram having been recorded as a fatal quantity. Yellow phosphorus is used commonly in rat poison pastes. Acute poisoning is usually accidental, although there are records of suicides and homicides in which phosphorus had been used. The method outlined here is applicable to yellow phosphorus only, and is satisfactory from a toxicologic standpoint.

Phosphorus may remain in the body for several days; the greater the delay in obtaining the specimen, however, the less the possibility of detecting phosphorus. The procedure of isolating it for analysis depends upon its volatility. Stomach contents are best suited for analysis. The liver is the organ of choice.

Symptoms.—Progressive pain and burning sensations along the gastrointestinal tract, eructation of gas, choking, vomiting, and diarrhea are symptoms of phosphorus poisoning. Other symptoms are frequently noted: garlic odor on the breath, jaundiced skin, bleeding from the nose and from the intestines, muscular paralysis, and impairment of the special senses. Terminally, stupor, delirium, and coma occur. Death ensues usually within two to six days.

Treatment.—Irrigate the stomach with 1 per cent potassium permanganate solution and large amounts of suspended charcoal. If this is done quickly, the treatment may be effective.

Post-Mortem Findings.—There is erosion of the mucous membrane of the gastrointestinal tract, with fatty degeneration and acute yellow atrophy of the liver. The stomach contents, as a rule, have the odor of garlic, and if viewed in the dark, give off a greenish phosphorescent light.

Chemical Analysis.—The following *qualitative* tests have been used to identify phosphorus:

1. **Odor.**—A garlic-like odor may be recognized upon opening the stomach.

2. **Scherer's Test.**—Have on hand Whatman No. 40 filter paper cut in strips, and impregnated with silver nitrate, and other strips impregnated with lead acetate.

Place a portion of the finely divided material to be examined in an Erlenmeyer flask. Suspend it in distilled water.

Suspend 2 strips of filter paper over the suspected sample, one impregnated with silver nitrate and the other with lead acetate.

Heat the contents at about 50° C. on a water bath, for approximately one hour.

If the silver nitrate paper turns black, either phosphorus or hydrogen sulphide may be present.

If both papers turn black, hydrogen sulphide is present, and phosphorus may also be present.

The fact that the silver nitrate paper turns black is not conclusive proof that phosphorus is present, since any volatile reducing agent, such as formaldehyde, may also give the same reaction. This test, therefore, is more important in indicating the absence of phosphorus rather than its presence.

---

[1] Kaye, Sidney: J. Lab. & Clin. Med. 28: 2, Nov., 1942.

Quantitative Test for Phosphorus (Kaye)

Set up a distillation apparatus as illustrated in Fig. 689.

Transfer a weighed aliquot of the sample to a steam distillation apparatus containing about 100 c.c. of distilled water. Use an ice-cooled receiver to collect the distillate.

Shield the light from the Bunsen burner by a sheet of asbestos to prevent interference in the visual detection of the phosphorescence emitted.

Carry out the distillation in the dark.

Collect the distillate in a small volume of 0.5 N silver nitrate, cooled in a 125 c.c. Erlenmeyer flask immersed in an ice bath.

Greenish, phosphorescence may be seen as the phosphorus vapors reach the condenser (Mitscherlich's phosphorescence test). As little as 60 gamma[2] in 200 grams of material will give a good phosphorescence. However, in the presence of alcohol, ether, benzene, turpentine, phenols, chloroform, essential oils, oxidizing agents, mercury, copper, and silver, there may be a marked diminution or complete absence of phosphorescence.

Continue distillation until about 75 c.c. are collected. As the first traces of phosphorus come over into the silver nitrate solution, a black precipitate of silver phosphide forms. After about 75 c.c. of distillate have been collected, no further precipitate will form.

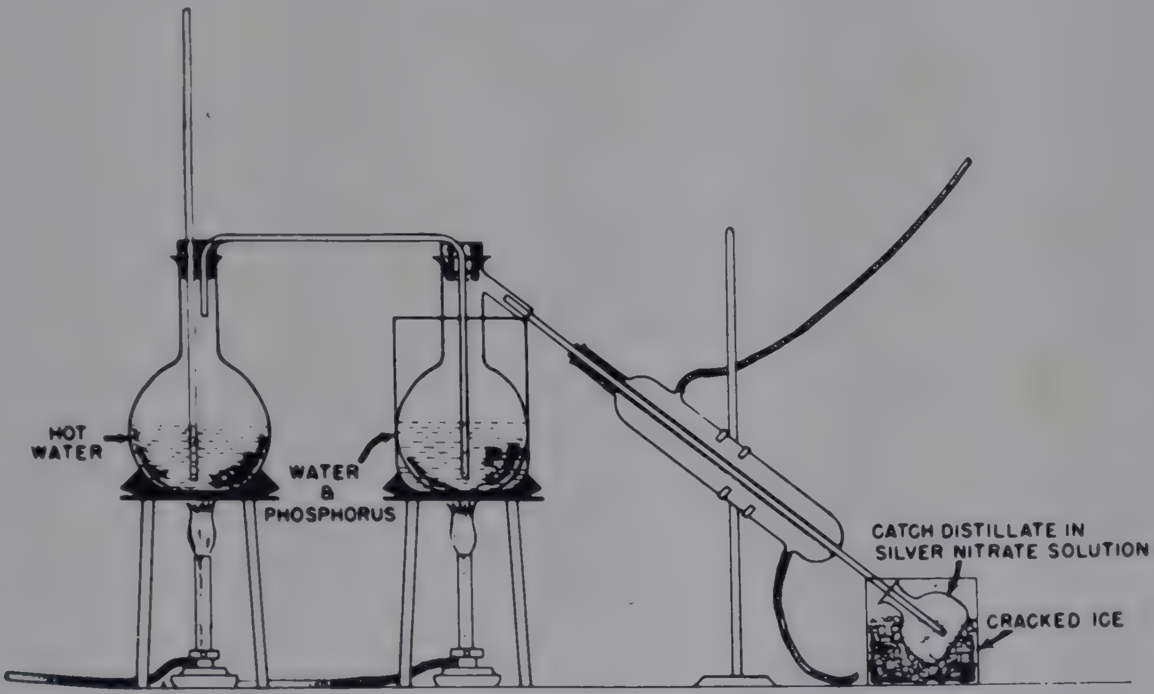

Fig. 689.—Distillation apparatus for phosphorus determination, method of Kaye.

Silver phosphide is a heavy precipitate and settles rapidly. Siphon off the supernatant liquid without disturbing the precipitate, leaving a small amount of the liquid behind.

Wash the precipitate in the flask with several portions of distilled water to remove the last traces of any silver nitrate which might have adhered to the precipitate.

Again siphon off the supernatant fluid. Two washings usually suffice.

Test the washings for silver ions by using a chloride solution.

If the precipitate in the receiving vessel is slight, make up the volume to 50 c.c. with distilled water.

If the precipitate is heavy, dilute to a larger definite volume with distilled water.

Swirl the solution well so as to divide the precipitate evenly, withdraw a small aliquot, and record the amount withdrawn.

Place this aliquot in a previously prepared modified Gutzeit apparatus. See Fig. 690.

Modified Gutzeit Apparatus.—The modified Gutzeit apparatus consists of a 125 c.c. Erlenmeyer flask containing some arsenic-free zinc, several drops of 5 per cent copper sulphate solution to activate the generating process, and 25 to 40 c.c. of 20 per cent sulphuric acid. The amount of sulphuric acid should be sufficient to dissolve the precipitate in the aliquot which is to be added. Excess does not interfere. The stopper in the flask supports a small calcium chloride drying tube into which is plugged some cotton impregnated with lead acetate. Above this tube is attached a pair of flanges[3] between which is placed a disk of mercuric bromide sensitized filter paper. When the silver phosphide comes in contact with the hydrogen generating solution, phosphine is liberated.

---

[2] One gamma = 0.000001 gram or 0.001 mg.

Keep the generating flask warm in a water bath at about 50° C. Phosphine travels upward and is purified from hydrogen sulphide by passage through the lead acetate-saturated cotton. On reaching the flanges, where it comes in contact with the moistened mercuric bromide paper, a yellow color results which is directly proportional to the phosphine produced.

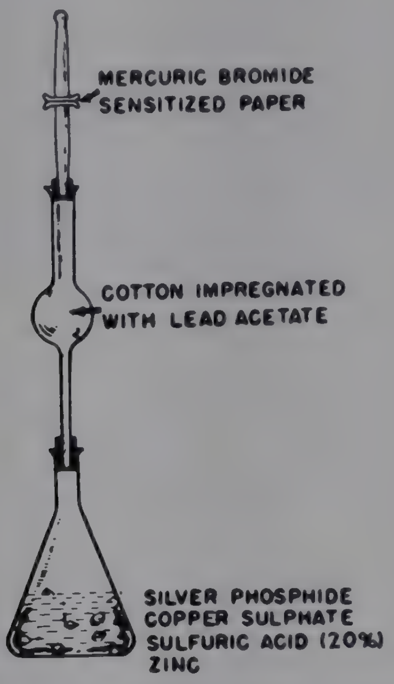

Fig. 690.—Modified Gutzeit apparatus for the determination of phosphorus.

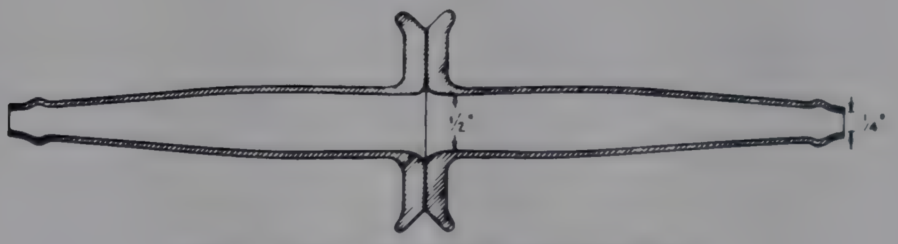
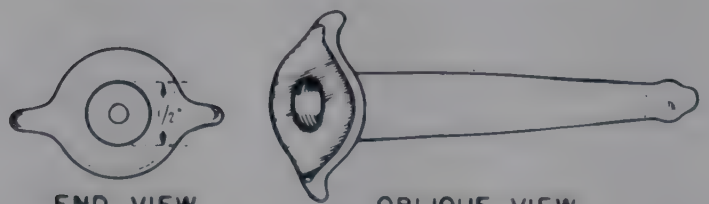


SIDE VIEW (TWO UNITS ASSEMBLED)



END VIEW (SINGLE UNIT)

OBLIQUE VIEW (SINGLE UNIT)

Fig. 691.—Microchemical flanges for the modified Gutzeit apparatus.

Since the bores of the several flanges are uniform, comparisons can be made with phosphorus standards prepared in a similar manner. These yellow standards are fairly stable and can be kept for several months once they have dried.

This color reaction is sensitive to less than 10 gammas of phosphorus.

CAUTION: To make sure that the zinc and other reagents are arsenic and phosphorus free, before adding the silver phosphide, liberate hydrogen for some time and then examine the filter disk. There should be no discoloration of the filter disk. Add the silver phosphide and put the flanges in place. Allow the generator to run for about half an hour.

---

[3] Flanges may be purchased from Eck and Krebbs, or from E. Machlett & Sons, both of New York.

Microchemical Flanges

The microchemical flange used for this determination is illustrated in Fig. 691. These flanges are of great value in quantitative gas and solution analyses where the intensity of a color reaction, which is proportionate to known amounts of the substance concerned, can be recorded.

They have been used in the determination of sulphides, cyanides, arsenic, antimony, carbon monoxide, and other substances. For substances in solution, which give brilliant graded colors with a detector, the flanges have also proved successful.

The flange device is used in the research Laboratories of the St. Louis Police Department, Toxicology Laboratories in New York City, Baltimore, Washington, D. C., and Virginia.

Mercuric Bromide Papers

Mercuric bromide sensitized paper is prepared by cutting disks of Whatman No. 40 filter paper which are then impregnated with 5 per cent mercuric bromide in 95 per cent alcohol for about 5 minutes. After shaking off the droplets, a disk is fastened between the flanges with a rubber band.

TEST FOR DETERMINING CHLOROFORM CONTENT OF THE BRAIN FOLLOWING ANESTHESIA

The problem of the determination of the chloroform content of the brain following anesthesia is sometimes of medicolegal interest. Gettler and Blume[1] described the technic which they have worked out for this determination. It has been shown that a brain of a person sufficiently anesthetized for a minor operation contains 120 mg. to 182 mg. of chloroform in 1,000 gm. of brain tissue. Gettler and Blume made intensive investigations on dogs which were killed by excessive administration of chloroform and then tested. Animals when fully anesthetized with chloroform showed in the brain 270 mg. and 284.6 mg. in 1,000 gm. of tissue. An animal in the stage of recovery showed a drop in the amount of chloroform in the brain during the first thirty-four minutes, so that only 51.3 mg. in 1,000 gm. of brain tissue were left. From this time on, the chloroform content decreased more slowly, and after 190 minutes there was only 0.16 mg. of chloroform present in 1,000 gm. of brain tissue. In the stage of recovery, the lungs contained much less chloroform than the brain.

Gettler and Blume's technic for their experimental work on animals is given below and can well be followed in dealing with human material.

Ten dogs were used in these experiments. After being tied to the animal board, they were anesthetized with chloroform, the open mask method being used. They were kept in a state of surgical anesthesia for definite periods. The mask was then removed, and the animals were allowed to recover spontaneously. Dog 6 was not allowed to recover but was sacrificed by excessive administration of chloroform. In dogs 5 and 7, the trachea was clamped while they were fully anesthetized. In order to investigate the chloroform content of the brain at various stages of recovery, the dogs were sacrificed at stated intervals. Painless death was obtained by injecting morphine and then exposing and clamping the trachea. Autopsy was then performed. The brain and lungs were removed, weighed and placed in the ice box in sealed containers until the analysis was started.

Method of Analysis.—The brain and lungs, when ice cold, were ground up, and quickly placed in a 500 c.c. distillation flask; about 100 c.c. of water was added and also a little tartaric acid, enough to make the mixture acid in reaction. The material was then subjected to steam distillation, a long, well-cooled condenser and an adapter being used. The receptacle for collecting the distillate, a 300 c.c. Erlenmeyer flask, contained about 10 c.c. of ice cold, acidified hydrochloric acid water and was packed in ice. The tip of the adapter reached into the ice cold water contained in the receptacle for distillate. With these precautions, there was no loss of chloroform during distillation. Our experiments have proved that, if 250 c.c. of distillate are collected, all of the chloroform in the tissues will have passed into the distillate. The distillate was well mixed, measured, stoppered, and kept cold; 5 c.c. portions of this distillate were taken for the colorimetric determination.

---

[1] Arch. Path., p. 841, June, 1931.

Colorimetric Estimation of Chloroform in Distillate.—The materials necessary for the colorimetric estimation of the chloroform in the distillate were: chemically pure pyridine (colorless), 20% sodium hydroxide solution, and the standards to be described.

Chloroform Standards.—One gram of pure chloroform was weighed by placing slightly more than 1 gm. of chloroform in a weighing bottle with a groundglass stopper, allowing the chloroform to evaporate spontaneously and weighing from time to time (with weighing bottle stoppered) until the weight of the chloroform in the bottle was just 1 gm. This gram of chloroform was then dissolved in about 900 c.c. of water contained in a 1-liter volumetric flask; 5 c.c. of hydrochloric acid were added, and finally enough water was added to bring the total volume to exactly 1 liter. The whole was thoroughly mixed. Precautions were taken to avoid evaporation of the chloroform during the transfer. This solution contained 1 mg. of chloroform in each cubic centimeter. From this stock solution, a series of weaker standards were made, having the following chloroform values: 0.5 mg. in 1 c.c.; 0.1 mg. in 1 c.c.; 0.01 mg. in 1 c.c.; 0.005 mg. in 1 c.c.; 0.0025 mg. in 1 c.c. These standards do not keep; new standards were made for each set of determinations.

Procedure.—Into five clean, dry, 50 c.c. test tubes were pipetted 5 c.c. portions of the five standards containing, respectively, 0.5 mg., 0.1 mg., 0.01 mg., 0.005 mg. and 0.0025 mg. of chloroform per cubic centimeter (see Preparation of Standards). Into a similar test tube were pipetted 5 c.c. of the distillate. To each of the tubes, 5 c.c. of chemically pure (colorless) pyridine and 10 c.c. of 20% sodium hydroxide solution were added. The contents of each tube were mixed and the tube loosely corked to avoid evaporation. The tubes were placed in a boiling water-bath for exactly one minute and then quickly cooled by running water; 20 c.c. of water were added to each tube, and the contents were mixed. Of the series of standards, the one that matched the color of the unknown closest was used as the standard and read against the unknown in the colorimeter.[1]

Calculation.—

$$\frac{\text{Standard}}{\text{Unknown}} \times \begin{matrix}\text{Value of standard used in}\\ \text{milligrams of chloroform}\end{matrix} \times \frac{250}{5} \times 1.087 \left(\begin{matrix}\text{correction for per-}\\ \text{centage of recovery}\end{matrix}\right)$$

$$= \text{milligrams of chloroform in grams of tissue used.}$$

DETECTION OF CHLOROFORM IN THE BRAIN, LUNGS, AND LIVER

The detection of chloroform in the organs of cadavers has been reported by a number of observers. Fischer[2] found 55 mg. in 780 gm. of lungs and blood in complete narcosis; 70 mg. in 480 gm. of brain; a trace in 445 gm. of liver, kidney, and spleen. Sedya,[3] in a case of beginning narcosis, found 4 mg. in the brain, 7.2 mg. in 1,000 gm. of stomach and contents; 2 mg. in liver, kidney, and spleen; 4.2 mg. in lungs, heart, and blood. Tissot[4] found 450 mg. in 1,500 gm. of brain; 350 mg. in 1,500 gm. of liver; 0.023 per cent in muscle (230 mg. in 1,000 gm.). Nicloux[5] found 0.0555 per cent in brain (555 mg. in

---

[3] Lesser Vierteljahrsschr. f. gerichtl. Med., 1899.

[4] J. de physiol. et de path. gen. **8**: 423, 1906.

[5] Compt. rend. Soc. de biol. **60**: 248. 1906.

1,000 gm.); 0.05 per cent in liver; 0.046 per cent in kidney; 0.038 per cent in spleen; 0.021 per cent in muscle; 0.07 per cent in arterial blood; 0.04 per cent in heart; 0.083 per cent in spinal cord. Results of other workers in this field show similar deviations.

Technic for this determination has given such uncertain results that Gettler and Blume suggested the following method, which is a modification of the colorimetric method described by Cole,[6] and is based on the Fujiwara reaction. The Fujiwara[7] reaction* has a pyridine color reaction with chloroform.

1. Use 5 c.c. of distillate for the colorimetric determination. Since the total distillate is 250 c.c., the actual value found in 5 c.c. is multiplied by 50 and not by 250, as is the case when 1 c.c. of distillate is used. This makes the method more accurate.

2. After the color has developed, there are present two layers; the upper pyridine layer contains the developed pink color. Cole pipettes this off into a colorimeter cup. The disagreeable, poisonous vapor of the pyridine makes this objectionable. It was found that if exactly 20 c.c. of water are added and mixed, the two layers merge into one, the entire mixture taking on the pink color; no turbidity, even in weak chloroform solutions, is then encountered. This modification reduces the sensitivity to 1:100,000 which is quite adequate for most toxicologic work.

3. Colored-glass disks were devised to be used as permanent standards in the Hellige-Klett colorimeter (comparative type).

With these modifications, the method used by Gettler and Blume is in detail as follows:

Method.—

Isolation of Chloroform From Tissues.—As soon as the brain, lungs, and liver are removed from the body, place in a clean jar, seal air-tight, and place in a refrigerator. When the material is ice cold, grind about 150 gm. of the tissue, weigh 100 gm. of the minced tissue, and quickly place it in a 500 c.c. distillation flask. Add about 100 c.c. of water and enough tartaric acid to make the mixture acid. Subject to steam distillation (Fig. 682), using a long, well-cooled condenser and an adapter. Collect the distillate in a 300 c.c. Erlenmeyer flask containing about 10 c.c. of ice cold, acidified hydrochloric acid water, keeping the collecting flask packed in ice. The tip of the adapter should reach into this ice cold water contained in the distillate receptacle. With these precautions there should be no loss of chloroform during distillation. Experiments have proved that if 250 c.c. of distillate are collected, all of the chloroform originally present in the tissue will have passed into the distillate. The distillate is well mixed, measured, stoppered, and kept cold. For the colorimetric determination, 5 c.c. portions of the distillate are taken.

Preparation of Standards for Use in Colorimetric Estimation of Chloroform in Distillate.—$R\text{-}C\text{-}halogen_3$ compounds, such as bromoform, carbon tetrachloride, chloretone, chloral, and iodoform, also give the Fujiwara color reaction. It is therefore essential at the outset to determine whether chloroform or some other one of the aforementioned group is present.

The materials necessary for the colorimetric determination of chloroform in tissues are: chemically pure pyridine (colorless), 20% sodium hydroxide solution, and standards such as are described in the following paragraphs:

Chloroform Standards: Place slightly more than 1 gm. of chloroform in a weighing bottle having a ground-glass stopper. Allow it to evaporate spontaneously, weighing from time to time, with the weighing bottle stoppered, until the weight of chloroform in the bottle is exactly 1 gm. Dissolve this 1 gm. in about 900 c.c. of water contained in a

---

*See p. 2275.

[6] J. Biol. Chem. 71: 173, 1926.

[7] Stizungsb. u. Abandl. naturfors. Geselsch. Rastock 6: 1, 1914.

1-liter volumetric flask. Add 5 c.c. of hydrochloric acid and enough water to bring the total volume to exactly 1 liter. Mix thoroughly. Take precautions to avoid evaporation of the chloroform during the transfer. The solution contains 1 mg. of chloroform in 1 c.c. Make a series of weaker standards from this stock, having the following chloroform values: 0.5, 0.1, 0.01, 0.005, and 0.0025 mg., respectively, per c.c. Keep in a refrigerator. These standards are then good for 1 week.

Permanent colored-glass standards (an alternate standard) are prepared as follows: Select a series of glasses with varying depths of orange pink color, simulating the different depths of colors obtained by various concentrations of chloroform when subjected to the pyridine test. Cut small disks of these glasses and fit into the circular openings of the wheel of the Hellige-Klett colorimeter, comparative type. Standardize these colored disks by chloroform solutions of known concentrations. The color disks 1 to 8, respectively, have the following values: Chloroform in 5 c.c. of solution, 0.125 mg., 0.25 mg., 0.375 mg., 0.5 mg., 1 mg., 1.5 mg., 2 mg., 2.5 mg. These colored-glass standards keep indefinitely if kept in the dark.

Colorimetric Estimation of Chloroform in Distillate.—The colorimetric method, using the chloroform standards, is applied as follows: Into five clean, dry, 50 c.c. test tubes (Folin digestion tubes may be used), measure 5 c.c. portions of the 5 standards containing, respectively, 0.5, 0.1, 0.01, 0.005, and 0.0025 mg. of chloroform per c.c. Into a similar test tube, pipette 5 c.c. of the distillate. To each of the tubes add 5 c.c. of chemically pure, colorless pyridine, and then 10 c.c. of 20% sodium hydroxide. Mix the contents of the tubes thoroughly, and cork loosely to prevent evaporation. Place in a boiling water bath for exactly 1 minute and then cool quickly with running water. Add exactly 20 c.c. of water to each tube and mix. Compare the color of the unknown with the colors of the five standards. Should the unknown match the color of the standard containing 0.01 mg. in 1 c.c. (0.05 mg. in 5 c.c.), the chloroform content of the entire distillate (250 c.c.) would be 50 times 0.05 mg., or 2.5 mg. Since 100 gm. of tissue were used in obtaining the distillate and the recovery is 92% (see under heading "Percentage of Recovery"), there are 2.5 times 1.087, or 2.72 mg. of chloroform in the 100 gm. used for analysis. If none of the five standards exactly matches the color of the unknown, the latter is compared in a colorimeter with that one of the five standards which has a color depth closest to the unknown. From the readings on the colorimeter, the chloroform content in 100 gm. of tissue is calculated as follows:

$$\frac{\text{Standard}}{\text{Unknown}} \times \begin{matrix}\text{value of standard used}\\ \text{in mg. of chloroform}\end{matrix} \times \frac{250}{5} \times 1.087 \left(\begin{matrix}\text{correction for per-}\\ \text{centage of recovery}\end{matrix}\right)$$

$=$ mg. chloroform in 100 gm. tissue.

The colorimetric method, using colored-glass standards, is especially adapted where routine determinations of chloroform are being done over long periods. The standard glasses are permanent. This method eliminates the preparation of a series of chloroform standards for each and every chloroform determination. It is applied as follows: Into a clean, dry, test tube pipette 5 c.c. of the distillate; add 5 c.c. of chemically pure, colorless pyridine, and then 10 c.c. of 20% sodium hydroxide; mix; cork the test tube loosely to prevent evaporation. Place in a boiling water bath for exactly 1 minute and then cool quickly in running water. Now add exactly 20 c.c. of water and mix. Place in the cell of the Hellige-Klett colorimeter. Turn the wheel of the instrument and compare the color of each disk with that of the solution in the cell. The disk that exactly matches the color of the solution in the cell is noted. The value of this disk in terms of milligrams of chloroform is known (see previous paragraph on permanent colored-glass standards).

Calculation:

$$\begin{matrix}\text{Value of colored}\\ \text{disk in mg.}\\ \text{chloroform}\end{matrix} \times \frac{250}{5} \times 1.087 \left(\begin{matrix}\text{correction for}\\ \text{percentage of}\\ \text{recovery}\end{matrix}\right) = \begin{matrix}\text{correction for}\\ \text{100 gm. tissue.}\end{matrix}$$

The chloroform content of the brain, lungs, and liver after chloroform anesthesia, given in preparation for surgical operation, is as follows (Gettler and Blume): brain, from 120 to 182 mg., lungs, from 92 to 145 mg., and liver, from 65 to 88 mg., in 1,000 gm. They stated that after death the chloroform content of the tissues decreases daily. After forty-two days, only 18 per cent of the original amount present is recoverable.

TESTS FOR CHLOROFORM AND CHLORAL HYDRATE

Hoffman Test

Place 5 c.c. of the unknown in a test tube.
Add 1 c.c. of aniline
and 1 c.c. of 10% sodium hydroxide.
Heat gently.

A sharp distinctive skunk-like odor (isonitrile) is produced if chloroform or chloral hydrate is present.

Fujiwara Test

Place 5 c.c. of the unknown in a test tube.
Add 1 c.c. of pyridine
and 1 c.c. of 10% sodium hydroxide.
Heat on a water bath for approximately 5 to 10 minutes.

A pink or red color develops if chloroform or chloral hydrate is present. This test may be used for partial quantitative estimation. Prepare varying standards using the same technic as used for developing color in the unknown solution. Match the color of the unknown with the color of these standards.

DETECTION OF SMALL AMOUNTS OF CHLORAL IN THE PRESENCE OF CHLOROFORM AND FORMALIN EMBALMING FLUID

The detection of chloral is quite difficult, especially when it is mixed with Formalin embalming fluid. Formalin interferes with the color reaction of chloral in that it gives the same color, namely, a brownish red. The objection to the Schwartz method, which is commonly used, is that other substances besides chloral give the green fluorescence supposed to be characteristic of chloral alone. Gettler,[4] in an investigation of this test, observed that chloroform does not produce the green fluorescence, but that chloral does, and that the red color does not appear in very dilute solutions of chloral, although the green fluorescence is always present; further, he showed that it was sensitive to 0.01 mg. in 1 c.c.; that formaldehyde, acetaldehyde, formic acid, benzaldehyde do not give the reaction; he also found that if formaldehyde is present together with the chloral, the reaction is not interfered with provided the test is done at room temperature. Gettler's technic is as follows:

To 1 c.c. of distillate add 6 drops of saturated resorcin and 1 c.c. of saturated sodium carbonate solution or less if only traces of chloral are present. Let stand for one-half hour, then dilute by adding 10 c.c. of water. A beautiful green fluorescence results. In cases of extremely small quantities of chloral, viewing by direct sunlight against a black, glossy background, is of great advantage. Any development of color or fluorescence after many hours is of no consequence.

ISOLATION AND IDENTIFICATION OF EASILY VOLATILE ORGANIC LIQUIDS IN HUMAN TISSUES

Method of Gettler and Siegel[5]

Among the organic liquids used in dry-cleaning, as general solvents, as fire-extinguishers, as anesthetics, and as therapeutic agents in hookworm disease are: ethyl chloride, ethylene chloride, propylene dichloride, carbon tetrachloride, dichlor-difluormethane, chloroform, carbon bisulphide, benzene, and diethyl ether. Fatalities have occurred from drinking some of these liquids or from inhaling their vapors. The layman, unaware of their toxicity, may inhale the vapors with impunity until unconsciousness and death result. Gradwohl in 1941 observed a near fatal case of carbon tetrachloride poisoning which bears out Gettler and Siegel's statement concerning the toxicity of the vapors of these liquids. This was the case of a man who went into his basement one night to extinguish a fire, using an extinguisher containing carbon tetrachloride. Severe and serious symptoms resulted, due unquestionably to the inhalation of vapors and to absorption from the thorough wetting of his clothing with this substance.

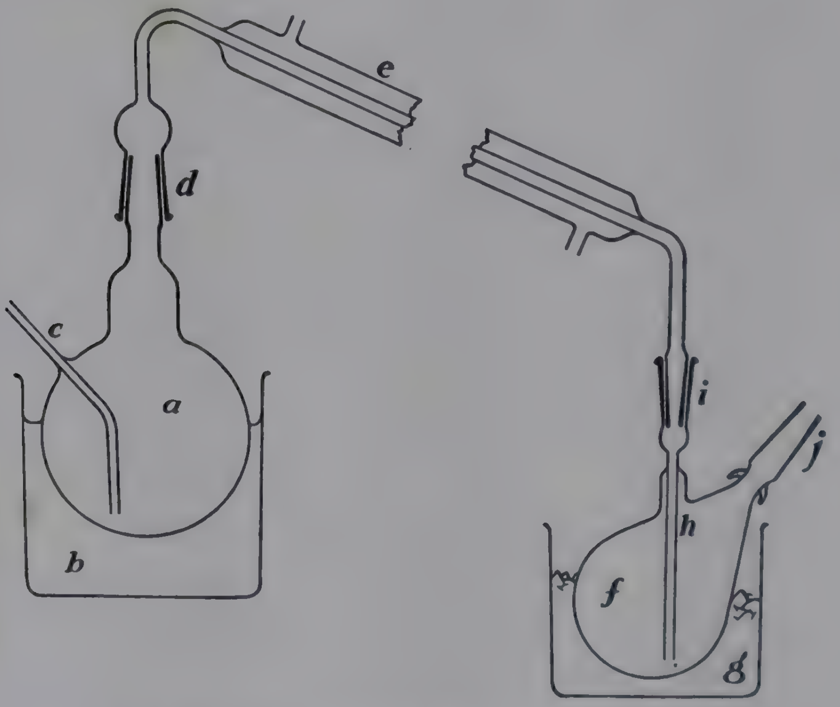

Fig. 692.—Apparatus for steam distillation.

Apparatus for Steam Distillation (Fig. 692).—The apparatus consists of: *a*, a distilling flask with a capacity of 2 liters; *b*, a bath for boiling water; *c*, a glass tube sealed into the side of the distilling flask for the delivery of the steam; *d*, an interchangeable No. 15 ground glass joint for connecting the distilling flask with the condenser; *e*, a water-cooled condenser; *f*, the bulb of the rectification flask, for the reception of the distillate from the tissues; *g*, an ice bath; *h*, a glass tube sealed into the side of the rectification flask; *i*, an interchangeable No. 7 ground glass joint for connecting the condenser with the bulb of the rectification flask which is used as a receiver for the distillate; and *j*, an interchangeable No. 9 ground glass joint used during rectification (Fig. 693).

Technic of Distillation of Volatile Organic Liquids From Tissues.—

Place the tissues, removed at autopsy, in glass jars, seal tightly, and place in a refrigerator.

---

[5] Arch. Path. 17: 510, 1934.

When ice cold, quickly grind 600 gm. in a grinder previously cooled by the application of ice.

Rapidly weigh 500 gm. of the ground material.

Mix with 200 c.c. of ice-cold water.

Introduce into the 2-liter distilling flask (Fig. 692*a*).

Add an additional 300 c.c. of water and 1 c.c. of liquid petrolatum.

Set up the apparatus for steam distillation as indicated in Fig. 692.

Continue the steam distillation until about 200 c.c. of distillate have collected in the ice-cooled bulb of the rectification flask (Fig. 692). Experiments have shown that this amount is ample for recovery of practically all the volatile organic liquid that may be present in the tissues.

Remove the rectification bulb and its contents from the distilling chain, and keep cold by surrounding with cracked ice.

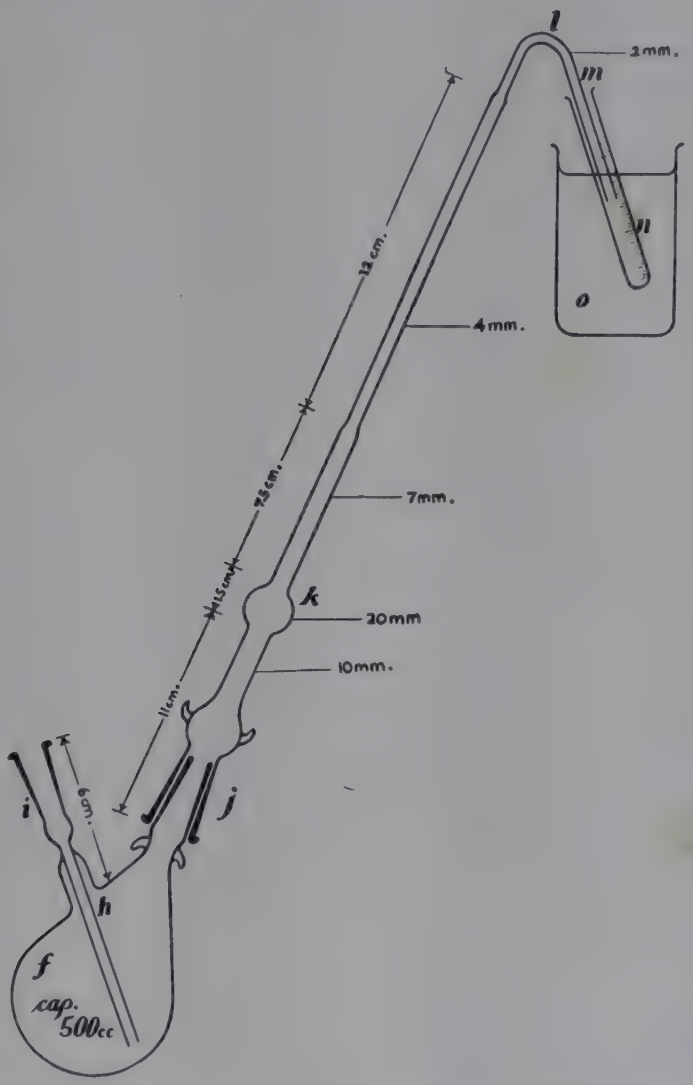

Fig. 693.—Rectification flask for isolation of volatile organic fluids.

Gradually add to the distillate in the flask 250 gm. of anhydrous calcium chloride, keeping the solution well mixed to prevent warming. The purpose of the addition of the calcium chloride is to effect a salting out of the volatile liquid present and also to lower the vapor pressure of the water.

Add about 1 gm. of granulated zinc to prevent bumping.

Set up the rectification bulb and its contents for rectification as indicated in Fig. 693.

Rectification Flask for Isolation of Volatile Organic Liquids (Fig. 693).

The apparatus consists of: *f*, a distillation bulb (capacity, 500 c.c.); *h*, a glass tube fused into the side of the distillation bulb, which acts as a safety-valve; *j*, an interchangeable No. 9 ground glass joint; *k-l*, a reflux condenser (air-cooled); *m*, a microcondenser (cooled by a freezing bath); *n*, a tube for collection of the distillate, the inside diameter of which measures 6 mm. and which is graduated in twentieths of a c.c.; and *o*, a solid carbon dioxide-acetone cooling bath.

The rectification flask used in these determinations is slightly modified from that used by Gettler and Siegel.[1] It is constructed in two parts, *f* and *klm*, connected by a ground glass joint (*j*). This change in structure facilitates the introduction and removal of material into and from the flask.

Technic of Isolation of Volatile Organic Liquids From Tissue Distillate.—

Rectification.—In order to obtain the best results it is essential that the condenser parts *k*, *l*, and *m* of the rectification flask be perfectly clean. Treat with hot concentrated nitric acid, or let them stand overnight in a cleaning mixture of sulphuric and chromic acids. Before attaching the condenser to the bulb of the rectification flask, thoroughly dry the inner surface of the portion of *k*, *l*, and *m* by playing a gentle flame over the outer surface. Keep the receiving tube (*n*) in a cooling bath (*o*). With volatile liquids of extremely low freezing points, the cooling bath consists of carbon dioxide snow in acetone. For the liquids which freeze at a point only a little below 0° C. an ice and salt mixture is used. For benzene which freezes at 5.4° C. ice-water is satisfactory.

To start the rectification, heat the material in the bulb of the flask carefully and slowly, using an asbestos-centered wire gauze and a microburner. As soon as the liquid in the bulb begins to boil, regulate the flame so that the liquid boils gently for about 15 minutes. During this time, the steam (as indicated by a visible rise of the condensate or by running the hand along the tube of the flask and determining the height of steam by the temperature of the tube) must not be permitted to rise beyond *k*. This is done by properly regulating the flame. The part of the tube from *k* to *l* acts as a reflux for the steam, whereas the vapors of the volatile liquid which rise past *l* condense and collect in the receiver *n*.

Continue gently boiling for 15 minutes.

Gradually increase the flame so that the steam is made to rise slowly (in one to two minutes) until it just passes the bend of tube (*l*).

From this point the procedure varies according to the cooling bath used. If a carbon dioxide snow-acetone mixture is used, continue the distillation at the same constant rate. After the volatile organic liquid has distilled over, steam will follow. Beyond *l* the steam will condense and freeze. Ice will clog the tube (*m*). The pressure produced within the flask will force the liquid in the bulb out through the safety-tube (*h*). This occurrence indicates the end-point in the distillation.

If an ice and salt or a plain ice-water cooling bath is used, the water vapor rising into *m* may not freeze and clog the tube, and hence no back pressure will be produced. In this case the end-point of the distillation is signified when the bend (*l*) attains the temperature of boiling water. Rectification is now completed. The volatile liquid, if present, will be found in the calibrated receiver (*n*).

Remove the receiving tube from the cooling bath.

Stopper lightly and allow to stand at room temperature until the ice present has melted.

At once centrifugate the tube and contents for 2 minutes.

Place in ice-cold water for 5 minutes.

Read the volume of the layer of isolated liquid

Identification of the Isolated Liquid.—

The following tests may be applied to identify the liquid:

(a) microdetermination of the boiling point by the method of Emich;[2] also described by Gettler, Niederl, and Benedetti-Pichler;[3]

(b) microdetermination of the molecular weight;[4]

(c) microanalytic determination of carbon and hydrogen;[5]

(d) microdetermination of halogen.[6]

---

[1] Arch. Path. 17: 510, 1934.

[2] Monatsh. f. Chem. 38: 219, 1917.

[3] Mikrochemie 11: 173, 1932; J. Am. Chem. Soc. 54: 1479, 1932.

[6] Elek, A., and Dill, D. W.: J. Am. Chem. Soc. 55: 2552, 1933.

Gettler and Siegel used the microdetermination of the boiling point for the identification of the isolated liquid. They are convinced, through the evidence of experiments, that the isolated volatile liquid need not be dried for use in the determination of the boiling point.

They succeeded in isolating the following from tissue: ethyl chloride, ethylene chloride, propylene dichloride, carbon tetrachloride, dichlor-difluormethane, chloroform, carbon bisulphide, benzene, and diethyl ether. Identification of the particular liquid present was accomplished by microdeterminations of the boiling point. One set of values obtained is charted in Table 220.

TABLE 220

RECOVERY AND BOILING POINT OF ISOLATED VOLATILE ORGANIC LIQUIDS

VOLATILE LIQUID	BOILING POINT OF THE LIQUID, ° C.	AMOUNT OF LIQUID ADDED TO 200 C.C. OF WATER, C.C.	AMOUNT OF LIQUID ADDED TO 500 GM. OF TISSUE, C.C.	AMOUNT OF LIQUID RECOVERED, C.C.	BOILING POINT OF THE ISOLATED LIQUID, ° C.

	34.8	--	0.3	0.24	34.7

*Carbon tetrachloride isolated from tissues always gave an abnormally low boiling point, which proved to be due to the fact that some of the tetrachloride is converted into chloroform, the mixture of chloroform and carbon tetrachloride giving the abnormally low boiling point. By means of Emich's microfractionating tube[1] the chloroform and the carbon tetrachloride can be separated. If this procedure is carried out, the fraction containing the tetrachloride gives the correct boiling point.

ISOLATION OF ETHER FROM HUMAN TISSUES

The work of Gettler and Siegel[2] has facilitated the isolation of ethyl ether from human tissues. Up to the time of their publication in 1934, methods which were based on oxidation-reduction reactions were used for the determination of ether. But these were unsatisfactory because other organic substances react just as ether does toward these oxidizing agents. The reliance of the pathologist or toxicologist on his sense of smell, when the body cavities are opened, is apt to be quite misleading. Gettler, Niederl, and Benedetti-Pichler[3] devised a specially constructed rectification flask to isolate ether from tissue distillates. Changes have been made in this microrectification flask as follows:

1. The bulb of the flask is of larger capacity (300 c.c.) which enables one to use the entire original tissue distillate rather than small aliquot portions. This enables one to measure the volume of ether isolated.

---

[1] Gettler, A. O., and Fine, J.: Indust. & Engin. Chem. **11**: 469, 1939.

[2] Arch. Path. **17**: 510, 1934.

[3] Mikrochemie **11**: 173, 1932; J. Am. Chem. Soc. **54**: 1479, 1932.

2. A glass tube running to the bottom of the flask is fused into the side of the flask, which facilitates the introduction of the material from which the ether is to be isolated and serves as a safety tube during the distillation and also makes it easier to empty and clean the flask.

3. The uppermost S-shaped part is straightened out and points downward at an angle of 45 degrees to the main tube of the flask. This was done so that all the ether could be collected in one portion rather than in a series of successive drops. See Fig. 694.

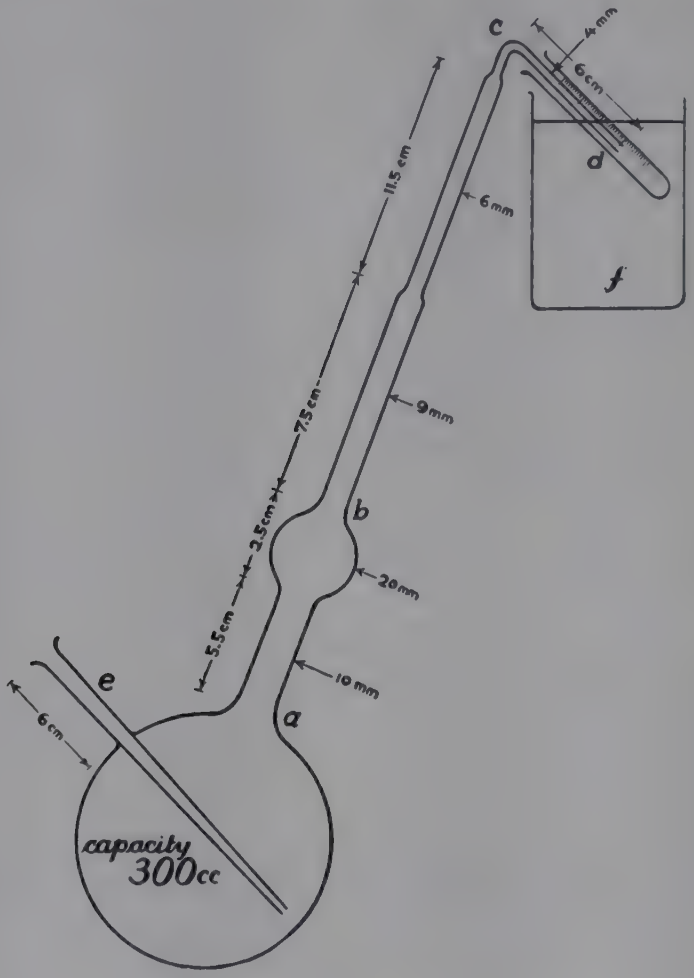

Fig. 694.—Microrectification flask.

Method of Gettler and Siegel[1]

Tissues and organs removed at autopsy are placed quickly in glass jars, tightly sealed and put in a refrigerator. When ice cold, quickly grind up about 600 gm. in a grinder previously cooled by applying ice. Of this ground material, rapidly weigh 500 gm., mix with 200 c.c. of ice cold water, and place in a 2-liter flask.

Add an additional 300 c.c. of water and 1 c.c. of liquid petrolatum. Distill the mixture with steam, using a long, well cooled condenser, the tip of which has been bent to resemble an adapter. The bent tip should dip into 25 c.c. of ice water contained in the receiving flask, the latter being at all times entirely surrounded by ice. Collect 200 c.c. of distillate. This is ample for recovering all the ether that is present in the tissues. The distillate is now ready for the isolation of the ether.

Use the rectification flask already described. It must be clean and part of it (from *b* to *d*) must be dried by playing a gentle flame over the outside surface.

Pour the entire 200 c.c. of distillate through the safety tube (*e*) into the rectification flask. Add 1 gm. of granulated zinc. The receiving tube (*d*), which is 6 mm. in diameter on the inside and is graduated in twentieths of a cubic centimeter, is surrounded by a bath

---

[1] Arch. Path. 17: 510, 1934.

(*f*) of solid carbon dioxide in acetone, and should contain about 0.15 c.c. of water (not more), so that the ether is collected over water as a separate layer. Now heat the rectification flask carefully and slowly, using an asbestos centered wire gauze and a microburner. As soon as the solution begins to boil, regulate the flame so that the liquid boils gently in the bulb for about fifteen minutes. During this time the steam (as indicated by a visible rise of the condensate or by running the hand along the tube and determining the height of the steam by the temperature) must not be permitted to rise beyond *b*. This is done by properly regulating the flame. The part of the tube from *a* to *c* acts as a reflux for the steam, while the ether vapors rise past *c*, condense and collect in the receiver. After mild boiling has been continued for fifteen minutes, gradually increase the flame so that the steam is made to rise slowly (in one minute) until it just passes the bend *c*. Rectification is now completed. The ether, if present, will be found unfrozen in the calibrated receiver. It sometimes happens that water vapor freezes in the tube beyond *c*, clogging it up; back pressure developed by continued heating will force the distillate out through the safety tube *c*. In that case, remove the flame; then remove the receiving tube, and warm the portion of the tube from *c* to *d* with the fingers. When the ice melts, it will be sucked back into the flask. Replace the receiving tube and continue the rectification.

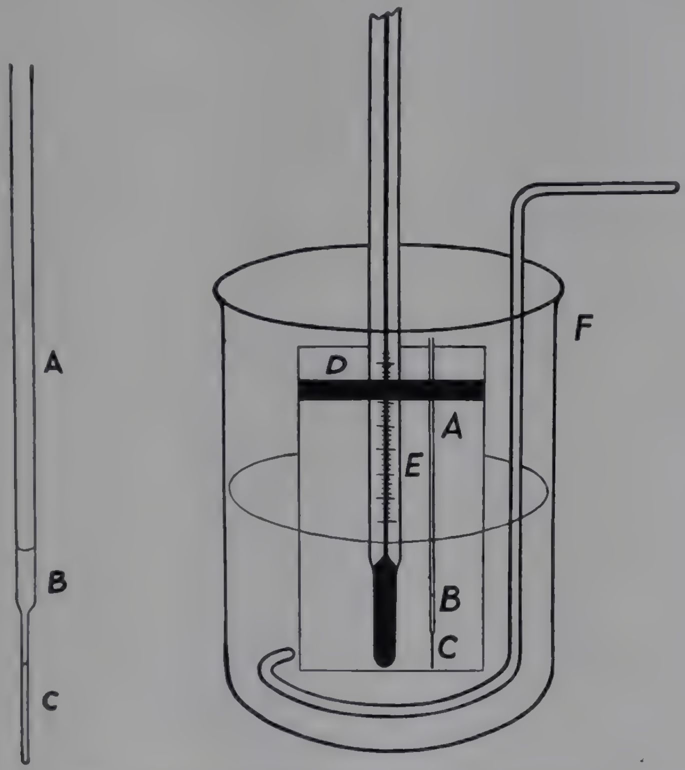

Fig. 695.—Microboiling point apparatus.

When the rectification is completed, as indicated by steam having passed the bend (c), remove the receiving tube from the acetone bath, lightly stopper, and allow it to stand at room temperature until any ice in the calibrated receiving tube melts. Read the volume of recovered ether (upper layer) immediately.

In order to identify this upper layer as ether, determine the micro-boiling point. Gettler and Siegel were convinced that the isolated ether need not be dried for determination of the boiling point. The isolated ether can be sealed in a capillary tube and kept as corpus delicti.

Determination of Boiling Point.[2]—Draw out a capillary tube (Fig. 695*A*), from 1.5 to 2 mm. in diameter, into a finer capillary tube at one end (*C*), about 8 mm. in length. Introduce the end (*C*) of the capillary tube into the ether to be tested. Ether is drawn into the tube by capillary action. Care must be taken to allow only a small droplet to enter. Then seal the tube by bringing the tip of it into the edge of a Bunsen flame for a second. As the walls of the tube are extremely thin, they fuse together almost instantly. Sealing in this way always leaves a bubble of air in the tip of the tube, between the sealed portion of glass and the drop of liquid (Fig. 695*C*). This bubble of gas serves to prevent superheating of the liquid during the determination of the boiling point. Mount the capillary tube (A) containing the drop of liquid and a thermometer (E) on a microscope slide and set up in a beaker (F) containing water, together with a stirrer. Raise the temperature of the bath slowly and uniformly. According to Emich, the true boiling point of a pure liquid is the temperature at which the droplet in the capillary reaches the surface of the bath. This is true only, however, if the bubble of gas in the tip of the tube is so small that the effect of its expansion is negligible, and also if the temperature of the bath is raised regularly and uniformly throughout.

---

[2] Emich, F.: Monatsh. f. Chem. 38: 219, 1917.

A series of determinations was made on the boiling point of pure, dry ether as well as of ether that had been in contact with water for an indefinite period. The boiling points obtained were: pure, dry ether, from 34.8° to 35° C., and moist ether, from 34.7° to 35° C. Since the boiling point of moist ether is practically the same as that of dry ether, it is not necessary to dry a sample of ether before determining its boiling point.

Explaining, Gettler and Siegel showed in Table 221 how much ether was recovered after known quantities were added to 500 gram portions of brain tissue and liver tissue.

This micromethod enabled these workers to isolate as small a quantity as 0.03 c.c. of ether when 0.06 c.c. was added to 500 gm. of tissue. The determinations of the microboiling point served to identify the isolated liquid as ethyl ether.

TABLE 221.—STUDY OF RECOVERY OF ETHER

NO.	TISSUE USED 500 GM.	ETHER ADDED, C.C.	ETHER RECOVERED, C.C.	ETHER LOST, C.C.	% RECOVERY
1	Brain	0.06	0.03	0.03	50

Distillation Capillary Method Useful to Determine Boiling Points

A further contribution to the isolation of volatile fluids was made by Gettler and Fine.[3] They showed that mixtures of low boiling liquids, in volumes as small as 0.02 to 0.1 c.c. can be fractionally distilled by means of the apparatus described below.

Preparation of Distillation Capillary (Fig. 696).—Heat a piece of Pyrex glass tubing, A, about 8 mm. in outside diameter, and with 1 mm. wall, in the blast lamp and draw out to a capillary, B, somewhat longer than 10 cm., with a uniform inner bore of approximately 2 mm. Cut off a 10 cm. section, C, of this capillary. About 5 cm. from one end, draw out the capillary to a much finer capillary, D, 0.25 to 0.5 mm. in outside diameter, and about 7 cm. long. Cut off any excess length. Seal the end of the finer capillary by heating in the flame.

Then seal the end of the larger capillary, using a small blast flame, and keep the glass soft by holding it in the flame until a hollow bulb about 5 to 6 mm. in diameter (0.06 to 0.1 c.c. capacity) forms, E, owing to the increased pressure of the heated air within. The size of the bulb will depend upon the length of time that it is kept in the flame. Excessive heating must be avoided, since this will gradually enlarge the bulb to the point of bursting. When cool, break off the tip of the fine capillary. Soften the stem of the fine capillary at a point 1 to 2 cm. from the larger capillary by heating in a luminous flame, and bend to an angle of about 45°. The distillation capillary is now ready for use.

---

[3] Indust. & Engin. Chem. 11: 469, 1939.

Filling the Distillation Capillary (Fig. 697).—Introduce the drop of liquid to be fractionated into the distillation capillary in the following manner:

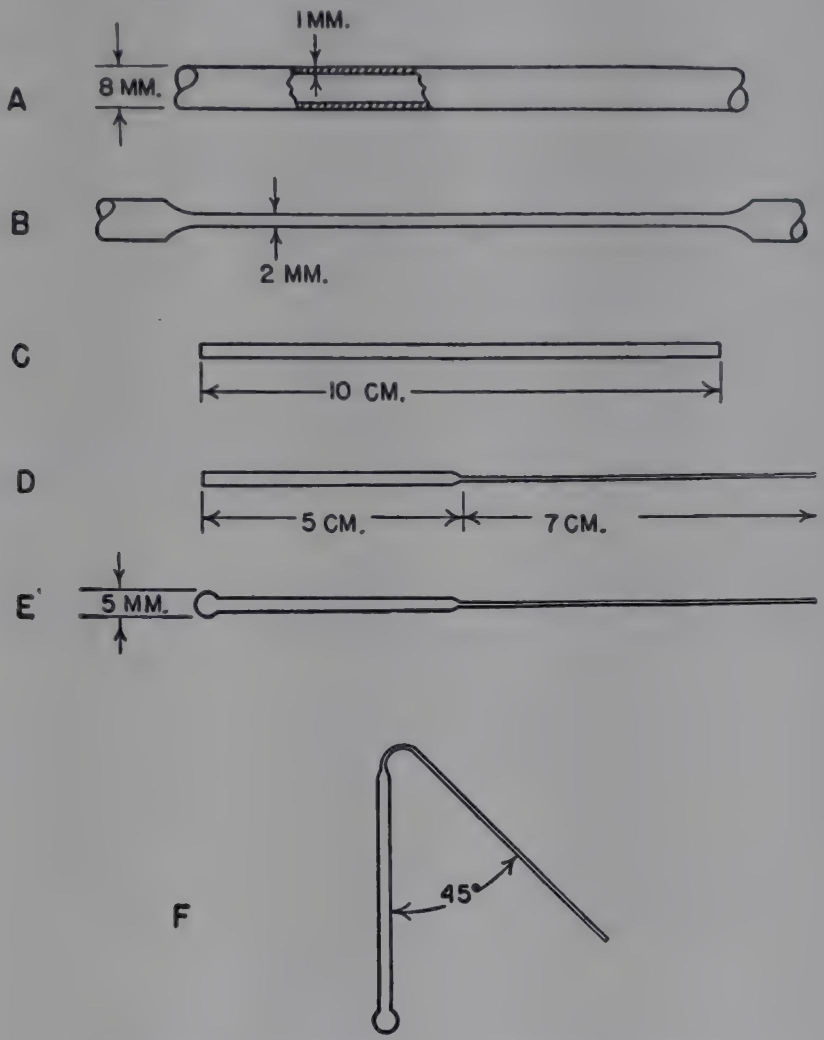

Fig. 696.—Preparation of distillation capillary.

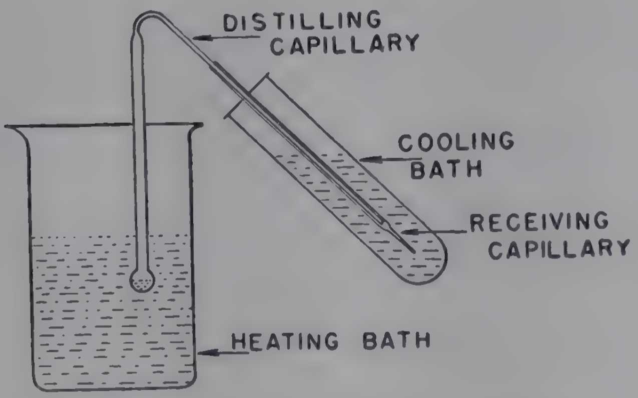

Fig. 697.—Filling the distillation capillary.

Warm the bulb of the distillation capillary by immersing for a few minutes in boiling water. While the bulb is still warm, dip the fine capillary tip into the drop of liquid to be fractionated, and then apply a cooling bath (solid carbon dioxide and acetone) to the bulb. The decreased air pressure within, due to the cooling, causes the liquid to flow up the fine capillary, down the larger capillary, and into the bulb of the apparatus. Should any of the liquid remain in the stem, it is easily forced into the bulb by shaking the apparatus two or three times, as is customary with clinical thermometers. For a successful distillation the bulb should not be more than half full of liquid. In order to remove all traces of adhering liquid from the fine capillary arm, carefully warm the arm, while keeping the bulb containing the bulk of the liquid in the cooling mixture.

The Distillation.—Use a test tube, 6 cm. long, partly filled with ice water, to cool the distillate-receiving capillary. For very low boiling liquids (30° C. or less) use a small Dewar flask containing liquid air.

Introduce a capillary, 9 cm. long, having an inside diameter just a trifle larger than the outside diameter of the fine arm of the distillation capillary, into the cooling bath, with its sealed end resting on the bottom of the test tube. Introduce the fine stem of the distillation capillary into the receiving capillary as far as it will go. The entire setup is held by means of the water-containing test tube during the distillation. Now insert the bulb of the distillation capillary into cold water contained in a small beaker. Then gradually and very slowly heat the water until a ring of condensate is seen rising up the column and condensing in the receiving capillary. At this point the flame should be at once removed, in order to keep the temperature of the water from rising too high. The distillation meanwhile is allowed to continue until a layer not more than 2 mm. thick (0.01 c.c. volume) has collected in the receiving capillary. At this point quickly withdraw the distillation capillary from the receiving capillary by means of a glass rod supporting the curved part of the distillation capillary, and quickly place the bulb in the solid carbon dioxide-acetone cooling mixture, in order to suck back into the bulb any liquid remaining in the capillary portion of the apparatus.

Store the receiving capillary containing this first fraction in the cooling mixture until ready for identification tests, such as the boiling point determination. Then continue fractional distillation of the remaining liquid in the bulb as described above. Not more than 2 mm. of each fraction should be collected in the receiving capillaries. Five to six fractions can be obtained in this way from 0.06 c.c. of liquid.

With this method, Table 222 shows experimental results in boiling points of different volatile substances.

TABLE 222.—EXPERIMENTAL RESULTS

C.C.	MIXTURES OF LIQUIDS USED	BOILING POINTS OF PURE LIQUIDS ° C.	EXPT.	BOILING POINTS OF SUCCESSIVE FRACTIONS ° C.
0.02	Ethyl ether	34.5	1	34.5, 35.0, 49.5, 55.8
0.02	Acetone	56.5	2	34.5, 35.3, 43.0, 55.5, 56.0
0.03	Methyl alcohol	64.6	1	33.0, 35.5, 37.0, 41.5, 60.5, 63.5
0.03	Methyl formate	31.5	2	32.0, 33.5, 38.5, 42.5, 63.2, 64.0
0.03	Ethyl ether	34.5	1	21.5, 21.5, 22.0, 33.0, 34.0
0.03	Acetaldehyde	21.5	2	21.0, 21.0, 22.5, 33.5, 34.0
0.03	*n*-Propyl chloride	46.4	1	37.5, 37.5, 42.5, 43.5, 45.0
0.03	Iso-Propyl chloride	36.5	2	36.0, 37.0, 40.5, 44.0, 46.5, 46.8

This apparatus can be used not only for the isolation from tissues of ether, but also for all other easily volatile liquids; that is, liquids with boiling points below that of water, such as carbon tetrachloride, propylene chloride, ethylene chloride, ethyl chloride, and many others.*

DETECTION OF PHENOLS

Distill tissue by steam distillation in the usual manner (page 2243). Test the distillate for phenol by the following tests.

1. **Ferric Chloride Test.**—

To 10 c.c. of the distillate, add a few drops of 10% ferric chloride. Phenol gives a blue-violet color. Cresols give a green to blue color.

---

*This apparatus is supplied by Eck & Krebs, 1313 West 24th St., New York City. It is listed as Rectification Apparatus, Micro, Gettler and Siegel, No. 3540.

2. Bromine Test.—

To 10 c.c. of the distillate, add 2 to 3 c.c. of saturated bromine water. Brominated phenol will precipitate (yellow) 2,4,6 tribromphenol. Melting point is 94° C.

3. Millon's Test.—

Millon's Reagent.—

Dissolve 10 grams mercury in 20 grams nitric acid, c. p.
Dilute with an equal volume of distilled water.
Allow to stand twenty-four hours.
Decant.

To 10 c.c. of distillate add 1 c.c. of Millon's reagent.

If no color develops apply gentle heat. A red color or precipitate may indicate phenols, cresols, or salicylates.

Since phenolic compounds may be produced by putrefaction and thus give a positive Millon reaction, caution must be exerted in examining putrified cadavers for phenol.

GROUP II. ACID-ETHER EXTRACTION

Carry out steam distillation as described on page 2243. Use the aqueous residue left in the flask after steam distillation to extract the nonvolatile poisons.

Place the residue in a large evaporating dish and add 2 to 3 times its volume of 95% ethyl alcohol.

Place on a steam bath for several hours. The alcohol dissolves most poisons. Heat and alcohol combined tend to denature the proteins present in the specimen, rendering them insoluble.

Filter. Heat the filtrate to volatilize all the alcohol.

Leach the syrupy residue with hot distilled water many times and then extract with several portions of ether. The ether extracts and isolates acid-ether soluble poisons. The tartaric acid, used in the original distillation process, is still a sufficient acidifying agent. It is well, however, to check the solution with litmus paper, to see if it is acid.

Collect these several ether extracts and evaporate on a steam bath.

Test the residue for the various common poisons in this group as described below.

In most cases, the residue is still impure; it has a yellow tinge due to nitrogenous impurities. This impure residue may be purified with selective solvents, or, better, by sublimation which usually yields fine pure crystalline material.

DETECTION OF BARBITURATES IN TISSUE AND URINE

Gettler Method

Gettler[1] gives the following procedure for isolation of barbiturates.

Isolation from Urine and Tissues.—The urine is best adapted for a rapid qualitative analysis for barbiturates. Extract 100 c.c. of urine (HCl acidified) in a separatory funnel with 100 c.c. of ether. Remove the ether layer containing the barbiturate and wash with two successive 10 c.c. portions of water. Pour the washed ether layer into a beaker, and place on a boiling water bath, until all the ether has evaporated. A white, and usually crystalline, residue indicates the presence of barbiturates. In the analysis of tissues, the procedure is somewhat more complicated, in that an alcohol extraction precedes the ether extraction, as described in the classical Stas-Otto procedure.

Identification of the Residue.—(a) Dissolve a small quantity of the purified residue in about five drops of chloroform and place in a micro test tube. Add a drop of 1 per cent cobalt acetate in methyl alcohol, and mix the contents. Then stratify two or three drops of 5 per cent isopropyl amine in methyl alcohol over the mixture. A blue-violet color develops between the stratified layers if barbiturates are present.

---

[1] Am. J. Clin. Path. 13: 169, 1943.

Most barbiturates are extracted in crystalline form from acid-ether. Since seconal usually does not appear in crystalline form, but has an oily appearance, it is imperative that the cobalt and Millon tests be made even though there are no visible crystals in the residue. The presence of color matter and impurities inhibits the blue-violet phase of the cobalt test. If, therefore, the cobalt test is negative, it is well to purify further by sublimation, or by hot and cold water or solvent recrystallization, or by shaking out with activated charcoal and filtering, and then to repeat the test. If the test is again negative, it is now at least a more reliable indication of absence of barbiturates.

(b) Place a small quantity of the residue in a test tube, and dissolve in a little hot water. Then add a drop of Millon's reagent. A voluminous white precipitate, which dissolves on adding an excess of the reagent, indicates barbiturates.

(c) In order to establish which one of the barbiturates is present, the melting point of the extracted material is determined. Since the residue very often is not pure enough for a melting point determination, it must first be sublimated. Place a glass slide with a crystal of the sublimate on the stage of a microscope, which is heated electrically, and is supplied with a thermometer. Observe the melting point of the crystal in a normal manner, through the microscope.

Once an identification is made, confirm by performing a mixed melting point determination with another crystal supposedly identical with the unknown. Obtain a derivative with either xanthydrol or *p*-nitro benzoyl chloride, and compare melting points with known compounds.

SUBSTANCE	MELTING POINT	MELTING POINT OF *p*-NITRO BENZOL DERIVATIVE
Veronal	190	194
Luminal	175	184
Evipal	144	115
Amytal	154	146
Dial	170	193

Quantitative Determination.—(a) By weighing the extracted, purified (by repeated extractions), and dried barbiturate.

(b) By determining the nitrogen content of the purified extract, from which the quantity of barbiturate may be calculated.

(c) Colorimetrically, using the color produced by cobalt acetate in methyl alcohol when added to a chloroform solution of the barbiturate, and made alkaline by a methyl alcohol solution of isopropyl amine. The extracted material must also be purified before this test is applied.

All three methods are not strictly quantitative, because there is an unavoidable loss during purification.

Distribution of the Barbiturates in the Various Tissues.—Quantitative chemical analyses revealed that the barbiturates are more or less evenly distributed in the blood, brain, liver, kidneys and muscles. A difference of more than 2 mg. in 100 gm. of any of the tissues is a rare occurrence.

The Minimum Lethal Tissue and Blood Level.—Over 400 barbiturate deaths have been analyzed in the chemical laboratories of the Chief Medical Examiner's Office of New York City over a ten-year period. The data show that the barbiturates can be divided into four groups, from the standpoint of the minimum lethal tissue or blood level. In 100 gm. of tissue or blood we find 1.5 mg. as the minimum fatal concentration for Amytal and Evipal; 4.0 mg. for Nembutal, Neonal, Ortal, Phanodorn and Seconal; 8.0 mg. for Dial, Ipral, Luminal, Numal (Allonal) and Propanol; 18.0 mg. for Veronal. The low tissue content of Amytal and Evipal is due to their greater toxicity, and to their more rapid destruction in the living body. The elimination from the system during life is quite rapid (thirty-six hours) for barbiturates having a low lethal tissue concentration such as Amytal and Evipal, and slow (four to five days) for barbiturates, such as Veronal, having a higher lethal tissue concentration.

BARBITURATES

Spectrophotometric Method of Goldbaum[1]

Both qualitative and quantitative tests for barbiturates can be made by a study of their characteristic ultraviolet absorption spectra. Concentrations as low as 1 mg. in 100 gm. of blood or tissue can be determined with an accuracy of approximately 95 per cent.

Principle.—

Absorption curves are determined in a Beckman universal quartz spectrophotometer using 1 cm. cells. Measurements are reported as density (2 - log G).

Fig. 698 shows the absorption spectra of some representative barbiturates. An intense maximum is present at wave length 255 for those barbiturates having a malonyl urea ring. At wave length 255 mμ there is a straight line relationship between concentration and density (2 - log G).

Reagents.—

Redistilled Chloroform.—

Acetate Buffer pH 5.0.—

Mix 59 c.c. of 0.1 N acetic acid
with 141 c.c. of 0.1 N sodium acetate.

0.5 N Sodium Hydroxide Solution.—

Reference Solution.—

0.5 N sodium hydroxide solution saturated with chloroform (or with ether for brain analysis).

Ether.—

Technic.—

(I) **In Plasma and Whole Blood.—**

Using a buret admit 15 c.c. of redistilled chloroform to a 50 c.c. separatory funnel.

Add 2 c.c. of acetate buffer pH 5.0.

Add 1 c.c. of blood or plasma.

Shake for 1 minute.

Allow the layers to separate. If an emulsion forms, which is rare, it can be broken by centrifugalizing the specimen.

Filter the chloroform through Whatman No. 42 filter paper into a calibrated 15 c.c. centrifuge tube.

Collect 10 c.c. of clear filtrate.

Transfer the chloroform to another clean 50 c.c. separatory funnel.

Add 5 c.c. of 0.5 N sodium hydroxide solution and shake the separatory funnel for about 1 minute.

Allow the layers to separate.

Discard the chloroform layer.

Transfer the alkaline layer to a 10 c.c. Pyrex tube.

Centrifuge for 2 to 3 minutes to bring down the suspended droplets of chloroform. The solution should now be crystal clear.

Pipette off 4 c.c. of this clear alkaline solution and use 1 c.c. to rinse the Beckman cuvette, the remaining 3 c.c. to fill the cuvette.

Compare the unknown alkaline solution in the Beckman instrument with the reference solution.

In using the Beckman spectrophotometer, put the alkaline solution containing the barbiturates in one of the cells and the reagent blank in the other. Adjust the instrument to 100 per cent transmission with the reagent blank. Then put the unknown in the instru-

---

[1] Goldbaum, L. R., Army Medical School. Personal communication.

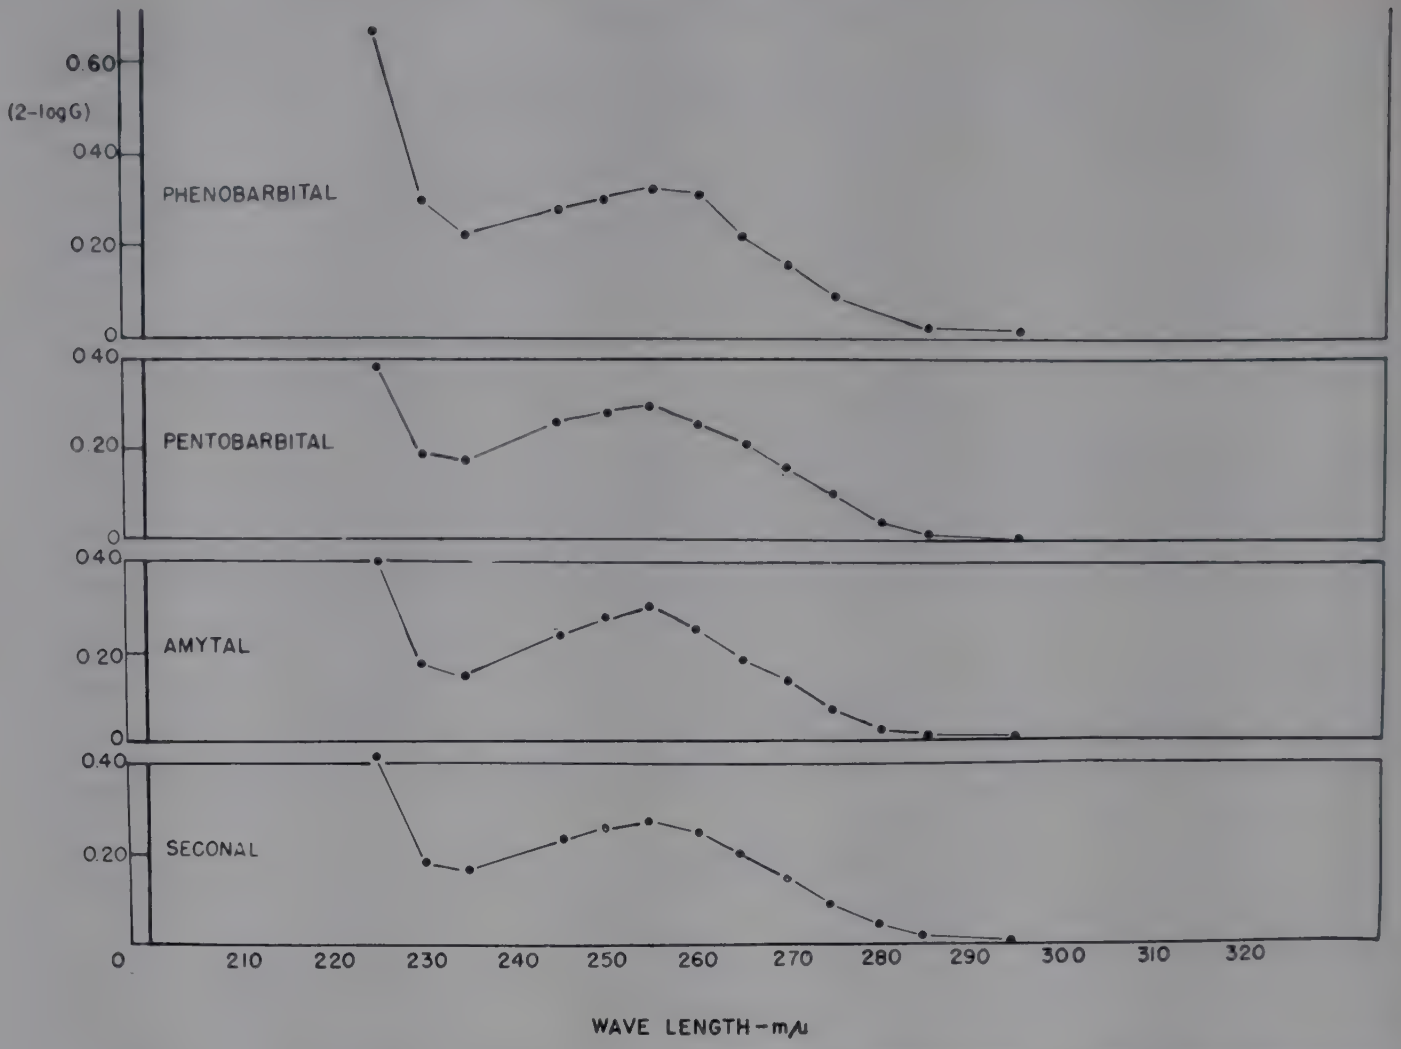

Fig. 698.—Absorption spectra of some representative barbiturates in 0.5 N sodium hydroxide solution. Each contains a malonyl urea ring structure and is characterized by an intense ultraviolet absorption spectrum with a maximum at 255 mμ and a minimum at 235 mμ. (Courtesy Dr. L. R. Goldbaum.)

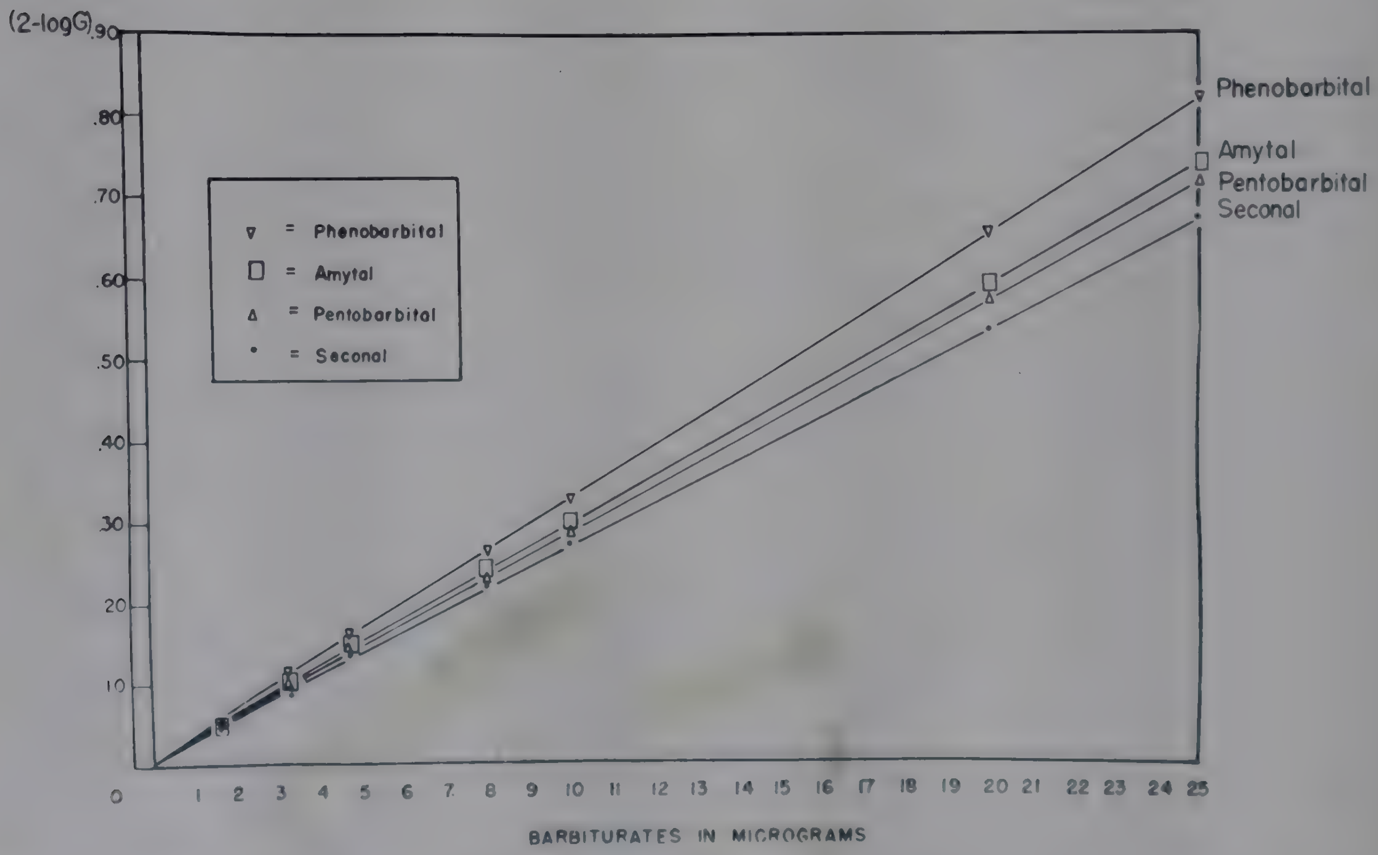

Fig. 699.—Barbiturates in micrograms obtained by the Goldbaum method. At maximal absorption, 255 mμ, the Beer-Lambert law relating to concentration and optical density is shown to be linear up to at least 20 micrograms per c.c. (Courtesy Dr. L. R. Goldbaum.)

ment and determine its transmission. Repeat at all wave lengths so as to obtain the entire absorption spectrum as shown in Fig. 698.

The maximum absorption of barbiturates is at 255 mμ; this means that they have their greatest density value at this wave length, and therefore the greatest sensitivity.

To identify the barbiturates, determine the whole band to see if it has a maximum at 255 mμ; then obtain its optical density at 255 mμ. Find the quantity by comparing either with a standard solution or with a known graph as in Fig. 699.

(II) **In Liver, Kidney, and Muscle.—**

Render 5 gm. of tissue homogeneous in a tissue blender using acetate buffer of pH 5.0, then make up the volume to the mark 25 c.c. in a volumetric flask, using the acetate buffer.

Pipette a 5 c.c. aliquot, equivalent to 1 gm., into a separatory funnel containing 15 c.c. of chloroform.

Carry out the procedure as in (I) above.

(III) **In Brain.—**

Brain cannot be extracted with chloroform because interfering substances produce emulsions and cause a high blank. Use ether instead of chloroform for the extraction of barbiturates from brain.

Render 5 gm. of brain tissue homogeneous using acetate buffer of pH 5.0.

Pipette 10 c.c. of this mixture, equivalent to 2 gm. of brain, into a 125 c.c. separatory funnel.

Extract twice with 50 and 30 c.c. of ether, respectively.

Shake the combined ether extracts with 3 c.c. of acetate buffer pH 5.0 to remove any adhering brain substances.

Discard the water layer.

Add 10 c.c. of 0.5 N sodium hydroxide solution to the ether and shake for 1 minute.

Allow the layers to separate until the alkaline layer is clear.

Run off the clear alkaline layer and analyze in the Beckman spectrophotometer.

Compare the alkaline solution with a reference solution of 0.5 N sodium hydroxide saturated with ether.

All tissues give some absorption at all wave lengths. It is necessary, therefore, to prepare blank curves on normal tissue. This is especially true when the tissues are not fresh or if they contain much fat.

Goldbaum has prepared average blank values at 255 mμ for fresh tissue.

TABLE 223

1 C.C.	OPTICAL DENSITY (MEAN OF A NUMBER OF DETERMINATIONS)	STANDARD DEVIATION FROM THE MEAN
Blood	0.045	±0.010
Liver	0.099	±0.026
Kidney	0.079	±0.020
Muscle	0.050	±0.022
Brain	0.12	±0.026

Experimental.—Rabbits weighing approximately 3 kilograms were injected intravenously or intraperitoneally with four different barbiturates representing various degrees of duration of action. Blood samples were withdrawn by cardiac puncture, at different time intervals. The rabbits were killed by air embolism and the distribution of the barbiturates in the tissues was determined. The results are given in Table 223.

Phenobarbital, a long-acting barbiturate, shows a blood level which falls very slowly; it remains at a high level 345 minutes after the injection of the drug. With the short-acting barbiturates, the blood levels fall at a more rapid rate. Disappearance of the barbiturates from the blood is related to the duration of their action; i.e., Amytal falls at a slower rate than Seconal. No evidence of cyclic behavior in barbiturate blood levels was found. Concentration of barbiturates was found to be highest in the liver and lowest in muscles.

This procedure is applicable to both pharmacologic and toxicologic investigation of barbiturates.

DETECTION AND DIFFERENTIATION OF BARBITURATES AND OTHER SEDATIVE DRUGS

Motley[2] describes the following procedures to differentiate opiates and barbiturates.

Test Reagents.—

Mercurous Nitrate.—15 per cent solution in 5 per cent nitric acid. A few drops of mercury must be kept in the bottom of the bottle.

Potassium Iodide.—N/1 (16.5 per cent) aqueous solution.

Mercuric Nitrate.—15 per cent solution in 5 per cent nitric acid.

Ferric Chloride.—N/1 (9 per cent) aqueous solution.

All of the test reagents must be kept in amber-colored bottles and must be discarded when they become hazy or turbid. Hard tap water (as Columbia, Mo., deep well water) may be used as a solvent for test materials with mercuric nitrate but is quite incompatible with mercurous nitrate, as are also hot water and alkalis.

Mercurous Nitrate Test

The addition of from 5 to 25 mg. of soluble barbiturate to 10 c.c. of water in a clean test tube containing 0.04 c.c. or one drop of the mercurous nitrate test solution produces a whitish to gray gelatinous or flocculent precipitate (Motley). *Sodium barbital* and *Pentothal sodium* form a finer precipitate with less tendency for flocculation. The barbiturate-mercurous nitrate precipitate is insoluble in acetic acid but soluble in nitric and sulphuric acids. The flocculent character of the precipitate is more marked when the pH is below 7.0, although the reaction occurs within a pH range from 4.5 to 9.5 as determined on a Beckman pH meter. The addition of a small amount of acetic acid does not interfere with the test and causes the precipitate to be more gelatinous. A large excess of barbiturate tends to dissolve some of the precipitate and make it less gelatinous. Alcohol up to 20 per cent may be used to dissolve drugs that are only sparingly soluble in cold water.

The addition of 0.08 c.c. or two drops of potassium iodide test solution to the barbiturate-mercurous nitrate precipitate produces a greenish color by reflected light and the character of the precipitate changes from gelatinous to one with no visible particles. On standing. the precipitate slowly settles, some sticking to the sides of the tube, and the greenish color by reflected light becomes yellow-green, somewhat like a blank. The reagents lose the green color most rapidly with phenobarbital of any of the barbiturate group, although, usually, a greenish tinge is perceptible after one or two hours. In the case of barbital sodium, the fine precipitate that settles out has a definite green color, being only slightly faded. With 10 mg. or more of Pentothal sodium, a thiobarbiturate, a slaty gray precipitate forms with mercurous nitrate and on the addition of potassium iodide the color does not change to the characteristic green by reflected light. The addition of potassium iodide to a blank produces a canary yellow color by reflected light and a fine colloid-like precipitate. Spectrophotometer determinations on light transmission from 400 to 700 angstroms revealed specific differences between the control and a sample with barbiturate.

As can be seen from Tables 224 and 225, this test is useful in the quick differentiation of the barbiturates from other sedative drugs, particularly the opiates; *dilantin sodium, theobromine,* and *theophylline* compounds give similar test and cannot be eliminated by these reactions. *Caffeine* compounds, *sodium benzoate,* and *sodium salicylate* produce the typical gelatinous precipitate with mercurous nitrate but on the addition of potassium iodide a coarse yellow precipitate results. Table 226 shows that the addition of mercurous nitrate alone identifies *aminopyrine* from *antipyrine* and these two in turn from *acetanilid*

and *acetophenetidin* which give no reaction with the reagent. *Avertin, carbromal, chloral hydrate, sulphates, sulphonmethane,* and *sulphonethylmethane* do not produce a precipitate with mercurous nitrate. *Morphine* and *codeine* with both reagents produce a greenish coarse precipitate, which settles quickly, and makes an easy distinction from the barbiturates. *Apomorphine* gives a white precipitate with mercurous nitrate which develops a pinkish tinge on standing a few minutes.

Mercuric Nitrate Test

The addition of from 5 to 25 mg. of a soluble barbiturate to 10 c.c. of water in a test tube containing one drop of mercuric nitrate test solution produces a white gelatinous precipitate, similar in character to the one produced by mercurous nitrate but whiter and more flocculent. (Table 225.)

The addition of two or more drops of potassium iodide test solution dissolves the barbiturate-mercuric nitrate precipitate of those tested, except in the case of *Ortal sodium* and *Seconal* in which the precipitate only partly disappears so that the test mixture becomes hazy. Potassium iodide does not dissolve the precipitate of *Dilatin sodium* with mercuric nitrate but does dissolve that of *Pentothal sodium.* The addition of two or more drops of ferric chloride solution also dissolves the mercuric nitrate-barbiturate precipitate except for *Ortal sodium* and *Seconal* which, as with potassium iodide, fail to clear completely. Ferric chloride does not dissolve the precipitate of *Pentothal sodium* or *Dilantin sodium.*

Table 226 shows that *Pentothal sodium* and *Dilantin sodium* may be distinguished from the barbiturates by using potassium iodide and ferric chloride in conjunction with mercuric nitrate. The various *salicylate compounds of theobromine and theophylline* give a gelatinous white precipitate with mercuric nitrate and a dark purple color appears on the addition of ferric chloride. The purple color will form with ferric chloride alone but is intensified by the mercuric nitrate. The salicylate part of the molecule is responsible for this chromogenic reaction.

Morphine sulphate with mercuric nitrate imparts a greenish tinge to the solution which remains clear and is not changed by ferric chloride or potassium iodide. *Codeine phosphate* gives a fine white precipitate with mercuric nitrate while the sulphate remains clear; but both the phosphate and sulphate salts of codeine produce a yellow precipitate on the addition of potassium iodide while the use of ferric chloride in place of the potassium iodide results in a clear solution in both cases. *Dilaudid hydrochloride* does not produce a precipitate with mercuric nitrate but the addition of ferric chloride yields a clear bluish solution, the color of which persists. With mercuric nitrate alone, *apomorphine* gives a clear red solution which does not fade. The opiates, *morphine, codeine, dilaudid,* and *apomorphine* can be differentiated from one another by these tests.

Ferric chloride with *aminopyrine* develops a deep purple color which fades in less than 60 seconds; however, if mercuric nitrate is added first the color persists for two or three minutes. *Antipyrine* gives a wine red color with ferric chloride while *acetanilid* and *acetophenetidin* do not. *Acetylsalicylic acid, Avertin, bromides, chloral hydrate, carbromal, sulphonmethane* and *sulphonethylmethane* give no color reaction or precipitate with any of the three test reagents.

Test for Acetanilid and Phenacetin

Acetanilids

(1) Hydrolyze with a few drops of dilute hydrochloric acid. Heat gently. Then apply the **isonitrile test**: Add a few drops of chloroform and a few drops of 10% sodium hydroxide and heat gently. A positive reaction is denoted by production of the strong pungent skunk-like odor of isonitrile.

(2) White crystals, melting point 114° C.

Phenacetin (Acetophenetidin)

(1) White crystals, melting point 135° C.

(2) Boil for a few minutes with several drops of concentrated hydrochloric acid to hydrolyze. Add 1 c.c. of saturated solution of phenol. Add several drops of freshly prepared saturated solution of calcium hypochlorite. The pink to red color of indophenol is produced, which becomes violet when concentrated ammonia is added, if phenacetin is present.

Note: The indophenol test is positive for both acetanilid and phenacetin. Differentiation is effected by using the isonitrile test which is positive for acetanilids but not for phenacetin.

Detection and Estimation of Aspirin or Salicylates in Tissue or Plasma[1]

Principle.—

Aspirin is hydrolyzed to salicylic acid by hydrochloric acid. Or the salicylic acid is extracted from acidified plasma with ethylene dichloride, then returned as the colored ferric complex to an aqueous phase and estimated colorimetrically.

Technic.—

Shake 2 c.c. of plasma in a separatory funnel
with 0.5 c.c. of 6N hydrochloric acid
and 30.0 c.c. of ethylene dichloride.

Shake well for complete extraction of the salicylate. Allow the two immiscible layers to separate. Discard the water layer.

Save the nonaqueous layer (ethylene dichloride).

Add 10 c.c. of 0.025% ferric nitrate solution to this nonaqueous layer and shake.

If salicylates are present, a blue color will develop, the intensity of which will vary directly with the concentration of salicylate present.

Treat varying concentrations of salicylates in a similar manner and use these for comparison of the unknown.

Serum Salicylates

Method of F. Velez Orozco and F. Guerra[2]

Reagents.—

2/3 N Sulphuric Acid.—

See page 225.

10% Sodium Tungstate Solution.—

See page 225.

9% Ferric Chloride Solution.—

Dissolve 9 grams of ferric chloride in distilled water and dilute to 100 c.c. with distilled water. For use dilute 1:10 with distilled water.

Technic.—

Place 2 c.c. of blood serum in a test tube.
Add 2 c.c. of 2/3 N sulphuric acid.
Add 9 c.c. distilled water
and 2 c.c. of 10% sodium tungstate solution.
Mix thoroughly, centrifuge, then filter through filter paper.
Place 9 c.c. of the filtrate in a colorimeter tube.

Add 0.2 c.c. of dilute ferric chloride solution (1 part reagent and 9 parts of water). Mix.

Read in the Lumetron within not more than 2 minutes, using green filter 530 against water as the blank set at 100 per cent transmission. Obtain the result in mg. per cent sodium salicylate from a calibration graph or card.

---

[1] Brodie, B., Udenfriend, S., Coburn, A.: J. Pharmacol. & Exper. Therap. **80**: 114, 1944.

[2] Archivos del Instituto de Cardiología de Mexico **16**: 131, 1946. Modified for adaptation to the Lumetron (Photovolt) model 400-A.

To convert these results from mg. per cent sodium salicylate to mg. per cent salicylic acid, multiply the result by 0.86.

Calibration Procedure.—

1% Sodium Salicylate Solution.—Dissolve 1 gram sodium salicylate, c.p., in distilled water in a 100 c.c. volumetric flask and dilute to volume with distilled water.

Add 1 c.c. of the standard sodium salicylate solution to 9 c.c. of pooled serum, free from salicylates (that is, from individuals known not to have taken any salicylates).

Dilute 1.0, 2.0, 3.0 c.c. of this serum salicylate solution respectively to 5.0 c.c. with salicylate-free serum. This yields sera containing respectively 20, 40, and 60 mg. per cent sodium salicylate.

Add 2 c.c. of 2/3 N sulphuric acid, 9 c.c. distilled water, and 2 c.c. of 10% sodium tungstate to each and continue as in the test.

Read the per cent transmission in the Lumetron, using green filter 530 against water as the blank set at 100 per cent transmission. If the calibration is carried out properly and if the proper reagents are used, 40 mg. per cent sodium salicylate will read somewhere in the region of 55% transmission.

Using Lumetron semi-log graph paper, assign to the concentration axis the values 0-125 mg. per cent sodium salicylate, and plot the transmission readings above the corresponding concentration values. The points will fall approximately on a straight line which intersects the transmission axis near the 100 per cent point. For the sake of convenience in use, the concentration values may be taken from the graph and entered into a Lumetron blank calibration card.

DETECTION OF MARIJUANA (CANNABIS SATIVA, LINN)

Marijuana is of great interest in many quarters due to the fact that its use by drug addicts is spreading in this country.

This plant grows wild along the roadsides in many states, particularly in the West. The proper name of the plant is *Cannabis sativa.* Marijuana is a mongrel Mexican word, meaning "pleasant feeling." In underworld argot, the drug is known by many different names, such as, "Indian hay," "greefo," "mu," "mooter," "reefer," and "Mary Warner." Yawger[1] has given a very complete description of this drug and its relationship to crime. He states that the Arabic word "hashishan" is responsible for our word assassin. In Persia, there lived a military and religious sect known as the Assassins, who were sometimes incited to greater violence in their atrocities by the use of hashish which is the historic name of marijuana. Hashish or marijuana was cultivated in China three centuries before Christ. It is alluded to in the Assyrian, Greek, and Roman writings. Napoleon's soldiers were forbidden to use it in Egypt in 1800. The use of hashish is common among the natives of India, Egypt, and North Africa.

The effects of this drug as it is commonly used are obtained through the medium of smoking cigarettes made from dried parts of the plant and leaves. The odor given off by the cigarette smoke is characteristic and distinctive. Smoking produces euphoria. John Stuart Mill, the philosopher, once wrote of its power to revive forgotten memories. Smokers will tell you that under its influence they are able to recall events long since forgotten.

---

[1] Am. J. Sc. **195**: 351, 1925.

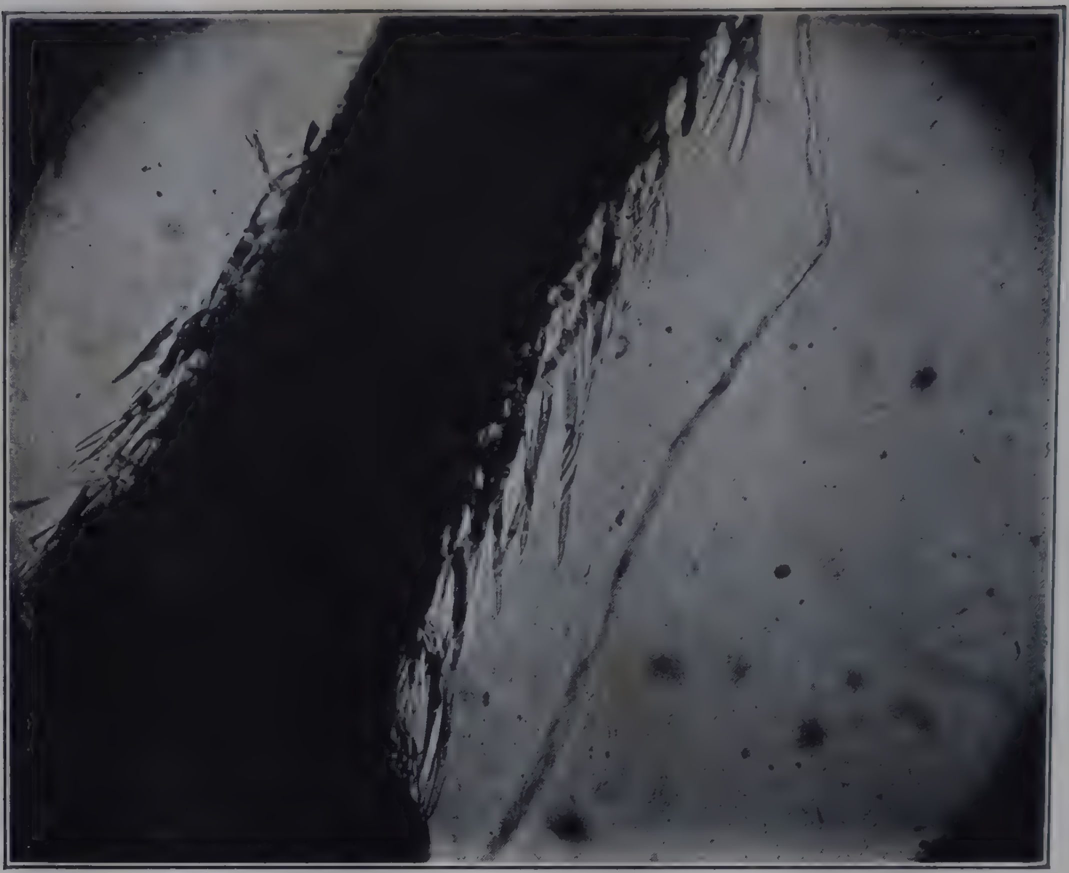

Fig. 700.—Stem of a marijuana plant. (About 75×.) Specimen found mixed with tobacco in the purse of a woman alleged to have committed suicide apparently under the influence of marijuana.

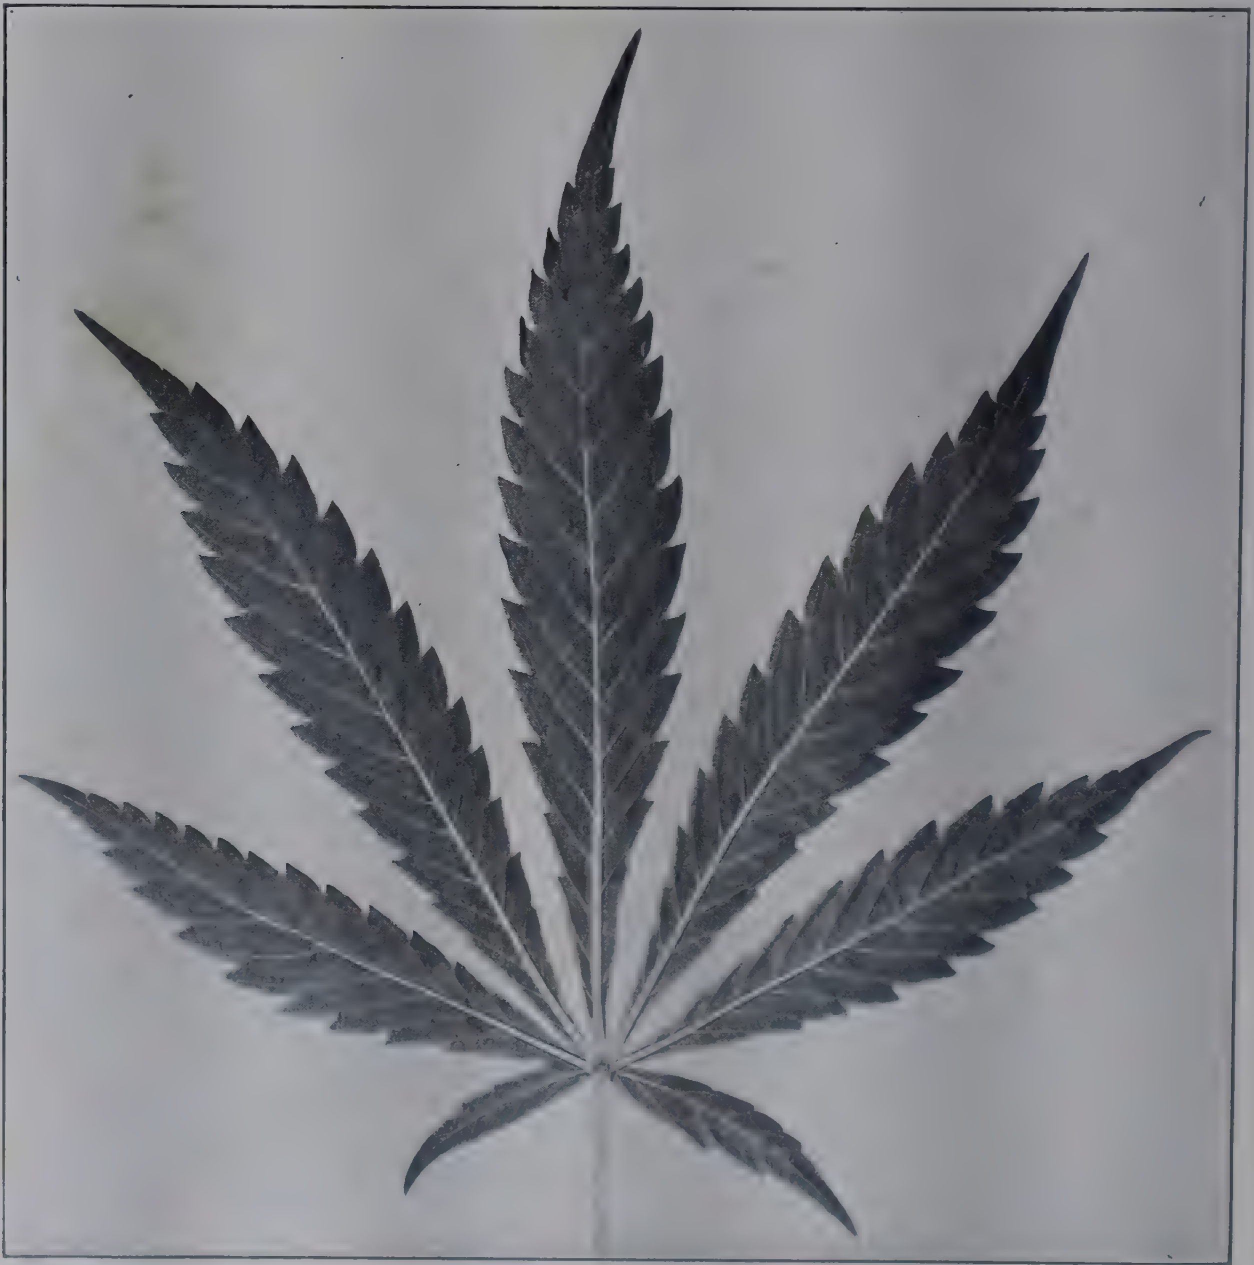

Fig. 701A.—Leaf of marijuana plant. (Courtesy Mr. H. J. Anslinger, Commissioner, Bureau of Narcotics, Treasury Department, Washington, D. C.)

The first noticeable change in the smoker is a lessening of his power to control his thoughts and actions fully. There are rapid interruptions in the continuity of thought. In addition to euphoria and exaltation, the smoker is aware of increased power and energy. Several Mexican addicts assert that they smoke the weed at night after a hard day's labor to secure relaxation. Only by determined effort of the will is the smoker able to withdraw from his reveries, but if there be further indulgence, such possible lucid intervals become shorter and less frequent. Illusions are common and faces of others often take on grotesque expressions. Imagination may be stimulated to the

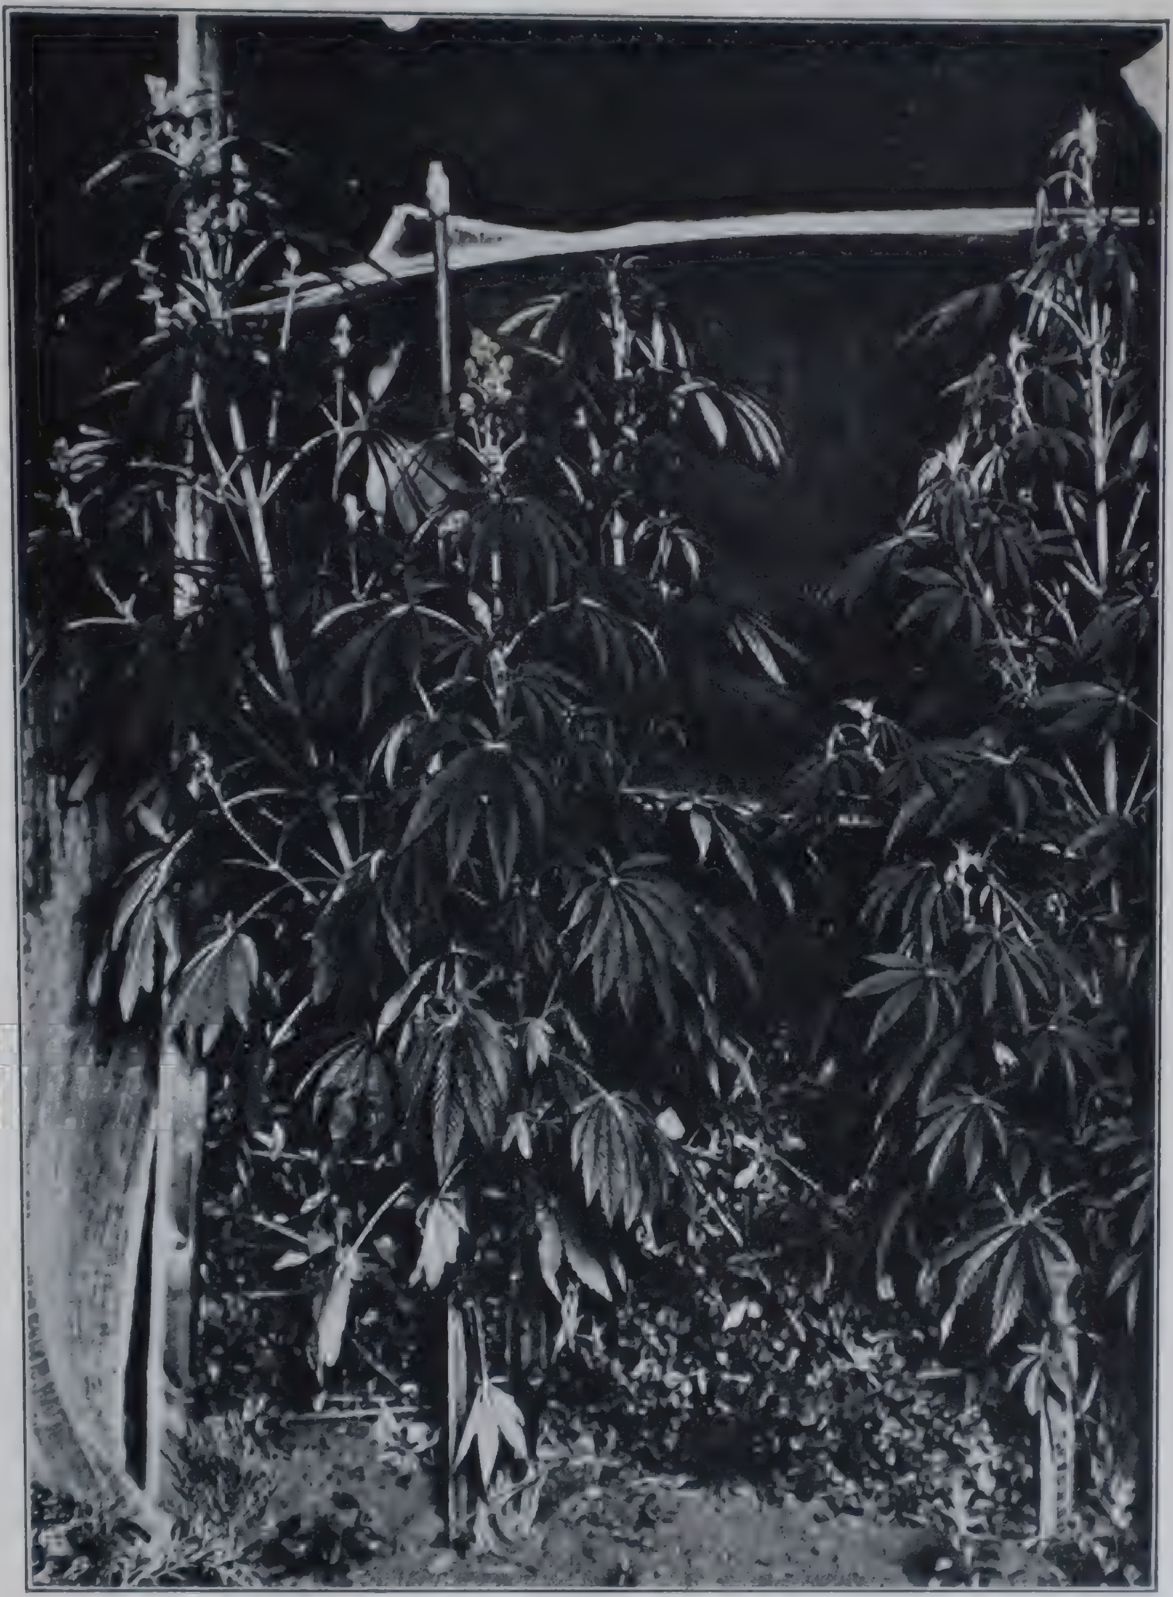

Fig. 701*B*.—Marijuana, flowering plant. These plants may grow more than six feet high. (Courtesy Mr. H. J. Anslinger, Commissioner, Bureau of Narcotics, Treasury Department, Washington, D. C.)

extent of delirium, sometimes with hallucinatory creations appearing. The effect may be pleasing, ludicrous, gruesome, or sensual. Dominant emotions become magnified—the genial man grows fonder of his fellows, the quarrelsome, more pugnacious, the timid more fearful, and the criminal emboldened. Exaggerations make the plainest food delicious. The hearing may be painfully intensified. Perception is disturbed in the matter of time and space; minutes seem hours and hours days; a long stride or a jump may be taken to step over a pebble or small stick.

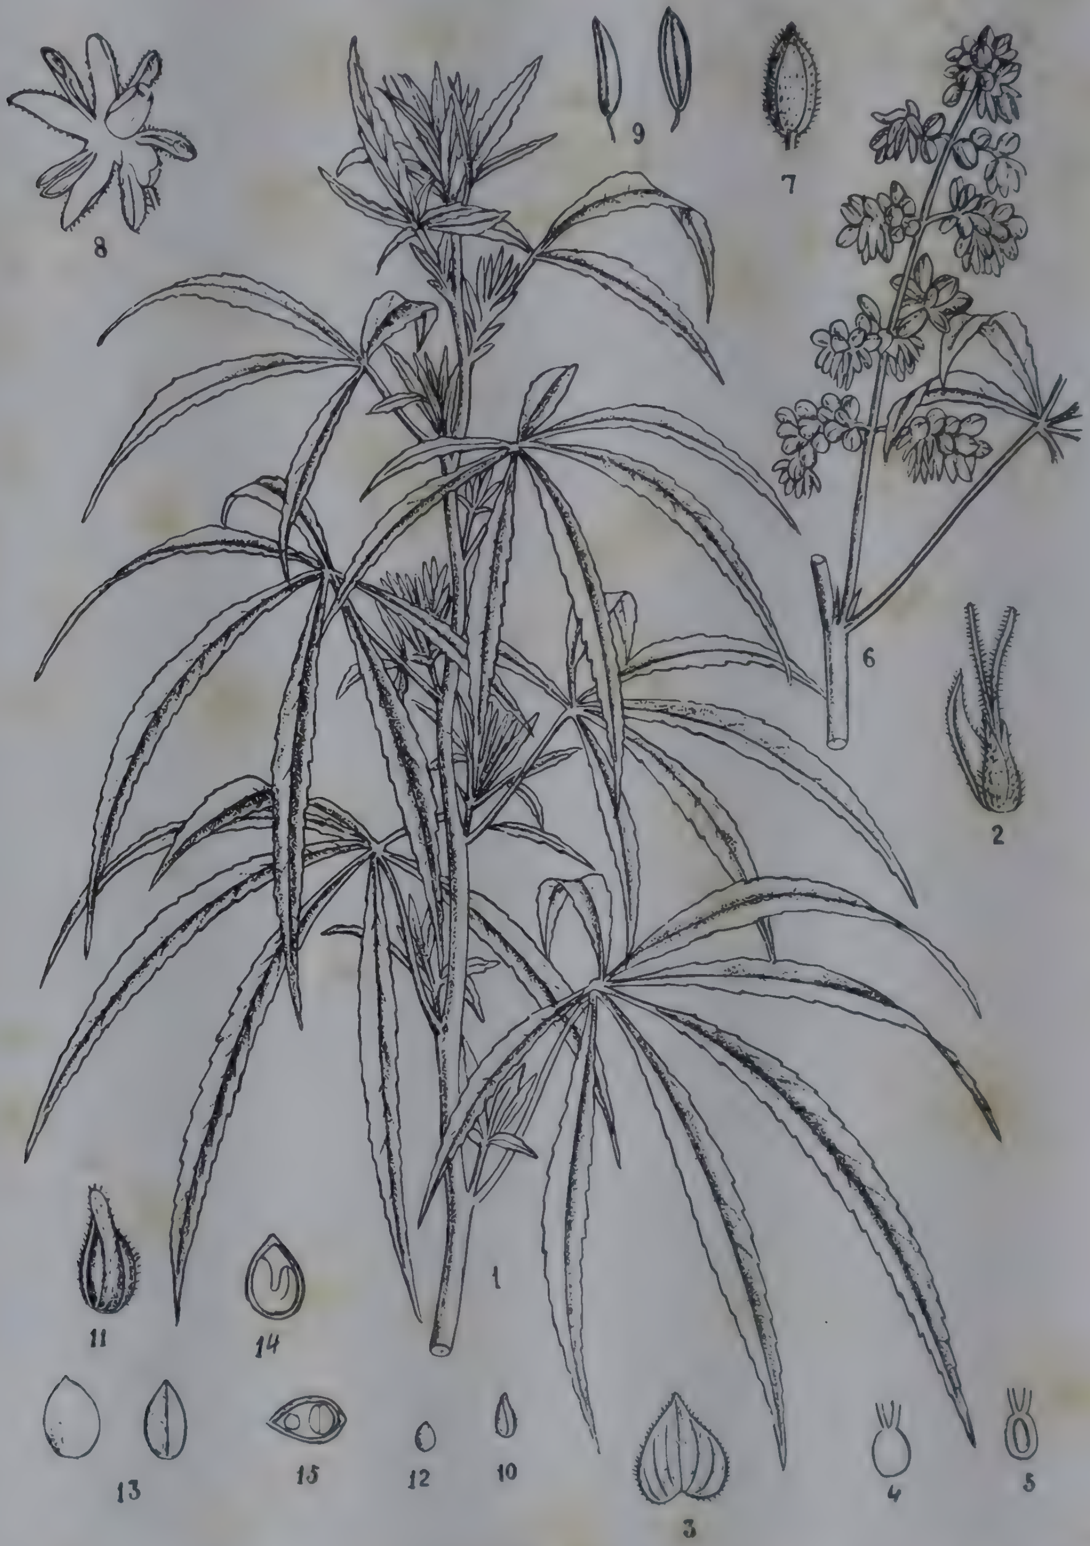

Fig. 702.—*Cannabis sativa.* Linn. (Drawn from specimens grown in Kew Gardens.) *1.* Upper part of a female plant. *2.* A female flower. *3.* Perianth unrolled. *4.* Ovary. *5.* Section of the same. *6.* A male panicle. *7.* A bud. *8.* A male flower. *9.* Stamens. *10, 11.* Fruit surrounded with the persistent perianth. *12, 13.* Fruit. *14.* Vertical, and—*15.* Transverse section of fruit. (Medicinal Plants by Robert Bentley and Henry Trimen. Vol. IV, Nos. 228-306, London.)

Relation to Crime.—It is generally believed that the use of this drug will cause chronic mental deterioration, an effect that has been noted for ages in India and Egypt.

Marijuana, in other words, is an American hashish and its effects correspond to those described in the literature of the hashish smoker of the Orient.

Fig. 700 is a photomicrograph of the stem of a marijuana plant, magnified about 75 times. Note the hooklike processes along both sides of the stem. This marijuana was taken from a specimen mixed with tobacco found in the purse of a woman who was alleged to have committed suicide, apparently under the influence of marijuana.

The identification of marijuana becomes necessary in view of the widespread use of the plant in cigarettes in this country. Marijuana comes within the bounds of the narcotic law and its use is also interdicted in a number of states by special legislative acts. It is a habit-forming drug and produces serious effects in addicts. It can be identified by microscopic examination. Fig. 701*A* shows the leaf and Fig. 701*B* the flowering plant which grows very tall. Fig. 702 is a plate drawn from specimens grown in Kew Gardens. These cuts are made from photographs furnished through the courtesy of Mr. H. J. Anslinger, Commissioner, Bureau of Narcotics, Treasury Department, Washington, D. C.

In the case of extracts and similar preparations containing marijuana, it is necessary to use the assay described in the tenth revision of the U. S. Pharmacopoeia under the monograph for cannabis.

Chemical Tests for Marijuana

Of all the methods of testing samples of material suspected of being marijuana, microscopic examination is generally the most satisfactory. An experienced observer should never be misled even though the marijuana present in the sample is only a small portion of the whole. The method is completely described in the Treasury Department publication *Marihuana—Its Identification.**

It is generally desirable to supplement microscopic examination by one or more chemical tests. Of the tests known at present only one is completely reliable, the modified Duquenois test. This test was first described by M. Pierre Duquenois and Hassan Negm Mustapha.[1] The test has not been shown specific for marijuana, but on the other hand no sample of marijuana has thus far been encountered which failed to respond. Certain samples of tobacco have been found to give a color response which might be confused with the color response of marijuana. The color response of marijuana may, however, be readily differentiated from that of tobacco by virtue of the different solubility characteristics of the colored product. The purple produced in the test by marijuana is readily extracted from aqueous solution by chloroform, while the color produced by tobacco is not extracted, but remains in the aqueous layer. The original test has, therefore, been modified to include this differentiation.

---

*For sale by the Superintendent of Documents, Government Printing Office, Washington, D. C., price 10 cents.

[1] J. Egyptian M. A. 21: 224, 1938; Chem. Abstracts 32: 5993, 1938.

Reagents.—

Duquenois Reagent.—

To 20 c.c. of 95% alcohol
add 5 drops of acetaldehyde
and 0.4 gm. of vanillin.

This reagent may be kept for some time in a glass-stoppered bottle, preferably in a refrigerator or in a cool, dark place. It should be discarded after the development of a deep yellow color.

Activated Charcoal.—

This is obtained as Darco, Norit, or similar material.

Petroleum Ether.—

30° to 80° C., B.P.

Hydrochloric Acid.—

Use the concentrated reagent grade.

Chloroform.—

Use the reagent grade.

Technic.—

Extract 0.5 gm. of bulk material or 2 cigarettes in a test tube with petroleum ether. Cigarettes need not be broken open. Allow about 1 hour for the extraction.

Add about 1 gm. of activated charcoal, shake, and centrifuge or filter.

Evaporate the filtrate in a white porcelain dish.

Add 1 c.c. of Duquenois reagent to the residue and swirl to dissolve.

Add 0.5 c.c. of hydrochloric acid and swirl again.

The presence of marijuana is indicated by a transitory series of colors: green, slate, and finally indigo-violet.

Transfer the solution to a test tube and add 2 c.c. of chloroform and shake.

The indigo-violet color will be transferred to the chloroform layer, if this is marijuana.

The Beam Test

Attach a suspected cigarette to a small test tube, or cylinder, with an ordinary paper clip, and with the aid of a small funnel pour 5 c.c. (1 thimble full) of petroleum ether into one end of the cigarette so that the liquid flows through the interior of the cigarette, extracting the filler on its way.

1. Pour about one-half of this extract into a small white porcelain dish and evaporate, add to the evaporated portion a few drops of Solution No. 1 (1% potassium hydroxide in alcohol). The residue in the dish should become purple in a minute or so, the color deepening gradually on standing.

—OR—

2. Add to the remainder of the solution in a test tube about 1 c.c. of Solution No. 2 (absolute alcohol saturated with hydrochloric acid gas) and shake; allow to settle. The lower layer should be distinctly pink.

The microscopic examination, as stated above, is possibly the most important part of the examination. The cellular hairs and cystoliths on the plant are very characteristic. If hydrochloric acid is added to the plant, bubbles are seen to escape microscopically due to the presence of calcium carbonate.

Bioassay in Animals

Bioassay in Dogs.—The degree of incoordination produced in dogs is the most common method for estimating biologic activity. The dogs at first are quieted and there is a characteristic expression suggestive of apprehension. Then a swaying of the body develops, which becomes progressively more intense, the direction of swaying being backward and forward as well as from side to side. The dogs try to stand in a characteristic position with the feet spread apart, to prevent them from toppling over. When placed in abnormal positions, the animals make no effort to correct the position. It has been said by Walton,[1] who has written an excellent book on this subject, entitled *Marihuana*, that a characteristic feature of the intoxication is the suddenness with which they can be aroused to an almost normal state of activity by some special stimulus. After the exciting stimulus, they return to the earlier depressed condition.

With large doses, the dogs show fibrillary tremors. Vomiting and retching occur; persistent scratching, uncompleted walking movements are observed; the head sinks lower and lower and is suddenly jerked back, only to sink again. Fraenkel compared this performance to a person dozing on a train, where he is frequently stimulated to a state of partial wakefulness and immediately dozes back.

Walton, Martin, and Keller defined six arbitrary stages of intensity of effects: First, a slight decompression; second, a barely recognizable ataxia; third, an obvious ataxia; fourth, a marked ataxia in which the animal frequently pitches forward and barely catches itself; fifth, inability to stand alone; sixth, inability to rise and plunge about.

Bioassay in Rabbits.—Rabbits do not exhibit swaying movement to as marked degree as dogs. They are usually made quiet by the drug. Walton, Martin, and Keller used the so-called von Frey hairs which elicit the wink reflex when pressed against the cornea of normal rabbits but would have no effect in narcotized animals. These men used von Frey hairs which bent at a pressure of 30 to 50 mg. The number of wink responses obtained with 20 strokes of the hair against the cornea was taken as a measure of the degree of anesthesia. They state that rabbits responded to about 16 of the 20 stimuli; with moderate doses the response would drop to about eight in twenty, and with larger doses would disappear altogether.

Bioassay in Rats and Mice.—Recognizable effects are seen in mice with 0.2 to 0.4 mg. of the vacuum distillate according to Walton, Martin, and Keller's method.

DETECTION OF OXALIC ACID

A solution of oxalic acid or of potassium binoxalate reddens litmus paper.

Either of these substances, with excess of calcium hydroxide, acetate, or sulphate, gives a white precipitate of calcium oxalate, which is insoluble in ammonia or acetic acid, but soluble in strong hydrochloric or nitric acid.

Vomited matter from a case of oxalic acid poisoning should be searched for the leaves of sorrel or green material of the rhubarb pie. This is to exclude the possibility of a complication in the analysis. In gastric contents, oxalic acid will be partly free and partly combined as the insoluble calcium or magnesium oxalates. For the free oxalic acid, the following method must be used:

1. Having made an extract with hot dilute hydrochloric acid and having filtered it, add lead acetate, which precipitates the lead oxalate along with various other lead compounds. Suspend this deposit in water and pass hydrogen sulphide through it for two hours. The oxalic acid is set free, the black lead sulphide being thrown down. Filter and test the filtrate with calcium acetate.

2. If the oxalic acid is in the combined state, use the following method: Digest the suspected material with warm dilute hydrochloric acid until the mixture is quite fluid, filter, and to the filtrate add ammonium hydroxide until an alkaline reaction is reached. Let stand, decant, and collect the deposit on a filter. This deposit is calcium oxalate. The filtrate is mixed with the decanted fluid, is treated with excess of calcium acetate, and the precipitate separated on a filter. This second deposit represents the free acid in the original material. Determine the nature and amount of the first deposit by washing with acetic acid on the filter and afterward putting into a beaker and dissolving by cautiously adding strong hydrochloric acid and gently heating. Excess of ammonia will precipitate it completely if sufficient time is allowed. After decanting the clear fluid wash the deposit by decantation, put into a tared dish, dry in a water bath, and weigh.

---

[1] Walton, Robert P.: Marihuana. J. B. Lippincott Co., 1938.

If this deposit is calcium oxalate, it will be white, and, when a portion is heated on platinum, leave a gray ash of calcium carbonate. Another portion warmed in a test tube with strong sulphuric acid evolves carbon dioxide gas, which can be identified by conducting it through a delivery tube into baryta-water. A third portion, suspended in water slightly acidulated with sulphuric acid, will discharge the purple color of potassium permanganate. This test can be applied by standard volumetric solutions and an estimation of quantity obtained.

GROUP III. ALKALINE-ETHER EXTRACTION

Use the residual aqueous solution from the acid-ether extraction, Group II. Alkalinize slightly with sodium hydroxide solution. Again extract with several portions of ether. Collect these extracts in a small evaporating dish and place them on a steam bath to drive off the ether.

The residue may be used for testing many poisons of the alkaloid group. The morphine group, however, is not soluble under the conditions of this extraction. To obtain the morphine group, neutralize the residual aqueous solution, above, with dilute hydrochloric acid and then alkalinize with *ammonia.* Extract with several portions of *ethyl acetate,* collect the extracts, and evaporate to dryness on a steam bath.

Purify these residues either by using selective solvents or by sublimation. Remember that with the presumptive tests many of the protein impurities give false positive reactions and may therefore be confused with true alkaloids. Further tests are indicated in such cases.

Reagents for Alkaloid Precipitation.—

Wagner Reagent.—

Dissolve 10 gm. potassium iodide, c.p.
and 1 gm. iodine, resublimed
in 100 c.c. of distilled water.

Mayer Reagent.—

Dissolve 1.4 gm. mercuric chloride, c.p.
and 5.0 gm. potassium iodide, c.p.
in 100.0 c.c. distilled water.

Marme Reagent.—

Dissolve 20 gm. potassium iodide, c.p.
in 20 c.c. of hot distilled water.
Add 10 gm. of cadmium iodide, c.p.,
and dilute to 100 c.c. with distilled water.

Picric Acid.—

Saturated solution of picric acid.

Platinic Chloride Reagent.—

Dissolve 5 gm. platinic chloride in distilled water and dilute to 100 c.c. with distilled water.

Technic for Precipitate Tests.—

Dissolve the residue in a minimum amount of very dilute acetic acid (1:100).
Place 1 drop of this dissolved residue on a glass slide.
Add 1 drop of precipitating reagent.
The various alkaloids yield typical crystals.
Protein products of putrefaction may interfere with this test.

Color Reactions.—

The following color reactions, which are usually more specific than the precipitating reactions, are made on the original dry residue.

Scrape off a small portion of residue and place it on a glass slide.

Carry out the color reaction from here using the proper reagent. These reactions are given in detail in Table 227.

Most of the chemical tests for alkaloidal poisons are color reactions, some are physiologic or biologic tests, and others are based upon the finding of specific crystals formed by specific precipitants.

There are many reagents used in the various color tests for alkaloids. The following list of color reactions is taken from Peterson, Haines, and Webster.[1]

1. **Concentrated Sulphuric Acid.**—No color, or only a faint straw shade is given by pure aconitine (which is rarely obtained), atropine, cocaine, codeine, scopolamine, hyoscyamine, gelsemine occasionally shows a yellow followed by brown (morphine often light red if reagent is impure), nicotine, quinine, quinidine, and strychnine.

Yellow, orange, or brown colorations are yielded by berberine, colchicine, delphinine, gelsemine, and lobeline. Yellow tints followed by red or violet are noted especially with the alkaloids of veratrum.

Red, purple, or violet colors are obtained with impure aconitine, apomorphine, brucine (due to impurity of nitric acid in the reagent), impure cocaine, coniine, impure gelsemine, narcotine, and physostigmine.

2. **Concentrated Nitric Acid.**—No coloration is noted with pure aconitine, atropine, cinchonine, coniine, gelsemine (may show yellow or green if impure), quinine, and strychnine.

Yellow tints are obtained with impure aconitine, berberine, codeine, gelsemine, morphine (may show red), narcotine, and veratrine.

Red, purple, or violet colors are given by impure aconitine, apomorphine, berberine, brucine (deep red), and physostigmine.

3. **Fröhde's Reagent.**—This is prepared by dissolving 1 or 2 mg. of molybdic acid in 1 c.c. of chemically pure sulphuric acid. Other directions specify higher proportions of molybdic acid, but these lessen the distinctiveness of the test.[2] This reagent must be freshly prepared just before use as it is gradually reduced on standing with production of colored oxides of molybdenum. While this reagent gives colorations with many alkaloids, its most distinctive reaction is with morphine.

No color is produced with atropine, cinchonine, coniine, hyoscyamine, nicotine, scopolamine, and strychnine. Yellowish colorations are observed with aconitine and colchicine. Reddish shades are noted with brucine and veratrine. Bluish colors are given by codeine and morphine (purple fading to violet, then dirty green, yellow, and finally to faint pink). Greenish shades are yielded by apomorphine, berberine, and quinine.

DETECTION OF MORPHINE IN ANIMAL TISSUES

(A) Separation from the Tissues

The entire specimen should be used. Weigh the material before testing.

Cut the viscera into fine particles.

Place in a flask to which is connected a reflux condenser, and cover with 50% alcohol distinctly acidulated with acetic acid (or if there is a possibility of conversion of morphine to apomorphine, use hydrochloric or salicylic acid).

Digest in the closed flask at 70° C. for one hour.

Cool.

Strain through gauze.

Wash the residue with a little of the dilute acidulated alcohol.

Return to the flask.

Repeat the digestion and straining of the residue for a second and a third time.

Evaporate the mixed alcoholic filtrates and washings in the water-bath to a syrupy liquid.

Add to this three times its volume of very slightly acidulated (acetic) alcohol, 95%.

---

[1] Legal Med. & Toxicol. 2: 427, 1923.

[2] Fröhde's original communication (Ann. Chem. **120**: 188, 1861) called for 0.01 gram of sodium molybdate in 1 c.c. of concentrated sulphuric acid. See, however, Arch. Pharm., **176**: 54, 1866.

Cork in a containing flask, shake, and set aside for from twelve to eighteen hours, agitating from time to time.

Filter the mixture, using a filter pump, and a Büchner funnel.

Wash the residue with successive small portions of alcohol of the same strength and acidulation as the filtrate.

Evaporate off all the alcohol in a water-bath.

Add water just perceptibly acidulated with sulphuric acid in quantity barely enough to bring the soluble matter into limpid solution.

Stir the whole thoroughly.

Filter out the insoluble matter.

The filtrate must be clear.

Shake out the filtrate with the immiscible solvents as follows:

(1) While acid, with chloroform in several small successive portions;
(2) On making the liquid alkaline with ammonia, with four small portions of a mixture of chloroform and ether;
(3) After slight acidulation and warming, with hot amyl alcohol in several portions;
(4) After making alkaline with ammonia and warming with hot amyl alcohol as the solvent for morphine, this being applied in repeated portions.

The immiscible solutions, (1), (2), and (3), being respectively chloroform, chloroform-ether, and amyl alcohol, should be once or twice shaken out with a small quantity of acidulated water.

These small water-washings should be added to the aqueous liquid treated in (4).

The final morphine extraction in (4) is made with the liquid and solvent both hot, and continued in at least three successive portions, and until, on evaporating 1 or 2 c.c., a negative result is obtained with one of the more delicate tests.

Filter the united amyl alcohol solutions (first wet the filter paper with amyl alcohol).

Cool.

Shake out with water in very small portions until the resulting washings give no precipitate with barium chloride.

Measure the amyl alcohol solution so washed. Hold in reserve for qualitative and quantitative tests.

To identify morphine positively, we must find the crystals.

To obtain these crystals, use the final residue, mix with warm alcohol, drop by drop, and then watch microscopically. Morphine crystallizes in single and group columns of orthorhombic system with hexagonal surface.

(B) Qualitative Tests

The Marquis Test

Reagent.—

3 c.c. of concentrated sulphuric acid.
2 drops of 40% formaldehyde (Formalin).

Technic.—

Obtain a dry residue by evaporation of some of the amyl alcohol filtrate. This should be on white porcelain.

Touch with the above reagent from the point of a glass rod.

An intense purple red color, changing to violet, and finally to blue is observed if morphine is present.

A marked reaction is obtained with 0.02 mg. morphine.

Codeine and apomorphine do not give the initial purple, but produce a violet changing to blue.

Oxydimorphine shows a green color, which changes to a flame red.

Dionine gives a dark blue violet.

Heroine shows the same colorations as does morphine.

Deniges' Test

Place in a test tube 10 c.c. of dilute solution of the residue. (Not less than 0.03 gram per liter.)

Add 1 c.c. hydrogen peroxide

and 1 c.c. ammonium hydroxide solution.

Add 1 drop of a 4% solution of copper sulphate.

Shake.

At once a rose red to a deep red color appears, depending on the concentration of the morphine present.

Codeine, thebaine, papaverine, narceine, and narcotine give negative results.

Oxydimorphine, apomorphine, heroine, and dionine give somewhat similar results.

(C) Quantitative Tests

Evaporate the amyl alcohol solution to dryness.

Dissolve this dried residue in a known amount of N/10 sulphuric acid solution.

Titrate the excess of acid with N/50 potassium or sodium hydroxide solution, using cochineal as indicator.

Each c.c. of N/10 sulphuric acid consumed in the combination with morphine in the residue corresponds to 0.028516 gram of anhydrous morphine.

Example:

15 c.c. N/10 sulphuric acid were used to dissolve the residue.

40 c.c. N/50 sodium hydroxide were used in the titration. This corresponds to 8 c.c. of N/10 NaOH.

8 c.c. of N/10 sulphuric acid were present, therefore, in excess.

15–8 equals 7 c.c. of N/10 sulphuric acid which combined with the morphine.

7 × 0.028516 equals 0.199612 gram of morphine present.

0.13 gram, or 2 grains, of morphine sulphate may be poisonous when swallowed and undoubtedly endanger the life of a person unaccustomed to the drug.

The average **minimum fatal dose of morphine** for an adult is about 1 grain, according to Haines.

THE APPLICATION OF ULTRAVIOLET ABSORPTION SPECTROSCOPY IN ANALYTICAL TOXICOLOGY*

Ultraviolet absorption spectra have been used for many years to establish the identity and structure of organic as well as inorganic compounds. The Beckman photoelectric spectrophotometer with ultraviolet attachments provides an instrument that is convenient, easily manipulated, and accurate so that ultraviolet absorption methods can be adapted for routine laboratory examinations. In the last ten years, numerous procedures have been developed for the identification and determination of a large number of compounds, many of which are of special interest to the toxicologist. These include sedatives, analgesics, antihistaminics, alkaloids, insecticides, and other aromatic poisons. Ultraviolet methods have the added advantage of retaining the sample for other tests. They are rapid and provide a highly specific identification and quantitative estimation for low concentrations of substances; thus the toxicologist can use ultraviolet analysis as a routine, rapid screening procedure for many compounds in all cases of accidental or unexplained deaths. For example, since the widespread use of barbiturates, it is necessary to rule out these hypnotics as a contributory cause of death in auto accidents, home accidents, etc. Analysis of a small sample of blood by the ultraviolet procedure detects barbiturates in concentrations well below the toxic range.

---

*After Kaye and Goldbaum in Gradwohl: Legal Medicine, The C. V. Mosby Co., 1954.

The basic laws governing the absorption of radiant energy are those of Beer-Bouguer (page 210).

Spectral Analysis.—The identification of compounds by their spectra is made by finding the curve of a known compound that agrees with the unknown. In spite of their empirical nature, spectrophotometric identifications are widely accepted, provided the work is done carefully. When the absorption spectrum of a compound is determined, identification is attempted first from the curve shape. Of primary concern is what maxima and minima occur with respect to wave length and then what are their relative heights. This is at best an identification of a particular chromophore group. However, even if two compounds have a similar chromophore group, they usually do not have identical spectra over the entire range of the ultraviolet as illustrated by the substituted barbiturate derivatives, Table 229. Generally, if compounds have many points of inflection which agree, identification is more certain than if there are relatively few. A compound like quinine is relatively easy to identify because it has a number of inflection points, while other compounds such as strychnine with only one maximum are not conclusively identified from their spectra.

It is important not to fail in a tentative identification of a compound because of trivial differences from small amounts of impurities. As a rule, impurities are more likely to cause greater changes at the lower wave lengths. An important principle in ultraviolet spectrophotometry is that, in almost all instances when two or more substances are present together, their absorbencies are additive. Thus the absence of absorbence at definite wave lengths precludes the presence of many substances.

The external solution conditions alter the absorption spectra of many compounds. This is important because, first, conditions must be kept constant to avoid errors in qualitative and quantitative analysis, and, second, changing the solution conditions may provide a means for more specific identification of compounds. Such factors as solvent, temperature, pH may increase, decrease, or completely change the absorption spectra of a compound. Any one or combination of these conditions may be used to further aid the identity of a substance.

As a general statement, the transmittancy range of 10 to 50 per cent is desirable in accurate work. High transmittancy should be avoided because inaccuracies arise due to accidental dirt on cuvettes, effects of slight turbidity in both the unknown and in the reference cell. Similarly, too low transmittancy should be avoided due to inaccuracies of the readings and the failure to follow Beer's law in some instances. The sensitivity of a procedure may be increased by resorting to cuvettes with longer light paths or by using 1 cm. light path microcuvettes with a capacity of 0.5 c.c.

Ultraviolet Spectrophotometric Analysis of Drugs.—The toxicologist is continually confronted with specimens of medicines, pills, capsules, and other substances submitted for analysis. These types of samples generally require no separation procedures. The substances are present in relatively high concentrations requiring usually considerable dilution with acid or base to arrive at the proper absorbency. At these high dilutions, the interference from absorption of preservatives and fillers usually can be eliminated. When two absorbing substances are present, it may be possible to determine both if one component can be identified by its absorption at the higher wave lengths. Then its absorption band can be subtracted from the total absorbencies and the remaining substance in turn identified by its characteristic absorption band. When two known components are present, the concentration of both can be determined by setting up a simultaneous equation and solving at two wave lengths. This procedure is used in the determination of aspirin, Phenacetin, and caffeine in pills.

Ultraviolet Spectrophotometric Analysis of Biological Samples

The isolation of relatively small amounts of organic drugs from normally occurring absorbing substances in blood, urine, and tissues presents a problem in the ultraviolet spectrophotometric analysis of biological samples. In general, the isolation procedure consists of adjusting the biological sample to the proper pH and then extracting with an organic solvent. The organic drug is transferred to the water phase by extracting the solvent with an acid or alkaline solution to form a water-soluble salt. The absorbencies of the water solution are determined in an ultraviolet spectrophotometer.

The solvents that have been used in the extraction of biological samples in order of increasing polarity are petroleum ether, hexane, carbon tetrachloride, chloroform, ethylene dichloride, ether, and the higher molecular weight alcohols. The choice of solvent depends upon the distribution coefficient of the particular component in water and in solvent. Most of the organic compounds encountered in toxicology require the use of somewhat polar solvents. Chloroform appears to be the solvent of choice for almost all drugs. Ethylene dichloride is the best polar solvent for extracting nervous tissue. Unlike chloroform, no emulsions occur.

The presence of absorbing substances in the final extract interferes with the specificity, sensitivity, and accuracy of the determination. To reduce absorbing substances, solvents are distilled, run through silica gel, or washed with acids and alkali. To offset any absorption by the reagents, a water sample is carried through the same extraction process as the unknown and used as the reference solution.

The use of the least polar solvent possible will reduce the extraction of normally absorbing substances present in biological materials. Adjusting the sample to a specific pH before extraction with solvent or washing the solvent layer with a solution of suitable pH after extraction of the sample also will reduce the extraction of interfering substances. For example, in the determination of barbiturates, strongly acid substances are not extracted by the chloroform when the biological sample is adjusted to pH 7.4. In the determination of quinine, the solvent extract of a biological sample is washed with an alkaline solution of pH 9.0 to reduce interfering absorbing substances.

When a drug has a high absorbency index or is present in relatively high concentrations as in acute poisonings, interference from normally absorbing substances may be insignificant. Pentothal, a thiobarbiturate, is an example of a compound having a high absorbency index. This drug is readily determined by ultraviolet spectrophotometric analysis.

A correction for the absorbency of the impurities at the wave length where the component is to be determined can be made if a straight line exists when the absorbencies of the impurities are plotted against wave lengths. This procedure has been used in the determination of barbiturates, caffeine, and benzene hexachloride.

In some instances, interfering substances can be eliminated if the absorbencies of the component change with pH while the absorbencies of the interfering substances remain the same. Another procedure used in overcoming interference from impurities is to bring a change in absorbency of the component by chemical means. In the determination of antipyrine, the absorbency of the solution is determined at 350 mμ, then sodium nitrite is added. If there is an increase in the absorbency at 350 mμ, 4-nitroso-antipyrine has been formed, indicating the presence of antipyrine. The change in absorbency is related to the concentration of antipyrine in solution.

Purification Procedures Used in the Preparation of Samples for Ultraviolet Spectrophotometry

The residues of the acid and basic group extracts in the Stas-Otto procedure (pages 2285, 2302, and 2313 ff.) contain large amounts of impurities that interfere with the identification of organic drugs by ultraviolet spectrophotometry. The following technics have been successfully applied to the purification of many organic drugs:

The procedure of microvacuum sublimation of Gettler, Umberger, and Goldbaum is an effective means of purifying a large number of drugs such as barbiturates, salicylates, alkaloids, and other compounds. Micro amounts of the sublimate can be easily isolated, dissolved in a suitable solvent, and its ultraviolet absorption spectrum determined.

Column absorption chromatography has been used to separate and purify barbiturates and alkaloids. The technic of ion exchange of resins also has been applied to the determination of narcotics. In both these processes, it is possible to obtain relatively pure compounds for ultraviolet spectrophotometric analysis. Paper iontophoresis and paper chromatography furnish an excellent purification procedure for the separation and final determination of alkaloids by ultraviolet spectrophotometry. The application of these technics is illustrated on page 2318 in the determination of morphine in urine.

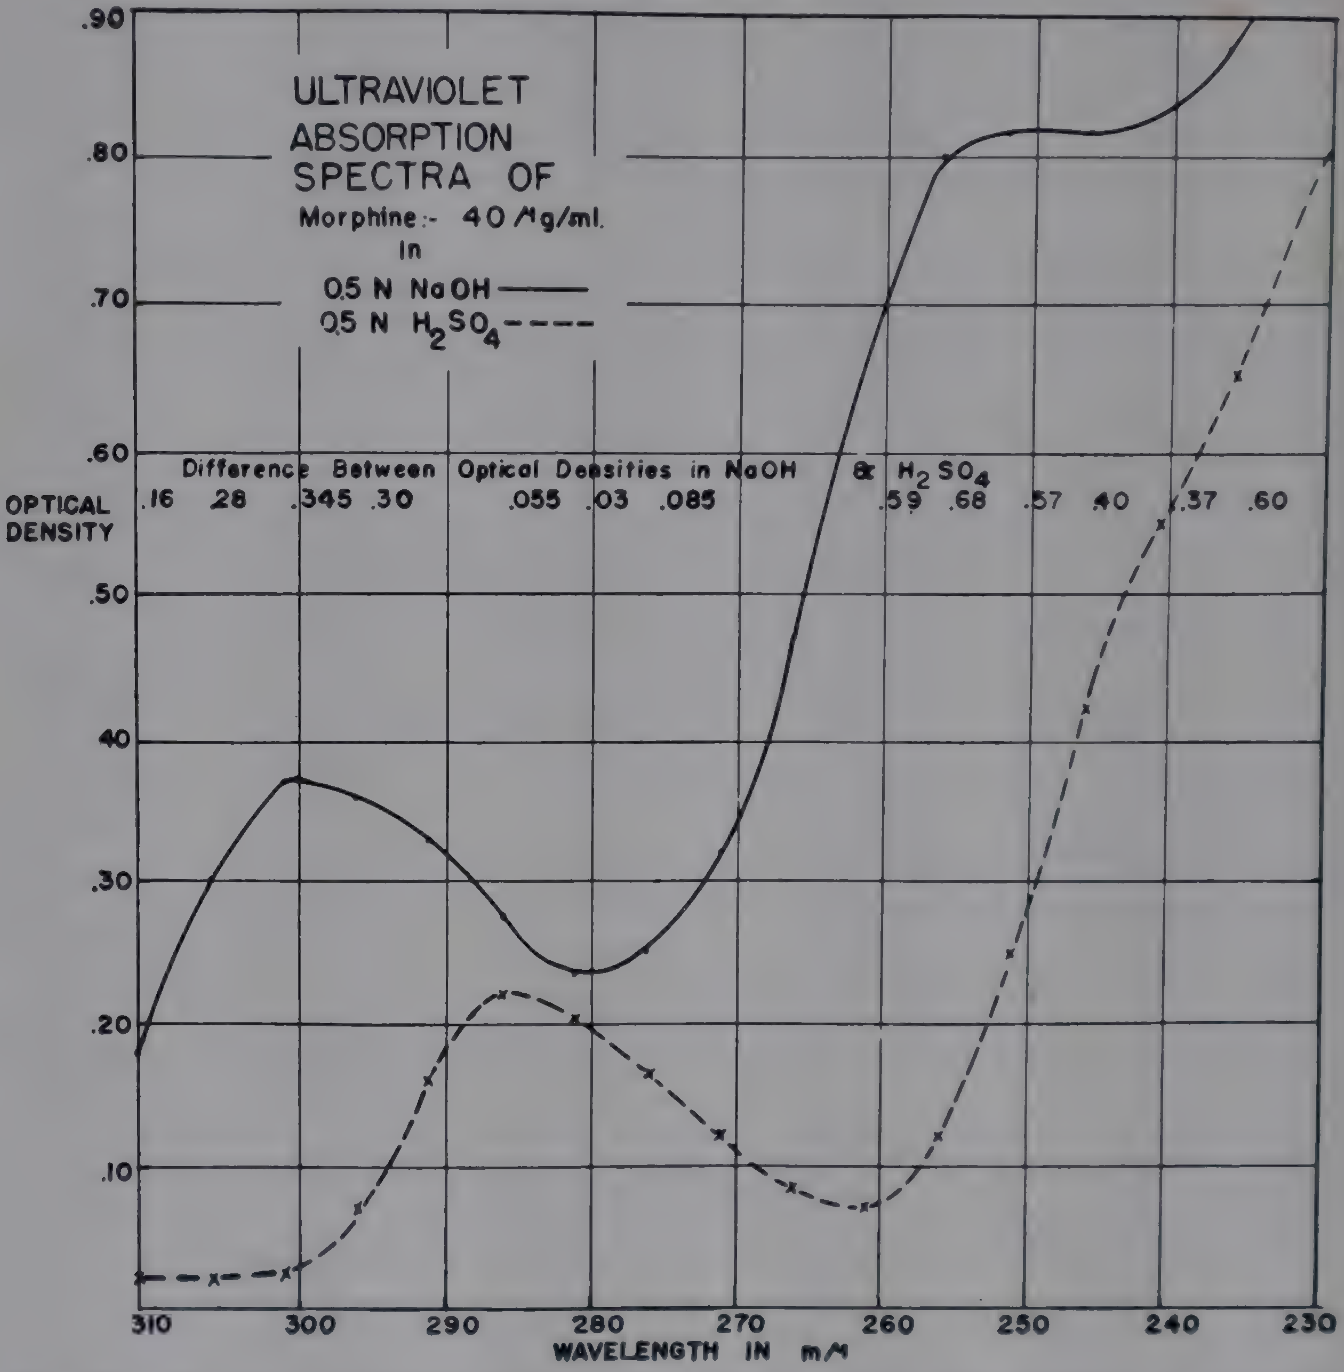

Fig. 703.—Ultraviolet absorption spectrum of morphine. (Kaye and Goldbaum in Gradwohl: Legal Medicine, The C. V. Mosby Co., 1954.

Ultraviolet Spectrophotometric Examination of Organic Compounds Appearing in the Stas-Otto Group Separations

Volatile Distillates.—Many aromatic compounds that are volatile with steam can be readily identified and quantitatively estimated by their characteristic ultraviolet absorption spectra. The absorbencies of the steam distillate of either stomach contents or tissue are determined at various wave lengths from 330 to 225 mμ, using distilled water as a reference solution. Insignificant absorbencies at specific wave lengths can preclude the presence of many compounds. Table 228 shows the maxima and the minima and the $E^{1\%}_{cm}$ for some compounds that may appear in the steam distillate. Since the $E^{1\%}_{cm}$ of benzene and camphor are low, a tenfold increase in sensitivity can be made by extracting 50 c.c. of the steam

							Strychnine	97.5
							Pentamidine	160
228	Cinchonidine	1190						

distillate with 5 c.c. of n-hexane. The absorbencies of the hexane extract which will quantitatively remove benzene and camphor can be determined. The reference solution is n-hexane previously shaken with 50 c.c. of distilled water.

Acid Solvent Extract.—The examination of this group of compounds by ultraviolet spectrophotometry is best made after a purification procedure such as vacuum sublimation. The purified compound is dissolved in an appropriate solvent and its ultraviolet spectrum determined. No purification is necessary when large amounts of compounds are present in the residue. For many drugs in the group, a direct extraction of small samples (1 to 5 gm.) is made for their determination by ultraviolet spectrophotometry (Fig. 703). Table 229 lists the maxima and minima $E^{1\%}_{cm}$ of many drugs in this group.

Alkaline Solvent Extracts.—Purification of the extracts is generally required before examination by ultraviolet spectrophotometry. Vacuum sublimation, chromatography, paper iontophoresis are effective purification procedures. The maxima and minima $E^{1\%}_{cm}$ of basic compounds are shown in Table 230.

Paper Iontophoresis and Paper Chromatography in the Determination of Alkaloids*†

The moving of mixtures on filter paper strips is a valuable microanalytical method for purification and identification of alkaloids. In paper iontophoresis, the mixture to be separated is applied at some intermediate position on a filter paper strip. An electropotential is applied across the ends of the filter paper strips saturated with an electrolyte. Separation of the constituents depends upon the fact that certain charged substances exhibit relative differences in mobilities at different pH values under the influence of an electrical field.

A suitable apparatus consists of a Lucite box with a center partition dividing it into anode and cathode compartments. Platinum foil electrodes dip into the electrolyte solution in the anode and cathode sides. The two com-

---

*Kaye, Sidney, in Gradwohl: Legal Medicine, St. Louis, 1954. The C. V. Mosby Co.
†See page 221 for paper electrophoresis.

partments are connected by a piece of Tygon tubing to permit initial equilibration of the liquid level of anolyte and catholyte in order to prevent electrolyte flow currents due to "siphoning." During operation, this tubing is clamped shut. Filter paper strips are supported by a glass support frame with their ends dipping into the electrolyte compartments. A peaked roof of the cover of the cell permits any electrolyte condensing on the cover to drain back into the electrolyte compartments without dripping upon the filter paper. For the movement of alkaloids, the electrolyte is 1N acetic acid. The filter paper strips can be Whatman No. 1, 2, 3, or 50. Three hundred to 600 volts are applied for ½ to 2 hours.

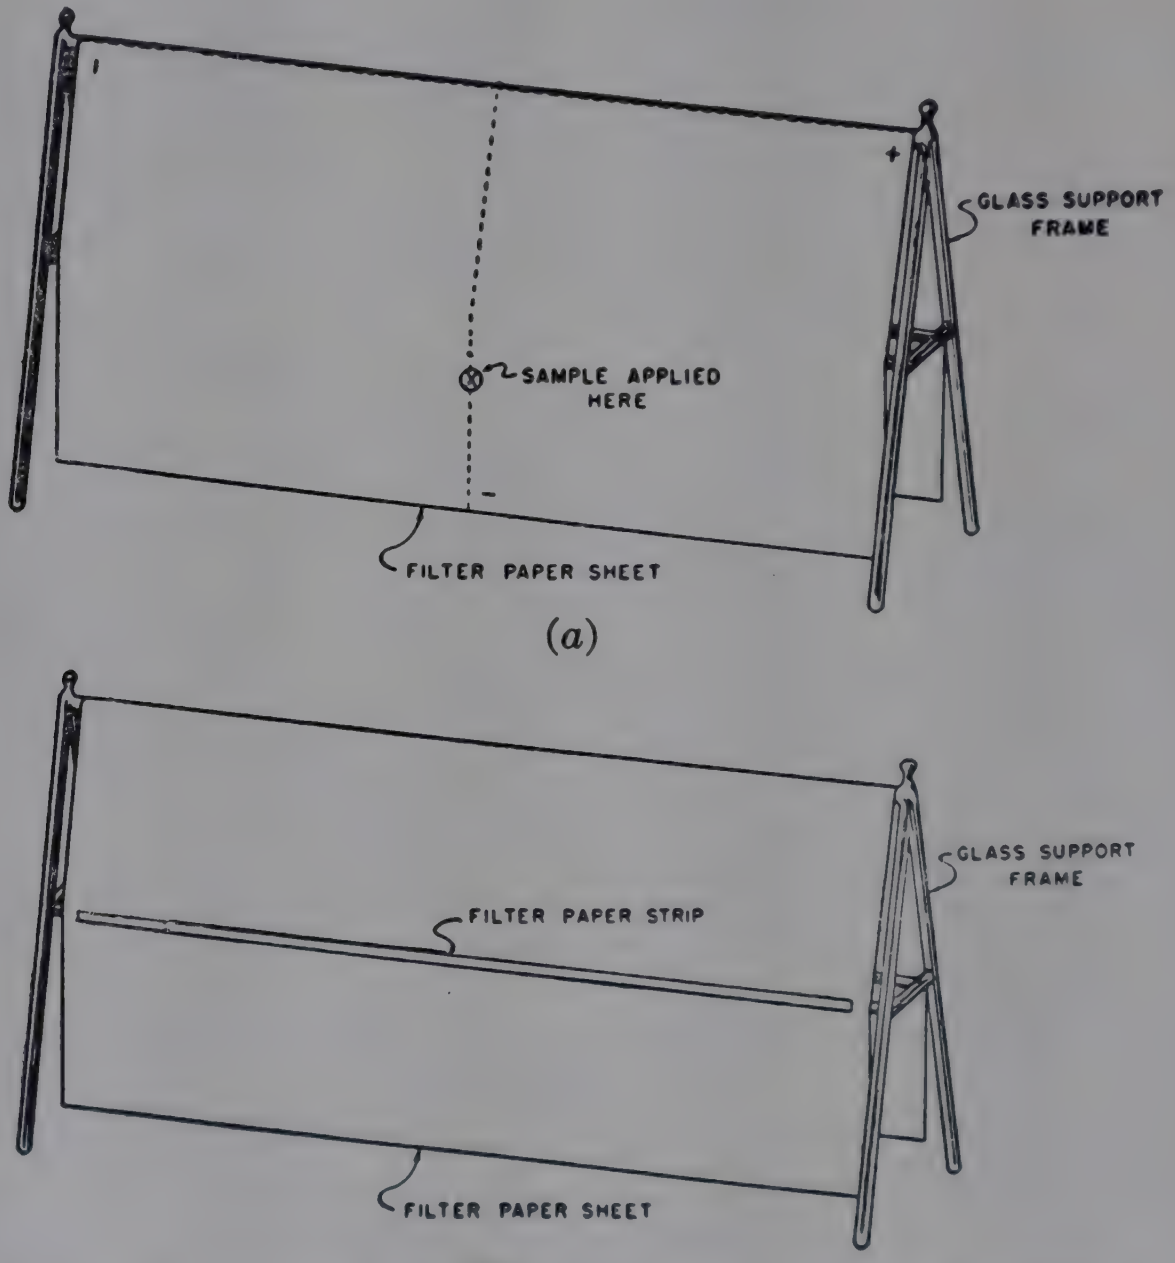

Fig. 704.—Durrum's apparatus for electrophoresis and iontophoresis. (From Gradwohl: Legal Medicine, The C. V. Mosby Co.)

In paper chromatography, the movement of a mixture along a strip of filter paper is accomplished by means of a solvent front. The ratio between the distance traversed by a component and the distance traveled by the solvent is known as the *Rf value*. This value depends mainly on the distribution coefficient of a compound in water and an immiscible solvent. It provides an identifying characteristic for a given compound. The mixture to be separated is applied near the end of a strip of filter paper which is dipped into the mobile solvent. The solvent front moves up or down the paper, depending on whether an ascending or descending technic is used. The chromatography apparatus consists of an enclosed tank or glass jar with a rack to suspend the filter paper strips and a container to hold the mobile solvent. The atmosphere inside the tank is saturated with water and the immiscible solvent. In the separation of alkaloids, Munier and Macheboeuf[1] use a mixture of n-butanol, glacial acetic acid, and water for the mobile solvent, while Carless and Woodhead[2] use filter paper strips saturated with N/15 phosphate buffer and a mobile solvent of n-butanol saturated with water. Whatman No. 1, 2, 3, or 50 filter paper strips can be used. The time necessary for adequate movement of the solvent front is from 6 to 15 hours.

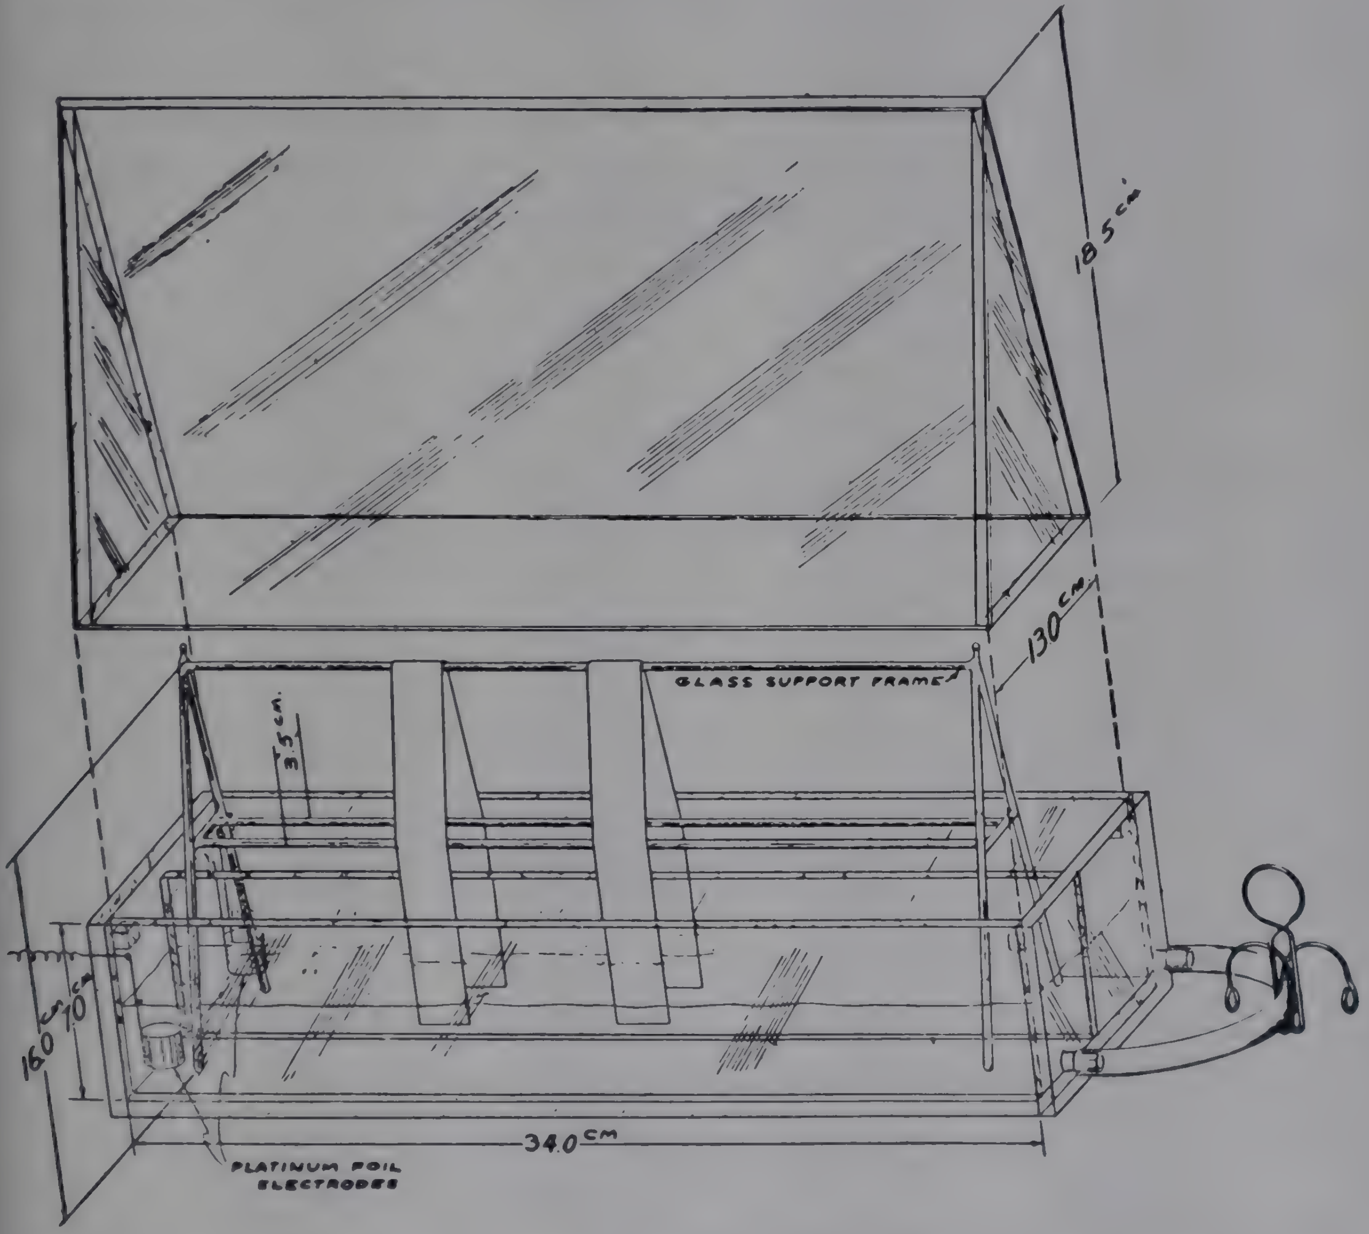

Fig. 705.—Durrum's apparatus for electrophoresis and iontophoresis. (From Gradwohl: Legal Medicine, The C. V. Mosby Co.)

Detection of Alkaloids

After separation of a mixture by paper iontophoresis or paper chromatography, dry the filter paper strips and examine for the presence of alkaloids.

Under ultraviolet light, the presence of fluorescent alkaloids like quinine, quinidine, Atabrine, and Nupercaine are readily discernible.

---

[1] Bull. Soc. Chem. Biol. 32: 192, 1950.

[2] Nature 168: 203, 1951.

Spraying the paper with such alkaloidal reagents as potassium iodobismuthate[3] and potassium iodoplatinate[3] will form orange and black complexes, respectively, with many alkaloids.

Recovery of the alkaloid is possible by cutting out the colored complex and decomposing it with an alkaline solution containing sodium sulphite.

The alkaloid can be isolated by extraction with a suitable solvent.

When a hard acid- and base-washed filter paper such as Whatman No. 50 is used in paper iontophoresis or paper chromatography, it is possible to apply directly on the paper any of the color-producing alkaloidal reagents containing concentrated sulphuric acid. Such alkaloidal reagents as Meckes, Mandelin, Marquis (see Bamford's systematic scheme, page 2322), and others can be applied directly to the dried filter paper, producing their characteristic colors with many alkaloids.

The use of paper iontophoresis and paper chromatography in the determination of morphine illustrates this microanalytical technic.

Morphine in Urine, Golbaum[4] and Kazyak[5]

Reagents.—

Concentrated Hydrochloric Acid.—

Sodium Carbonate, Solid.—

Solvent.—

Isobutyl alcohol	2 parts
Chloroform	8 parts

Half-Saturated Sodium Borate Solution.—

Adjust to pH 9.0.

0.5N Sodium Hydroxide Solution.—

95% Alcohol.—

Whatman No. 1 Filter Paper.—

Whatman No. 50 Filter Paper.—

1N Acetic Acid.—

Iodoplatinate Reagent.[3]**—**

Combine 5 c.c. of 5% platinum chloride in N/1 hydrochloric acid
45 c.c. of 10% potassium iodide
100 c.c. of distilled water.

Store in a dark glass-stoppered bottle.

Mobile Solvent of Munier and Macheboeuf.—

This is a mixture of 100 c.c. of n-butanol and 25 c.c. of glacial acetic acid, with enough water added to the mixture to produce a slight turbidity.

Mobile Solvent of Carless and Woodhead.—

This is n-butanol saturated with M/15 phosphate buffer pH 5.0.

For Quantitative Determinations of Morphine.—

2% Sodium Sulphite Solution in Half-Saturated Sodium Borate pH 9.0.—

0.1N Sodium Acetate-Acetic Acid Buffer pH 4.0.—

Technic.—

(A) **Preparation of the Specimen.—**

Reflux a sample of urine for 3 hours with 1/10 its volume of concentrated hydrochloric acid to completely hydrolyze any combined morphine.

Adjust the reaction of 50 c.c. of the urine with solid sodium carbonate to pH 8.5 ± 0.5.

Extract with 250 c.c. of isobutyl alcohol-chloroform solvent.

Separate the solvent layer.

Shake with 25 c.c. of half-saturated sodium borate solution pH 9.0 to remove some interfering substances.

---

[3] Zaffaroni, A., Burton, R. B., and Keutmann, E. H.: J. Biol. Chem. 177: 109, 1949.

[4, 5] In press.

Run the solvent layer through filter paper.

Determine the volume of the aliquot (aliquot 1).

Separate the basic constituents by shaking the solvent with 25 c.c. of 0.5N sodium hydroxide.

Discard the solvent layer.

Acidify the alkaline layer containing morphine as the sodium salt, using first concentrated phosphoric acid, then adjusting the reaction to pH 8.5 ± 0.5 by adding solid sodium carbonate.

Extract with 125 c.c. of solvent.

Run the solvent layer through filter paper to remove any traces of water.

Record the aliquot (aliquot 2).

Evaporate to dryness in a beaker containing 2 c.c. of 1N hydrochloric acid.

(B) **Purification of Residue: Paper Iontophoresis.**—

Take up the residue in 1.5 c.c. of 95% ethyl alcohol.

Streak 1 c.c. across the center of a strip of Whatman No. 1 filter paper 13 cm. wide and 32 cm. long.

Evaporate the alcohol. This can be speeded by applying a stream of hot air from an electric hair dryer.

Evaporate 0.1 c.c. of the alcohol in the center of a filter paper strip 5 cm. wide and 31 cm. long.

Streak the remainder of the alcohol across a strip of Whatman No. 50 filter paper.

Suspend the three filter strips in an electrophoresis or iontophoresis apparatus and wet with the electrolyte 1N acetic acid.

Apply an electrode potential of 600 volts across the ends of the filter paper strips.

After 1 hour, remove the strips, dry, and test for alkaloids.

(C) **Test for Alkaloids.**—

Spray the wide and narrow strips of Whatman No. 1 filter paper prepared as above with iodoplatinate reagent.

The presence of morphine is indicated by the appearance of a black iodoplatinate-morphine complex. An estimation of the morphine concentration can be made by comparing the black spot on the narrow strip with those produced by known morphine concentrations.

Color tests for morphine can be made by applying Marquis, Meckes, and other reagents directly on the Whatman No. 50 filter paper. These reagents are capable of producing characteristic colors with less than 5 micrograms of morphine.

(D) **Paper Chromatography.**—

As described under paper iontophoresis, aliquots of the alcoholic residue can be streaked across the base of strips of Whatman No. 1 and No. 50 filter paper and suspended in a chromatographic apparatus.

With the method of Munier and Macheboeuf their solvent is used.

After the solvent front moves from 20 to 30 cm., dry the filter paper strips.

Continue with the tests for detection and identification of morphine as above.

The Rf value for morphine is approximately 0.60.

If the procedure of Carless and Woodhead is used, saturate the filter strips with M/15 phosphate buffer pH 5.0.

The mobile solvent is described above.

The Rf value for morphine is approximately 0.17.

A quantitative determination and specific identification of morphine can be made using the wide strip of Whatman No. 1 filter paper.

Cut out the section of paper containing the black iodoplatinate-morphine complex and transfer to a glass-stoppered cylinder containing 2 c.c. of a 2% sodium sulphite solution in half-saturated sodium borate pH 9.0, which destroys the complex and liberates free morphine.

Add 25 c.c. of solvent and shake the cylinder.

Remove the water layer.

Filter the solvent layer into another glass-stoppered graduated cylinder.

Measure the aliquot (aliquot 3).

Add 4 c.c. of 0.1N sodium acetate-acetic acid buffer pH 4.0, and shake.

The buffer solution now contains morphine as the acetate.

Transfer to a cuvette of a Beckman ultraviolet spectrophotometer.

Determine absorbencies at a number of wave lengths between 310 and 245 mμ, using as a reference solution a sodium-acetate-acetic acid buffer extract of 25 c.c. of the solvent.

(E) **Results.**—

To compare the absorbencies obtained at pH 4.0 with those on the alkaline side, pipette 2 c.c. of the test solution and of the reference solution into tubes containing 1 c.c. of 1.5N sodium hydroxide.

Return the alkaline solutions to their respective cuvettes, and determine absorbencies at the previous wave lengths, correcting for dilution with alkali by multiplying by 1.5.

Subtract the absorbencies for the solution at pH 4.0 from those of the alkaline solution.

The presence of morphine is indicated by the highly characteristic differences, having a maximum difference at 300 mμ, a minimum at 280 mμ, and another maximum at 255 mμ.

A quantitative estimation of the morphine in the sample can be made from the differences at 255 mμ.

(F) **Calculation.**—

Calculate the morphine in the sample from the following formula: Morphine in 50 c.c. of urine in mg. $= \dfrac{a \times b \times c \times d \times e \times f}{g \times h \times i \times j \times k}$.

(a) equals volume of solvent used to extract 50 c.c. of urine

(b) equals volume of solvent used to extract alkaline extract after adjusting the pH (125 c.c.)

(c) equals volume of alcohol used to dissolve residue (2 c.c.)

(d) equals volume of solvent used to extract the morphine liberated after destroying the iodoplatinate complex (25 c.c.)

(e) equals the amount of morphine standard in mg. (0.04 mg.)

(f) equals optical density difference at 255 mμ of the unknown

(g) equals aliquot of *a* (aliquot 1)

(h) equals aliquot of *b* (aliquot 2)

(i) equals aliquot of *c* applied to the filter paper strips

(j) equals aliquot of *d* (aliquot 3)

(k) equals optical density difference at 255 mμ of morphine standard (0.04 mg. = 0.68)

Morphine standard is 40 μg/c.c. (0.04 mg.) in 0.5N sodium hydroxide for the alkaline solution and in 0.5N sulphuric acid for the acid solution.

The recovery of known morphine concentrations added to urine is 75 ± 0.5%. Characteristic absorption spectra for morphine can be obtained with less than 0.1 mg. of morphine in 50 c.c. of urine.

DETECTION OF STRYCHNINE IN ANIMAL TISSUES

(A) Separation of Strychnine From Tissues, Food, or Contents of the Stomach

If a quantitative estimation is to be made, a weighed portion is selected. Divide into fine particles. Place in a flask, and cover with enough strongly acidulated distilled water to make a free-flowing mixture. Acetic or sulphuric acid is used.

Digest in the water-bath for about one hour.

Strain through gauze while hot.

Concentrate the liquid in the water-bath to about one-fourth its first volume.

Add to this concentrated liquid, while hot, five or six times as much strong alcohol. Stir the alcohol in slowly.

The alcohol precipitates a good deal of organic matter. Filter this organic matter out, washing the precipitate with portions of alcohol of the same strength as that of the filtrate.

Evaporate the whole filtrate on the water-bath to a syrupy liquid.

Cool.

Treat with enough water, slightly acidulated with acetic or sulphuric acid, to make it feasible to filter the whole into a separatory bulb or strong, large test tube.

Filter through filter paper into a separatory bulb or strong, large test tube. Render very slightly alkaline by adding potassium or ammonium hydroxide solution.

Shake out with chloroform. The shaking out is to be done thoroughly, but guard against making an emulsion.

Draw off the separated chloroform, and repeat a second and a third time.

Retain the chloroform extracts.

If the chloroform refuses to separate, add ether equal in volume to that of the chloroform. Centrifuging helps, but must be done cautiously. Chloroform alone is to be preferred.

Evaporate the combined chloroform extracts carefully on a water-bath. The residue contains the strychnine, if present in the original specimen.

To purify the residue further, take up with dilute acetic acid or sulphuric acid.

Filter.

Make alkaline, and repeat the chloroform extraction.

Add chloroform in a separatory tube.

Again evaporate the chloroform in a porcelain dish.

To purify further, add 2 or 3 drops of sulphuric acid.

Heat on a water-bath for one or two hours, or at 120° C. in a dry-heat oven for fifteen to twenty minutes. The residue becomes black.

Stir with water.

Filter.

Wash.

Make faintly alkaline.

Shake out with chloroform.

Concentrate the chloroform solution sufficiently, then keep in a well-stoppered tube for the testing.

(B) Qualitative Tests

The **biological test** is the most reliable. Frogs are selected.

Take up a portion of residue prepared by drying a portion of the chloroform extract on a water-bath.

Dilute in a small amount of sterile water or saline.

Inject into the abdominal sac of a frog. Note the time.

Keep the animal under a glass jar for observation.

Tetanic spasms are caused by strychnine, the spasms being preceded by a period of uneasiness with accelerated respiration. If tetanic spasms appear when the frog is stimulated, it points to strychnine or brucine. If convulsions set in, they may be due to a great number of poisons, or even to acidosis, brought about by having injected an acid solution of the organ or stomach extract. Acid or alkaline solutions themselves when injected may cause convulsions.[1] It is therefore imperative that the acid solution of the tissue extracts be neutralized with sodium bicarbonate before injection.

The frog test, if positive, must be followed by chemical tests for identification in medico-legal inquiries. If negative, then strychnine can be positively ruled out.

Wormley obtained, with frogs of from 15 to 50 grains (0.98 to 3.3 grams) in weight, from $\frac{1}{5000}$ grain (0.000013 gram), distinctive symptoms in from ten to thirty minutes; from $\frac{1}{500}$ grain (0.00013 gram), symptoms in three or four minutes, and death in from fifteen to thirty minutes. Kobert mentions $\frac{1}{30}$

---

[1] Gettler, Alexander O.: Personal communication.

grain (0.002 gram) as a fatal dose for a frog. The paroxysms at first have remissions, and their return is hastened by agitation or vibration, as by striking on the table. Fatal dose is ½ grain or 0.032 gm. of strychnine or one of its salts.

A Rapid Bedside Test for Alkaloids

Method of Kaye

The procedure of Kaye has been found to be especially effective as a rapid means of detecting fairly large doses of various alkaloids.

Reagent.—

Dissolve 3.0 grams of red mercuric iodide
2.0 grams of potassium iodide
in 20.0 c.c. of glacial acetic acid.
Add enough distilled water to make a total volume of 60 c.c.
Keep the solution in a small brown dropping bottle.

Technic.—

Place 2 c.c. of urine in a small test tube.

Add 5 to 10 drops of the reagent.

An immediate turbidity which appears on slight agitation indicates the presence of either albumin or alkaloids.

Heat the tube. If the turbidity is due to albumin, the precipitate intensifies on heating, and persists.

If the turbidity is due to alkaloids, the precipitate completely dissolves upon heating and reappears upon cooling.

This method is very good when testing for alkaloids given in larger doses, such as, quinine, etc.

BAMFORD'S SYSTEMATIC SCHEME FOR THE IDENTIFICATION OF ALKALOIDS*

Group 1

Group Reagent.—Pure Concentrated Sulphuric Acid.

The following alkaloids yield definite colors:

1. Thebaine—immediately red, slowly turning orange.
2. Narceine—immediately greenish brown turning orange-yellow.
3. Narcotine—immediately lemon-yellow.
4. Hydrastine—green and brown patches, the whole slowly turning pink.
5. Solanine—yellow to yellowish brown.
6. Cytisine—orange, faint at first, becoming much deeper.
7. Piperine—reddish orange, turning brown.
8. Veratrine—yellow to orange-red, turning violet at the edges.
9. Delphinine—brown.
10. Colchicine—yellow.
11. Ergotoxine—yellow, becoming olive green at the edges and finally dark green.

Group 2

Group Reagent—Marquis Reagent (page 2307).—

This group contains alkaloids which give little or no colors with sulphuric acid alone, but give colors with the Marquis reagent.

Violet colors (various shades from bluish to reddish) given by morphine, apomorphine, heroin, Dilaudid, codeine, Dionin, eucodal, Dicodid.

---

*Abstracted by permission from: Bamford, F.: *Poisons*, ed. 1, Philadelphia. The Blakiston Company. Pages 255-283.

Cherry red to reddish violet—lobeline.

These alkaloids are subdivided into groups 2a and 2b according to their behavior in Oliver's test. Group 2c consists of alkaloids which give colors with the Marquis reagent not closely resembling that given by morphine.

Violet with tinges of green—pseudomorphine.

Yellowish, becoming pale red-violet (not sensitive)—papaverine.

Light brown, becoming darker—ephedrine.

If a strong violet color is produced, Oliver's test should be applied. To a faintly acid solution of the alkaloid, add a drop of hydrogen peroxide and a drop of dilute copper sulphate solution. Then make the liquid alkaline with ammonia.

Group 2a—red to brown colors—morphine, apomorphine, heroin and Dilaudid.

Group 2b—no color—codeine, Dionin, Dicodid, eucodal or lobeline.

Group 2a

Colors with Oliver's Reagent

Morphine } red, quickly fading to brown
Apomorphine }
Dilaudid—yellow to brown
Heroin—bright red which persists for ½ hour.

Group 3

This group contains the alkaloids which respond to Vitali's test (below), or give colors with nitric acid and are not included in Groups 1 and 2.

Group 3a—atropine, hyoscyamine and scopolamine.

Group 3b—physostigmine, brucine, antipyrine and Pyramidon—these do not respond to Vitali's test.

Vitali Test.—Evaporate the alkaloid to dryness on a water bath with a drop of fuming nitric acid.

Treat the brownish residue, when cold, with a drop of alcoholic solution of potassium hydroxide.

The alkaloids of the atropine group, atropine, hyoscyamine, scopolamine (hyoscine) yield a strong bluish color.

Group 4

This group consists of the alkaloids which yield characteristic colors when dissolved in sulphuric acid and a minute crystal of potassium dichromate is drawn through the liquid.

Yohimbine—blue, changing blue violet and then to green
Strychnine—blue-violet, changing to red-violet, then to red and finally to orange.
Gelsemine—bright red, changing to brown
Curare—red-violet
Cotarnine—pink, changing to green
Hydrastine—salmon-pink, changing to brown

The group can be subdivided by use of Fröhde reagent.

Group 5

Group Reagent.—

Alcoholic solution of *p*-dimethylaminobenzaldehyde acidified with concentrated sulphuric acid.

The only natural alkaloids included are nicotine, mescaline, and pilocarpine, the other substances being artificial cocaine substitutes—Novocain, Anesthesin, Tutocaine, Pantocaine, and Stovaine.

All the substances in this group are local anesthetics—produce numbness when applied to tip of tongue.

The group is subdivided into the substances which yield colors in the cold and those of which the colors develop on evaporating just to dryness on the water bath.

Group 5a

Colors produced in the cold:

Strong yellow color—Novocain, Anesthesin, Tutocaine.
Pale yellow color—Pantocaine and Stovaine.

Effect of evaporating to dryness on the water bath—

Novocain, anesthesin and tutocaine become bright reddish orange.

Pantocaine—the color becomes strong lemon yellow.

Stovaine—the color becomes fainter and almost colorless.

Group 5b

Colors develop only on warming:

Blue violet at the edges, red-violet in the middle—nicotine.

Orange to red, rapidly fading on cooling—mescaline.

Strong yellow, pink at the edges—pilocarpine.

Group 6

This is a miscellaneous group of alkaloids all of which react with nascent chlorine to form products which are either colored themselves or become colored on treatment with ammonia.

Dissolve a few particles of the solid substance in a drop of concentrated hydrochloric acid, adding a minute quantity of potassium chlorate, and evaporating to dryness on the water bath. Note the color if any is produced and then expose the residue to ammonia fumes or touch with a glass rod moistened with ammonia—excess of ammonia should be avoided.

The following results are obtained:

Alkaloid	Color of dry residue	Color with ammonia
Caffeine	Red at edges	Purple
Quinine	Yellow at edges	Green
Quinidine	Yellow	Green or brown
Sparteine	Colorless	Reddish purple
Emetine	Pink (red before it is completely dry)	Brown
Percaine	Yellow	Olive green

Quinine and quinidine salts of oxyacids are strongly fluorescent in dilute solution.

Group 7

This group contains the alkaloids for which, with one exception, no satisfactory color reactions are known.

The group includes cocaine, tropacocaine, psicaine, alypin, cinnamyl-cocaine, α-eucaine, β-eucaine, aconitine, coniine, lupinine, and arecoline.

The first seven are local anesthetics and produce the characteristic feeling of numbness when applied to the tip of the tongue.

GROUP IV. HEAVY METALS

In testing for heavy metals, it is advisable to begin the analysis using fresh material. If history indicates general symptoms of metallic poisoning, that is, abdominal pain, vomiting, purging, metallic taste, bloody diarrhea, digest a definite weight of tissue or a definite volume of body fluid. When testing for a specific poison, it is far easier and more reliable to use the specific technic indicated for that poison and to select the organ best suited for this analysis. Consult Table 217 on page 2235.

Acid Digestion.—

For metals such as arsenic, lead, bismuth, antimony, thallium, etc.

Transfer 100 c.c. of urine to a 600 c.c. Kjeldahl flask.

Add 100 c.c. of nitric acid, c.p.

Then add 8 c.c. of sulphuric acid, c.p.

Heat the contents gently at first to prevent foaming. When the foam is broken, increase the heat and continue heating until the volume is approximately 20 c.c.

Allow to cool.

Add 50 c.c. nitric acid.

Then add (carefully) 5 c.c. of concentrated perchloric acid (72%).

Heat again until the solution clears and white SO_3 fumes are copiously evolved.

Continue heating for an additional several minutes. The solution is now completely digested and should be clear. Volume is approximately 6 c.c.

Allow to cool.

Dilute with distilled water to exactly 50 c.c. Final solution contains approximately 10% sulphuric acid. Tests for metals may be made on aliquots of this solution.

Spectrographic analysis of metals, especially for thallium and barium, is the best method of analysis. Transfer a small aliquot of acid digested material, above, to the crater of the carbon electrode and concentrate by complete drying. Attach to the spectrograph and analyze.

THE DETECTION OF ARSENIC

Spread the material in a thin layer in a large dish, and search carefully for white particles of arsenic. If these are found the test may be made on them. If not found, proceed with the extraction from the tissue.

(a) **Extraction from Tissues. Method of Taylor.—**

Cut the material into fine shreds.

Dry well in a water oven.

Pulverize the dried material in a mortar.

Stir the powder in strong, pure hydrochloric acid.

Set aside for twenty-four hours.

Distill through a Liebig condenser, heating the flask over a sand-bath. The distillate is collected in a flask containing distilled water. Material should be heated almost to dryness.

Treat a second time with hydrochloric acid.

Again distill.

(b) **Tests**

Marsh Test

In a flask suitable for generating hydrogen place several pieces of pure, arsenic-free zinc. Fit a two-hole rubber stopper in the flask. Through one of the holes place a thistle tube and through the other place a right-angle tube, which in turn is connected with a drying tube containing calcium chloride. Connect a piece of glass tubing, drawn out to make a very fine jet, with the drying tube. This tube should be bent upward at about a 60° angle. Through the thistle tube add dilute sulphuric acid (1 to 6 dilution) to the zinc. Hydrogen gas passes through the drying tube and is conducted through the jet. After a few minutes hold a test tube over the jet and collect some of the escaping gas. Carry the tube to a Bunsen flame and if it pops with the characteristic explosiveness of hydrogen, the apparatus may be considered safe to use. Ignite the gas escaping from the jet and hold a cold porcelain evaporating dish in the flame. If the chemicals are free from arsenic there will be no discoloration upon the dish and the unknown may be added to the flask. Add small amounts of the unknown solution through the thistle tube. If arsenic is present the flame becomes livid and more luminous. Hold a cold porcelain evaporating dish in the flame and if arsenic is present it will be coated, at the point of contact, with a black or deep brown spot, the typical ''arsenic mirror.''

Modified Gutzeit Method

Use of the modified Gutzeit apparatus, Fig. 690, page 2270, and Fig. 706.

Cut a disk of Whatman No. 40 filter paper. Impregnate with 5 per cent mercuric bromide in 95% alcohol for about 2 minutes. Shake off the droplets and fasten between the flanges of the apparatus using a rubber band. Prepare this just before beginning the test.

Into the small drying tube supported by the rubber stopper, plug some cotton moistened with lead acetate solution, above which the set of flanges is placed.

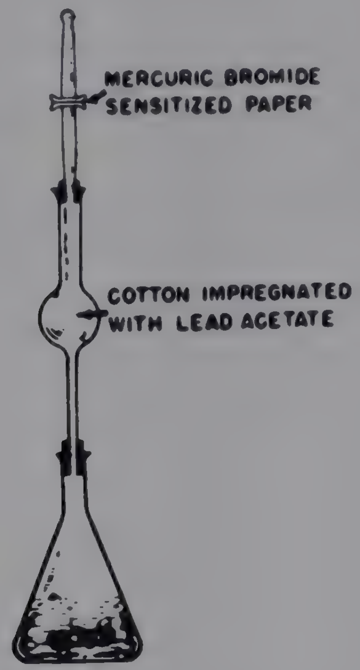
Place in the modified Gutzeit apparatus a few pieces of arsenic-free mossy zinc.

Add a few drops of dilute stannous chloride.

Add an exact aliquot of an acid digest solution of suspected arsenic (page 2324).

Quickly put the assembled flange in position in the flask.

The liberated hydrogen forms arsine on reacting with the deposited arsenic. Arsine travels upward and any impurity of hydrogen sulphide is removed by passing through the lead acetate moistened cotton. The arsine, upon contact with the mercuric bromide paper, turns the paper a yellow to brown color which is directly proportional to the amount of arsine produced.



MERCURIC BROMIDE SENSITIZED PAPER
COTTON IMPREGNATED WITH LEAD ACETATE

Fig. 706.—The modified Gutzeit apparatus for detection of arsenic. The rubber stopper in the flask supports a small drying tube into which is plugged some cotton moistened with lead acetate solution. Above this tube is attached a set of flanges (Fig. 691) between which is placed a disk of mercuric bromide sensitized filter paper. The liberated hydrogen forms arsine on reacting with the deposited arsenic. Arsine travels upward and any impurity of hydrogen sulphide is removed by passing through the lead acetate moistened cotton. The arsine, upon contact with the mercuric bromide paper, turns it a yellow to brown color which is directly proportional to the arsine produced.

Approximately 30 to 40 minutes is sufficient time in which to liberate all of the arsine. To prevent possible interference of antimony, which may act similarly to arsenic under the conditions of the test, expose the canary yellow disk to hydrochloric acid fumes from an open bottle. The yellow color of antimony will completely fade, while the arsenic yellow color will persist.

This test is specific for arsenic and is sensitive to 0.005 mg.

For a quantitative analysis, prepare standards for comparison by making the test with various known quantities of arsenic, and saving the disks. The best range for comparison is made by using varying concentrations of arsenic from 0.005 to 0.040 mg. Compare the color of the disk from the specimen with the standard disks and record the result.

Reinsch-Gutzeit Test for Arsenic, Kaye Modification

This test is a further development of the Reinsch test for arsenic using the Gutzeit test as a confirmation for the arsenic deposit.

Apparatus.—

Copper Spiral.—

Make a copper spiral from 20 gauge copper wire, spiraled to about three-quarters of an inch in length. Clean with water, then alcohol, and finally with ether.

Gutzeit Apparatus.—

See Fig. 690, page 2270, and Fig. 706.

Reagents.—

Mossy Zinc, Arsenic-Free.—

5% Copper Sulphate Solution.—

Dissolve 5 gm. of copper sulphate, c.p., arsenic-free, in distilled water with a little heat. When cool, dilute to 100 c.c. with distilled water.

20% Stannous Chloride Solution.—

Dissolve 20 gm. of stannous chloride in 2 per cent hydrochloric acid and dilute to 100 c.c. with 2 per cent hydrochloric acid.

Mercuric Bromide Sensitized Paper.—

See pages 2271 and 2325.

Technic.—

Grind the material to be analyzed and place 10 grams of the ground material in a 50 c.c. Erlenmeyer flask.

Add 10 c.c. of distilled water.

Add 3 c.c. of concentrated hydrochloric acid.

Insert a copper spiral into the mixture, and heat on a steam bath for approximately 45 minutes, shaking occasionally.

Remove the copper spiral and wash it with distilled water. Darkening of the spiral may be due to arsenic, antimony, bismuth, silver, mercury, or even to prolonged heating. If only traces of any of these metals are present, the deposit might not be visible. In all cases, with or without a visible deposit, complete the determination.

Test for arsenic using the Gutzeit reaction, page 2325, but substituting the copper spiral for the acid digest solution.

Under these conditions only antimony and arsenic will produce the canary-yellow color which indicates a positive reaction. To remove any coloration which may be due to antimony, expose the strip or disk to hydrochloric acid fumes from an open bottle. The color due to arsenic will persist, while that due to antimony will disappear.

This reaction will detect as little as 0.010 mg. of arsenic in body fluids.

For quantitative tests, prepare standards as under the modified Gutzeit method, above.

When arsenic is deposited on the copper spiral, approximately one-half of the arsenic is deposited electrolytically, the other half forming a chemical reaction with the copper. With the Gutzeit test, therefore, only half of the arsenic is liberated. This has been proved experimentally. For a quantitative estimation of arsenic, multiply results by 2 after comparing with arsenic standards.

THE DETECTION OF MERCURY

Mercury is to be separated from the tissues and other organic matter by mincing them and heating on a water bath for some time with equal parts of water and hydrochloric acid, while potassium chlorate is added in small amounts until a clear solution is made. This is similar to the method described for lead. After filtration the solution is heated gently to expel the chlorine, and a stream of hydrogen sulphide is passed until the metal is all precipitated as sulphide. This may be tested by reduction and sublimation, or it may be dissolved by gentle heat in nitrohydrochloric acid, the solution evaporated to drying on a water bath, redissolved in warm water, and a test applied.

1. Sublimation Test for Compounds in the Solid State

The suspected solid is first thoroughly dried, mixed with dry sodium carbonate, and heated gently in a reduction tube. A shining ring forms on the inside of the tube in the cooler part. A lens resolves this sublimate into minute shining spheres of metallic mercury.

The corresponding sublimate of arsenic and antimony are not of this shape. Rubbed with a glass rod, these globules run together into larger rounded masses. A few scales of iodine left in the closed tube for a few hours will vaporize and convert the mercury into a film of yellow, and later of red, mercuric iodide. If this test is done in a small subliming cell, and collected on a slide for microscopic examination, it is of very great delicacy.

2. Hydrogen Sulphide Test

A solution of a mercurial salt acidulated with hydrochloric acid yields a black precipitate when treated with a stream of hydrogen sulphide. The formation of the mercuric sulphide through intermediate stages is shown if the tested solution is strong; the precipitate becomes successively yellowish white, dark yellow, orange, brown, and black. The precipitate is insoluble in caustic alkalies, alkaline sulphides, and nitric or hydrochloric acids. It can be identified by yielding the globular sublimate when dried and heated with sodium carbonate, as directed above. By drying the sulphide in an air-oven and weighing, the quantity of mercury may be calculated.

3. Reinsch's Test

A strip of bright pure copper-foil will receive a gray or silvery deposit in a few minutes from a boiling mercurial solution acidified with hydrochloric acid. After the coated copper is carefully washed in water and dried, the slip is heated in a small dry reduction tube, and the resulting sublimate is examined for globules and tested with free iodine. Certain of the organic mercurials may not readily respond to this test.

Fallacies.—This test yields a metallic deposit on copper from arsenic, antimony, bismuth, silver, and some rarer metals. Coatings of arsenic, antimony, and mercury are the only ones that give a sublimate when heated in a reduction tube.

Mercury is peculiar in its opaque globular form and the bright high lights under reflected light.

Delicacy.—Using capillary reduction tubes of peculiar construction, Wormley[1] has obtained characteristic globules from 1/500,000 grain of corrosive sublimate; under ordinary manipulation 1/100,000 grain is nearer to the limit of delicacy.

4. Potassium Iodide Test

On adding potassium iodide to a solution of corrosive sublimate or other mercuric salt, a precipitate falls, at first yellow, but rapidly changing to red mercuric iodide. This will dissolve in excess of the potassium iodide.

Quantitative Determination of Mercury

Since mercury is volatile, certain precautions are necessary when carrying out the digestion process. An aliquot of urine is digested with a reflux apparatus. Gettler and Lehman suggested the use of sulphuric acid and potassium permanganate. Ellmore suggested using fuming sulphuric acid, fuming nitric acid, and then potassium permanganate as digesting agents. With either method, after digestion is complete, the excess oxidizing agent liberated from the solution must be titrated with standard dithizone.

Reagents.—

Fuming Sulphuric Acid, 30% SO_3.—
Fuming Nitric Acid.—
Saturated Solution of Potassium Permanganate.—
Hydroxylamine.—
Ammonium Hydroxide.—
Dilute Sulphuric Acid.—

---

[1] Wormley, Micro-Chemistry of Poisons, 1885, p. 204.

Standard Dithizone Solution.—

Dissolve 5 mg. of dithizone in 200 c.c. of carbon tetrachloride. Standardize as described on page 2346, substituting standard mercury solution for the lead solution.

Standard Mercury Solution.—

Dissolve 17 mg. of mercuric nitrate $Hg(NO_3)_2$ in distilled water in a liter volumetric flask and dilute to 1000 c.c. with distilled water. 1 c.c. contains 10 gammas of mercury.

Technic.—

Place 50 c.c. of urine in a flask.
Add 10 c.c. of fuming sulphuric acid.
Add fuming nitric acid, a few c.c. at a time, until the solution clears.
Connect the flask to a reflux condenser.
Heat for 20 minutes.
Cool, add water, and boil to remove all of the NO_2.
Add a slight excess of saturated solution of potassium permanganate.
Decolorize with hydroxylamine.
Make alkaline with ammonium hydroxide.
Very slightly acidify with dilute sulphuric acid.
Titrate with standard dithizone solution. The mercury-dithizone end point is orange. It can easily be detected after a little practice.

Calculations.—

Proceed with the calculations in the manner described for lead analysis on pages 2338 ff. and 2346.

A RAPID METHOD FOR THE ESTIMATION OF BISMUTH IN URINE[1]

Ever since bismuth was first introduced as an antisyphilitic agent, many methods have been developed and proposed for quantitative estimations in biological material. These methods include the well-known oxychloride test, the yellow color reactions with potassium iodide or thiourea, and the orange-red colored flecks produced when potassium iodide and cinchonine or quinine are added to a solution of bismuth. All of these methods, when applied to urine, require preliminary wet or dry digestion for the destruction of organic matter. The interference of other metallic ions such as lead, silver, copper, mercury, and iron have been pointed out by many workers.

The following method for the estimation of bismuth in urine may be used for the routine analysis of urine of patients under treatment with antisyphilitic therapy.

The essential features are: (1) depositing of the bismuth on a copper wire spiral (Reinsch test) under controlled conditions; (2) redissolving the deposited bismuth in dilute nitric acid in the presence of sodium sulphite. The interference of copper is eliminated by the addition of the sodium sulphite prior to redissolving the deposited bismuth in the dilute nitric acid. And (3) formation of bismuth-quinine-iodide and (4) the nephelometric comparison of this with known bismuth standards.

Reagents.—

Copper Wire Spirals.—

Make these from No. 20, B & S gauge wire. The spirals should be approximately one-fourth inch in diameter and three-eighths inch in length. They are easily made by winding the wire tightly and closely over a piece of glass rod and then cutting at intervals of 10 windings.

---

[1] Kaye, S., and Castillo, J.: Am. J. Clin. Path. **14**: 7, 1944.

Hydrochloric Acid, c.p.—

Nitric Acid, 20 Per Cent by Volume.—

To 50 c.c. of distilled water in a 100 c.c. volumetric flask
add 20 c.c. concentrated nitric acid, c.p.
Dilute to 100 c.c. with distilled water.

Sodium Sulphite, 5 Per Cent Aqueous.—

Dissolve 5 gm. sodium sulph*ite*, c.p., in distilled water and dilute to 100 c.c. with distilled water.

Quinine-Potassium Iodide Reagent.—

Dissolve 1 gm. of quinine sulphate
in 100 c.c. of distilled water containing 0.5 c.c. of concentrated nitric acid.
When solution is complete, add 2 gm. of potassium iodide and dissolve.
Keep the solution in a brown bottle. It is stable.

Bismuth Standard Solution.—

Dissolve 0.1 gm. of metallic bismuth
in 10.0 c.c. of 35 per cent (1:1) nitric acid.
Dilute to 1000 c.c. with distilled water.
Store in a Pyrex bottle.
1 c.c. = 0.1 mg. of bismuth.

Standard Suspensions for Comparison.—

Use six small test tubes similar to those used in the test.
Place 1 c.c. of 5 per cent sodium sulphite solution in each tube.
Add 1 c.c. of 20 per cent nitric acid solution to each tube.

Add, respectively, 0, 0.1, 0.2, 0.4, 0.7, and 1.0 c.c. of the bismuth standard solution to the tubes. This corresponds to 0, 10, 20, 40, 70, and 100 gammas of bismuth, respectively.

Make the volume in each tube up to 3 c.c. with distilled water.
Add 1 c.c. of quinine-potassium iodide reagent to each tube and shake.

Technic.—

Thoroughly mix the twenty-four-hour specimen of urine to be tested.
Determine the total volume.
Place 10 c.c. of urine in a 50 c.c. Erlenmeyer flask.
Add 2 c.c. of concentrated hydrochloric acid.
Wash a copper spiral with alcohol, followed by ether, then dry.
Place the washed spiral in the flask and boil gently for 45 minutes.

Maintain the volume by adding 10 per cent (by volume) hydrochloric acid as required. If the mixture is boiled gently, approximately 5 c.c. of the dilute hydrochloric acid added every 15 minutes will suffice.

At the end of the boiling period, pour off the liquid, leaving the spiral behind.

Wash the spiral with distilled water by filling up the flask and pouring the water off as before. Repeat these washings several times.

Place the washed spiral on a piece of filter paper to remove any excess water.
Transfer to a small test tube (1 cm. diameter by 10 cm. in length).
Add 1 c.c. of 5 per cent sodium sulphite solution.
Add 1 c.c. of 20 per cent nitric acid solution.

Mix. Allow the mixture to act on the spiral, agitating frequently, until the bismuth which has been deposited on the spiral has dissolved. Approximately 5 minutes is sufficient time for deposit to be dissolved if the bismuth deposit is not too heavy.

Add 1 c.c. of distilled water
and 1 c.c. of quinine-potassium iodide reagent.
Shake and remove the copper spiral with the aid of a wooden applicator.

Compare the suspension of quinine-bismuth-iodide with the standard suspensions to determine the amount of bismuth present in 10 c.c. of urine. Calculate the amount in the twenty-four-hour specimen.

In using a copper spiral for the isolation of bismuth, interference of lead and iron is eliminated since these substances are not deposited on copper. Of the other metals which do form deposits on copper, namely, mercury, arsenic, antimony, and silver, none was found to give the double iodide with the reagent under the conditions of the test. Experiments were carried out to determine if the presence of these metals influenced depositing of bismuth on the copper. It was found that the presence of even as much as 50 gammas of any of these metals did not prevent depositing of bismuth on the spiral.

Although the degree of darkening of the copper spiral is a good indication of the amount of bismuth present in the urine, Kaye and Castillo found that the quinine-bismuth-iodide reaction detects deposits of bismuth not visible to the naked eye. Sensitivity for visible deposits is approximately 30 gammas. Sensitivity of the bismuth-quinine-iodide reaction is faint for 20 gammas and definite for 30 gammas of bismuth.

The number of standards is arbitrary. Where greater accuracy is desired than described here, a larger number of standards with a narrower range may be used. The upper limit of sensitivity, however, should be kept at 100 gammas because, with this test, differences in concentrations of bismuth above this level are difficult to estimate. Kaye and Castillo found that the best range for accurate estimations is between 20 and 70 gammas of bismuth in a 10 c.c. sample of urine. The total recovery of bismuth, as compared with the standards, is 80 to 90 per cent.

The copper spirals may be used for many determinations before being discarded if they are cleaned with dilute nitric acid after use.

If a more accurate quantitative determination is needed, first prepare an acid digestion of urine (page 2324). Then use an aliquot of this digest for determination with bismuth reagent as described above.

RAPID ESTIMATION OF MERCURY, BISMUTH, AND ARSENIC IN BODY FLUIDS (IN THE PRESENCE OF ONE ANOTHER)

Method of Kaye[1]

This is a rapid, simple, and reliable procedure for the microdetermination of mercury, bismuth, and arsenic in body fluids. Using the Reinsch principle, these metals can be isolated with rapidity and simplicity. Previous oxidation destruction of interfering organic materials is eliminated.

The Reinsch test previously served reliably only in a negative sense Various metals give similar appearances on the copper wire; prolonged heating of the organic material may also cause a similar tarnishing of the copper wire even in the absence of these metals. Several good confirmatory tests have been described to identify these metals when they are specifically indicated. A scheme of analysis for these metals in the presence of one another is, therefore, desirable.

Technic.—

Transfer a 20 c.c. or 20 gram aliquot sample of stomach contents, food, ground tissue, or concentrated urine to a 50 c.c. Erlenmeyer flask.

Add 4 c.c. of concentrated hydrochloric acid.

Introduce into the flask a 20 gauge copper wire, previously wound to a length of ½ inch and washed in alcohol and ether (page 2329).

---

[1] Am. J. Clin. Path. **14**: 7, 1944.

Boil gently for 45 minutes.

Remove the spiral, wash it thoroughly with water, and dry it on absorbent filter paper.

A dark discoloration may indicate the presence of either bismuth or arsenic; discoloration is faintly visible in the presence of 0.030 mg. of bismuth and 0.020 mg. of arsenic.

Deposits due to mercury are usually grayish or silvery, faintly visible in amounts of 0.08 mg., definitely silvery in approximately 0.15 mg. amounts.

It is recommended that the procedures for identification be continued even in the absence of visible discoloration of the copper coil.

Identification and Estimation.—

1. Mercury

Cuprous Iodide Reagent.—

This is made according to the method of Ganassini.

Dissolve 5 gm. copper sulphate ($CuSO_4$)
and 3 gm. ferrous sulphate ($FeSO_4$) (anhydrous, precipitated with alcohol)
in 10 c.c. distilled water.

Add 7 gm. potassium iodide (KI) dissolved in 50 c.c. distilled water, stirring constantly.

Filter the precipitate and wash with distilled water.

Transfer the precipitated cuprous iodide to a brown bottle with the aid of a little water. Keep in the form of a suspension. It is quite stable.

Technic.—

Mercury can be quickly identified by the simple test described by Gettler.

Place a small filter paper on a watch glass.

Place 2 drops of a suspension of cuprous iodide on the filter paper.

Now place the copper spiral on the spot of cuprous iodide, and cover with another watch glass.

Allow to stand for 10 to 15 minutes.

A rose to salmon-pink color, due to the formation of mercury iodide, develops if mercury is present in amounts even as small as 0.025 mg.

By treating similarly known quantities of mercury, 0.025 mg., 0.050 mg., 0.10 mg., a set of standards may be prepared for matching colors produced by the unknown spiral: 0.025 mg. of mercury yields a very faint pink color, 0.050 mg., a more definite pink, and 0.10 mg. a distinct salmon-pink.

This test is specific for mercury; mercuric iodide is formed. All other metals which form deposits on copper when treated as outlined above give negative results with this test.

If a more accurate quantitative determination is necessary, once the presence of mercury is established, the dithizone procedure described on page 2329 is very satisfactory.

2. Bismuth

Wash the copper spiral free from any adhering cuprous iodide left from the previous test and allow it to dry on absorbent filter paper.

Transfer the spiral to a small test tube 1 cm. in diameter by 10 cm. in length.

Add 1 c.c. of 5 per cent sodium sulphite solution.

Add 1 c.c. of 20 per cent nitric acid solution.

Mix and allow to act on the spiral, agitating frequently until the deposited bismuth is dissolved. Approximately 5 minutes suffice if the deposit of bismuth is not too heavy. Arsenic will not dissolve under these conditions.

Add 1 c.c. of distilled water.

and 1 c.c. of quinine-potassium-iodide reagent (page 2330).

Shake and remove the copper spiral with the aid of a wooden applicator.

Save the spiral for the test for arsenic.

Compare the suspension of quinine-bismuth-iodide with standards described on page 2330.

This method is specific for bismuth under the conditions of the test. None of the metals which form deposits on copper give false positive reactions; the addition of the sodium sulphite prevents the copper iodide from reacting.

3. Arsenic

Wash the copper spiral again with water.

Prepare the modified Gutzeit apparatus as directed on page 2325. The flask contains some mossy zinc, arsenic-free, to which several drops of dilute stannous chloride solution and approximately 20 c.c. of 10 per cent sulphuric acid have been added. The sulphuric acid should be sufficient in quantity to cover the copper spiral completely.

Immediately connect the apparatus and allow 30 minutes for all the arsine to be liberated. An explanation of this method is given on page 2325. Differentiate from antimony as described on page 2326.

The test is specific for arsenic and is sensitive to 0.005 mg. Approximately only 50 per cent of the arsenic present can be recovered by this method because of the partial liberation of the deposited arsenic from the copper spiral. Kaye suggests that a factor of ×2 be used to compensate for this partial recovery.

For quantitative estimations, prepare standards covering the range of 0.005 to 0.040 mg. concentration of arsenic. Use these for comparison with the unknown.

Mercuric Bromide Paper.—

Cut Whatman No. 40 filter paper into disks.

Impregnate with 5 per cent mercuric bromide in 95% alcohol for about 2 minutes.

Shake off the droplets and fasten the disk between the flanges[1] of the modified Gutzeit apparatus, using a rubber band.

LEAD POISONING

The question of lead poisoning is a matter of great concern in connection with industry. Lead gains entrance to the body through inhalation, through ingestion by way of the gastrointestinal tract, and through the skin. Industrial exposure usually comes from inhalation of dust and fumes. Ingested lead may be excreted unchanged and even if absorbed may be carried into the liver and excreted into the bile.[2] Lanza[3] gives a complete story of the epidemiology of lead poisoning and states that the following summary refers to the main classification of industries and processes in which lead is a hazard:

1. Lead mining. In this case, lead is in the form of soluble carbonates or other soluble salts. If the ore is galena (lead sulphide), it is doubtful if lead poisoning occurs to any appreciable extent.
2. Lead smelting. Lead refining.
3. Fabrication and handling of lead:
    a) In the manufacturing of lead articles, poisoning is due to the formation of lead oxide on the surface of metallic lead.
    b) In lead burning, soldering, tempering lead, plumbing.

---

[1] Flanges may be purchased from Eck and Krebb, New York City. Item No. 2080.
[2] Aub, J. C., Fairhall, L. T., and others: Medicine 4: 1, Feb.-May, 1925.
[3] J. A. M. A. **104**: 85, 1935.

c) Founding in which lead is used; for example, brass.

d) Buffing and polishing lead surfaces when lead is an ingredient of such substances so handled.

4. Manufacture of lead salts; for example, lead oxide by Dutch method, Carter method, etc.; lead pigments; organic lead compounds.

5. Manufacturing compounds which utilize lead: storage batteries, paints, rubber compounding, and chemical manufacturing.

6. In painting with lead paints, the application and removal thereof: painting, spray-painting, vitreous enameling, pottery, dipping, sandpapering, scraping and chipping painted surfaces. Flame cutting of painted metal. The spraying of trees with lead-containing insecticides.

7. In the typographic trades, such as, type founding, electrotyping, and stereotyping.

Lanza stated that when one comes across an outbreak of lead poisoning today, it is usually in an establishment where the lead process is but one step in the plan of manufacture. He also called attention to lead poisoning among industrial workers not engaged in handling lead but who, through negligence, are exposed to dust or fumes from lead processes not protected.

The amount of lead that is present in the atmosphere under varying conditions and the minimum dosage that will cause lead poisoning have been thoroughly studied. Bloomfield[1] reported that in a number of industrial establishments he found 0.10 mg. of lead to 10 cubic meters of air; in automobile repair shops, he found 0.13 mg., and in street air 0.09 mg. to 10 cubic meters. Greenburg[2] reported that exposure to 1.45 mg. of lead daily for two and one-half years will cause lead poisoning. Lanza states that in general lead in the form of vapor is more dangerous than as dust, and that lead in a molten condition gives off fumes; the higher the temperature, the more fumes. Oxide forms on the surface and gets into the air as dust. He calls attention to the fact that many lead cases are diagnosed as chronic appendicitis and even as gall bladder disease.

The biochemical behavior of lead in the blood is one of the most interesting aspects of lead poisoning. The work of Aub and others on this point has been already referred to. (See chapter on Hematology.) Aub[3] has epitomized the known facts on this subject. It was formerly thought that lead was carried in the blood stream as an albuminate, but present studies are rather convincing that lead is precipitated in the bones as the very insoluble tertiary lead phosphate and carried in the blood as the more soluble di-lead phosphate. Maxwell and Bischoff[4] have shown that lead, when injected intravenously, is carried as a diphosphoglycerate. Jowett[5] believes that it forms a complex inorganic phosphate with calcium and chlorine. No matter how it is transported in the blood stream, it causes deleterious effects on body cells.

Some absorbed lead is excreted without ever having been stored. There is a small daily excretion of lead in the urine in the vast majority of persons.

[3] J. A. M. A. 104: 87, 1935.
[4] J. Pharmacol. & Exper. Therap. 37: 413, 1929.
[5] Biochem. J. 26: 2108, 1932.

the average excretion being from 0.05 to 0.1 mg. in the urine of normal persons daily. According to Barth,[6] a very small amount of lead may be gradually accumulated in normal bones during advancing years (from 0.02 mg. found in infancy to 0.1 mg. per 3 gm. of bone ash in the aged).

Absorbed lead is distributed throughout the viscera, but to the greatest extent in the liver, spleen and kidneys. A few days after absorption it collects in the bones. Aub and Minot* originally claimed that the direction of the lead stream is similar to that of the calcium stream or that, when calcium is being deposited in the bones, circulating lead is also deposited in the bones; and, when calcium is being pulled from the bones, some stored lead is also liberated. It is probably true that not all the calcium and lead thus liberated is excreted. X-ray evidence seems to indicate that it may circulate and be redeposited in bone, especially in childhood. Vogt shows by x-ray pictures that lead is repeatedly dissolved and redeposited along the epiphyseal line of growth. Aub states that because of this great avidity of growing bone for salts, as well as the difficulties precipitated by calcium deficiencies, deleading therapy seems an unwise and unsuccessful procedure in children.

The problem of treating lead poisoning is closely interwoven with these facts. If rapid deleading is to be avoided, one must simply give a large calcium intake in the diet, which lowers the demand on calcium stores, calcium is stored, and the only excretion of bone calcium and lead comes from the normal metabolism of the bones. This method should be used during any toxic lead episode.

Aub discussed in his work the problem of free deleading which should be undertaken after the episode has subsided and concluded as follows: (1) That lead is stored in relatively large quantities in the area of bone and is readily available for liberation; (2) that the liberation of this store is an obvious factor in the onset of toxic lead episodes during metabolic upsets; and (3) that this liberated lead may not be excreted but may circulate and be redeposited. (No one knows the extent of this possibility.)

In favor of deleading we have the possibility, under controlled conditions, of reducing the lead contamination in the bone trabeculae, then replenishing the trabeculae with uncontaminated calcium. Against deleading is the consideration that it may not be desirable to liberate the lead, but to keep it stored, largely in the bones, during good health. Theoretically, deleading appears advantageous in that it would seem to avoid sudden liberation of this lead in time of metabolic stress. Practically, that procedure should be followed which will most promptly return the patient to health. Aub has found that following the ordinary toxic lead episode a vigorous course of deleading usually is followed by prompt return to normality, and that this recovery is more rapid and much more complete than when a continued deposit of lead stores is maintained. He believes that in lead palsies thorough deleading approximately halves the period of disability. Although this opinion may possibly be altered, Aub stated that the biochemical knowledge on which this treatment is based seems to be thoroughly established, not only for lead but also for several other related heavy metals.

---

*Aub, J. C., Fairhall, L. T., Minot, Anne S., and Reznikoff, Paul: Lead Poisoning, Medicine Monographs, Baltimore, Williams & Wilkins Company, 7, 1926.

[6] Virchows Arch. f. path. Anat. 281: 146, 1931.

The question of the normal absorption and excretion of lead has been thoroughly studied by Kehoe, Thamann, and Cholak[*] They studied the incidence of lead ingested normally and lead excreted. They found that normal lead found in the excretions came largely from food. They found that the mean daily lead content of twenty-four samples of food was approximately 0.25 mg. and the mean daily fecal output amounted to about 0.26 mg. They found that in twenty-four-hour samples of normal feces, there might be 1 mg. of lead, while in a normal sample of urine, we might find as much as 0.20 mg. per liter rarely and 0.1 mg. per liter not uncommonly. They warn against the danger of interpretation from any single analytical result, and state that in normal individuals not even exposed to lead, there should be repeated examinations of urine and feces before diagnosis is established.

DETERMINATION OF LEAD IN BIOLOGIC TISSUES AND FLUIDS

Determination of Lead by Dithizone

Bambach (Modification of the Hubbard-Clifford-Wichmann Method)

The method by Bambach[1] is an improvement of the method reported by Hubbard,[2] who based his photometric dithizone procedure upon work done by Clifford and Wichmann,[3] and by Wilkins, Willoughby, Winter, and their co-workers.[4-6] These improvements have made possible increased accuracy and the saving of time.

Apparatus.—The apparatus used by Bambach is essentially the same as that described by Hubbard. This is a neutral wedge photometer, as described by Clifford and Wichmann, with slight modifications.

TABLE 231.—ANALYSIS OF REAGENTS COMMONLY USED IN DITHIZONE METHOD

REAGENT	LEAD CONTENT GAMMA/LITER
Water (regular double-distilled, Barnstead still)	2
Water (triple-distilled, third distillation in Pyrex)	Trace[a]
HNO_3 concentrated	10-30
HNO_3 concentrated (triple-distilled, in quartz)	Trace[a]
HCl concentrated	10-30
HCl constant-boiling (triple-distilled, in quartz)	Trace[a]
H_2SO_4 concentrated	Ca. 800
KCN solution, 10 per cent W/V	80
Ammonium citrate solution, 40 per cent W/V	Trace[a]

[a] Less than 1 gamma.

Light Box.—The light source consists of nine 32-candlepower, 12- to 16-volt, automobile headlight bulbs (Mazda ''Tung Sol'' T-1144) wired in series from a 122-volt alternating current circuit and arranged in a circle around two 2.5 cm. (1-inch) circular apertures in the interior of the box. The light is reflected from a piece of solid opal glass 15 × 15 cm. (6 × 6 inches) mounted about 2.5 cm. (1 inch) from the light source, so as to give diffuse reflected light.

Eyepiece.—Prism system and housing complete, from the Bausch & Lomb No. 3600 hemoglobinometer.

Wedge.—A neutral density wedge constructed of Bausch & Lomb smoked "C" neutral glass, length 150 mm., height 20 mm., thickness at thick end 8.0 mm. and at thin end not more than 0.5 mm. The wedge is compensated and reinforced by a wedge of clear glass of the same dimensions cemented to the wedge proper.

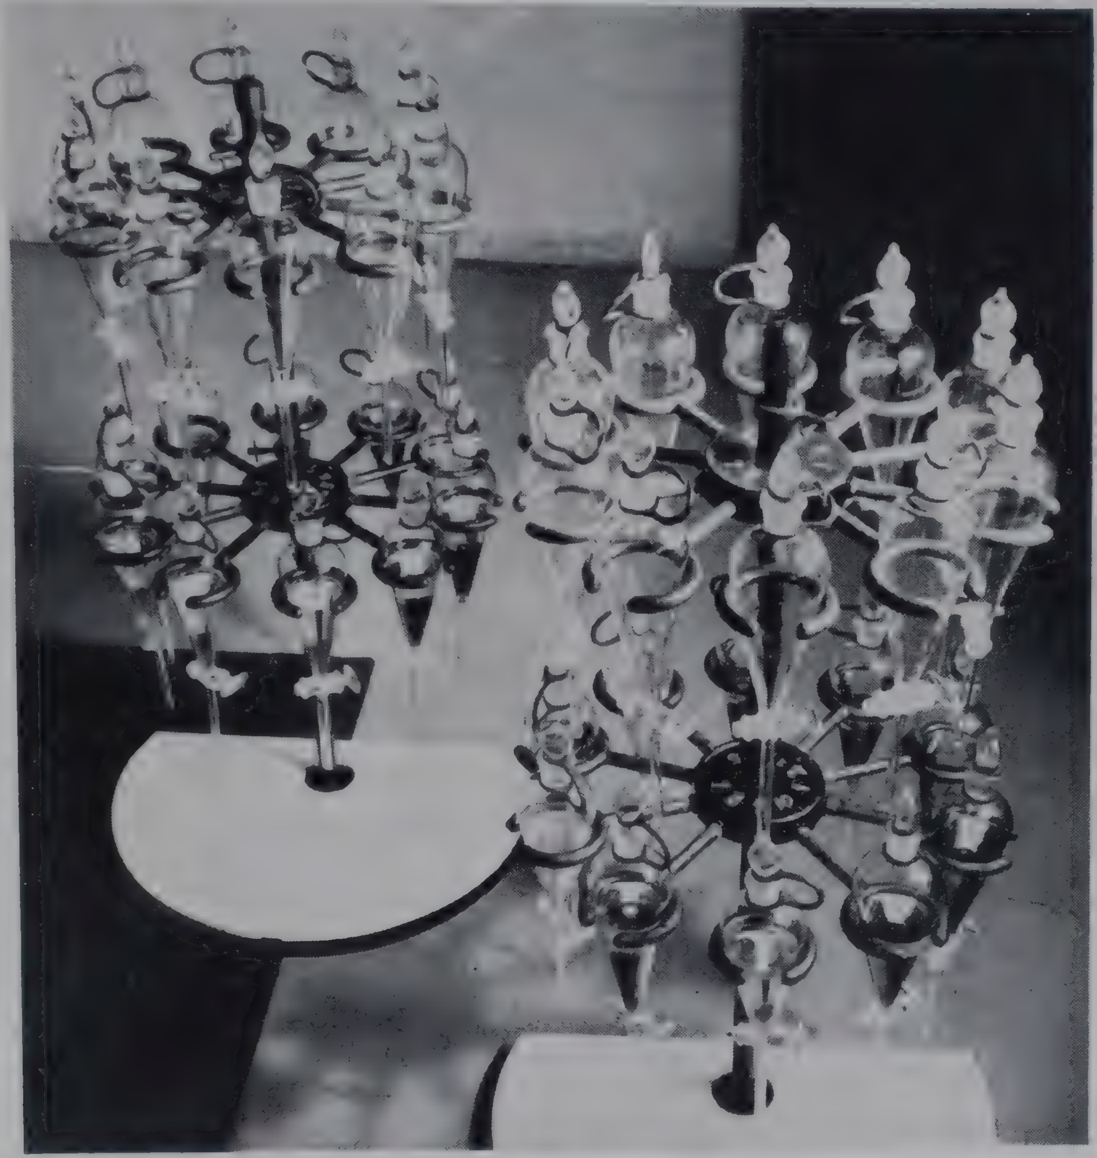

Fig. 707.—Rotary funnel racks, dithizone determination of lead. (Bambach, Karl: J. Ind. & Eng. Chem. July, 1939.)

Cells.—All cells are constructed of Pyrex glass with ground and polished fused-on windows of Corex glass. The windows are parallel and optically plane. No flux or cement is used in the construction. Vents are placed in the tops of the cells to permit of ready emptying and filling. Three cells are used having internal lengths of 12, 25, and 50 mm. (tolerance of ±0.1 mm.) for ranges of 0 to 10, 0 to 50, and 0 to 100 gamma of lead, respectively. The internal diameter for these cells is 14.5 mm. with a tolerance of ±0.5 mm.

Filter.—The spectral region employed (510 mμ) is obtained by means of a Wratten compound filter (Eastman Kodak No. 45 and No. 58). The maximum transmission of this filter (10 per cent) occurs at 510 mμ and it decreases sharply for regions on either side of the maximum, reaching a value of only 0.1 per cent at 478 and 550 mμ.

Bambach introduced a neutral wedge photometer improved with a few changes. A small compensating wedge of Bausch & Lomb neutral "C" glass was placed in the light path, as suggested by Clifford, in order to make the comparison fields of the instrument ''shade off'' similarly. In addition, the compound gelatin filter has been replaced by a permanent glass filter with maximum transmission at 510 millimicrons. These changes necessitated a stronger light source and accordingly 50-candlepower bulbs have been substituted for the 32-candlepower bulbs originally used.

A special device, suggested by R. R. McNary, of the Kettering Laboratory of Applied Physiology, University of Cincinnati, is advised. This consists of special rotary funnel racks fitted with opaque glass bases. The metal rings which hold the funnels have been rubber-plated by the anode process. This rubber covering resists the reagents used in the analysis much better than any type of paint available (Fig. 707).

Complete Procedure for Lead Determination*

Preparation of Samples

Urine.—

Add concentrated nitric acid (10 per cent of the sample volume) to the measured sample. Evaporate to dryness on a hot plate or steam bath, and ignite at 500° C. in a silica or Pyrex evaporating dish. Moisten the ash with nitric acid, dry, and ignite for a few minutes until it is white; dissolve in dilute nitric acid and the sample is ready for analysis. Filtration is not necessary.

Feces.—

Dry the sample on a hot plate or steam bath to constant weight in a tared silica or Pyrex dish. Place the dish on an electric heater at a low red heat to drive off volatile matter which would otherwise flame in the muffle furnace. After constant weight is attained ignite at 500° C. in a muffle furnace. Weigh the ash and dissolve it in a mixture of hydrochloric and nitric acids. The sample is now ready for analysis. Filtration is not necessary.

Foods.—

Digest the weighed sample of mixed food with concentrated nitric acid on a hot plate or steam bath until all lumps have disappeared. This may require over a week, with repeated additions of acid. If a food homogenizer, such as a Waring Blendor, is used, the time may be materially shortened, especially since aliquots may be employed. Evaporate the sample to a syrupy consistency, transfer to a silica or Pyrex evaporating dish, and add concentrated sulphuric acid (15 c.c. for a normal day's mixed food). Place the dish on an electric heater at a low red heat and treat as described under ''Feces.''

Tissues.—

Weigh the sample and treat in the same general way as a sample of mixed food.

Blood.—

Transfer the sample to a tared silica or Pyrex evaporating dish, weigh, and add concentrated nitric acid (5-10 c.c. per 10 gm. of blood). Evaporate the mixture to dryness on a hot plate or steam bath, place on an electric heater at a low red heat, and ignite in a muffle furnace at 500° C. Add a few c.c. of hydrochloric acid to the ash, then nitric acid, and heat the dish on the hot plate until the sample is dissolved. It is then ready for analysis.

Alternate Procedure

The perchloric procedure is an alternate method for digesting any of the biological materials discussed above.

Place in a 300 c.c. Pyrex Kjeldahl flask 10 c.c. of concentrated sulphuric acid.

Add 100 c.c. of concentrated nitric acid. The quantity of these acids will vary with the quantity and nature of the biological material digested.

---

*Personal communication: William E. Crutchfield, Jr., Kettering Laboratory of Applied Physiology, College of Medicine, Cincinnati, Ohio.

Weigh the specimen.

Introduce a small quantity into the Kjeldahl flask.

Heat gently at first to retard foaming. Increase the heat and continue heating until the volume is approximately 20 c.c.

Cool the solution and add an additional 100 c.c. of concentrated nitric acid and 5 c.c. of concentrated perchloric acid (72%).

Heat again, continuing until the solution is completely digested and copious white fumes of sulphur trioxide begin to evolve. Solution is now approximately 5 c.c.

Allow to cool.

Add 3 c.c. of 5 per cent hydrochloric acid saturated with sodium chloride.

Heat again to dissolve the lead sulphate precipitate.

Filter while hot.

Wash the filter paper with several 5 c.c. portions of *hot* distilled water.

The solution is now ready for analysis.

Technic.—

Note: All glassware should be cleaned with sulphuric acid-chromic acid mixture and with dilute nitric acid (1 + 1). Careful attention is necessary to avoid dust contamination, especially during the evaporations. If reagent acids are used in the sample preparations, lead determinations should be made on them for deduction as reagent blanks. This can be eliminated by using distilled acids.

Reagents and Apparatus.—

Ammonium Citrate Solution.—Dissolve 400 grams of citric acid in water with sufficient reagent ammonium hydroxide added to make the solution alkaline to phenol red. Dilute the solution to one liter with water and purify by shaking it with repeated portions of a solution of dithizone in chloroform until the dithizone retains its original green color.

Distilled Ammonium Hydroxide.—Distill reagent ammonium hydroxide into double-distilled water chilled in an ice bath.

Hydroxylamine Hydrochloride Solution.—Dissolve 20 grams of hydroxylamine hydrochloride in sufficient water to make about 65 c.c. and add a few drops of m-cresol purple indicator solution. Add concentrated ammonium hydroxide until a yellow color results. Add sodium diethyldithiocarbamate in water (an approximately 4 per cent solution) in sufficient quantity to combine with all the lead (and most other metals) present and to leave a considerable excess. After a few minutes completely extract the organo-metallic complexes and the excess reagent with chloroform. (The absence of a yellow color in the chloroform when a portion of the chloroform extract is shaken with a dilute solution of a copper salt indicates when this point is reached.) Add distilled hydrochloric acid to the hydroxylamine hydrochloride solution until the indicator turns pink, and add double distilled water to make the final volume 100 c.c. It is not necessary to filter the solution.

Potassium Cyanide Solution.—Shake a substantially saturated solution containing 50 grams of potassium cyanide in sufficient water to make 100 c.c. with portions of dithizone in chloroform (30 mg. per liter) until the lead is removed. Part of the dithizone dissolves in the aqueous phase but sufficient remains in the chloroform to color it and to indicate when the lead has been completely extracted. Most of the dithizone in the aqueous phase can be removed, if desired, by repeated extractions with pure chloroform. Dilute the strong potassium cyanide solution with double distilled water to the proper strength (10 grams per 100 c.c.). It is not necessary to filter the solution. (If, instead of the concentrated solution, the final one is shaken with dithizone in chloroform in an attempt to delead it, the increased alkalinity of this dilute solution causes the removal of all the excess dithizone from the chloroform and renders the complete extraction of the lead more difficult.)

Dithizone Extraction Solution.—Shake one liter of chloroform with 100 c.c. of water containing about 0.5 gm. of hydroxylamine hydrochloride which has been made alkaline to phenol red with ammonium hydroxide. Drain the chloroform off, and dissolve 30 mg. of dithizone in the chloroform. Add approximately 5 c.c. of alcohol to the solution if part of it is to be kept for several days. Filtration is not necessary. Shake the quantity of dithizone solution to be used for one day with about 100 c.c. of dilute nitric acid (1 c.c. per 100 c.c.) just before use.

Standard Dithizone Solutions.—Make these solutions from distilled chloroform which has been treated with hydroxylamine as in the instructions for the dithizone extraction solution. In this case, however, filter the chloroform through a dry paper into a glass-stoppered Pyrex bottle, which is protected from light by being wrapped with heavy paper or by a wooden box. Dissolve the proper amount of dithizone (5 mg. per liter for the 0-10 microgram range, 10 mg. per liter for the 0-50 microgram range, and 20 mg. per liter for the 0-100 microgram range) in the chloroform, add absolute alcohol (5 c.c. per liter) and the solution is ready for standardization. It should be kept in a refrigerator.

Ammonia-Cyanide Mixture.—Each liter of the mixture contains 20 gm. of potassium cyanide and 150 c.c. of distilled ammonium hydroxide, specific gravity 0.9, or its equivalent; dilute to volume with double distilled water. This solution should be kept in a cool place.

Buffer Solution, pH 3.4.—Dilute 9.1 c.c. of reagent nitric acid to approximately 500 c.c. with double distilled water in a one-liter volumetric flask, add bromthymol blue indicator, and bring the pH to 3.4 with distilled ammonium hydroxide. Add 50 c.c. of Clark and Lubs potassium acid phthalate-hydrochloric acid buffer, pH 3.4, double strength (50 c.c. M/5 potassium acid phthalate, 9.95 c.c. M/5 hydrochloric acid, per 100 c.c.) and dilute the solution to one liter with double distilled water.

Chloroform Recovery.—Collect used dithizone solution in glass-stoppered amber bottles containing alcohol (about 0.5% of capacity of bottle). Wash each liter of solution with about 200 c.c. of water, then with two 100-c.c. portions of concentrated sulphuric acid. Add 5 c.c. of alcohol to the chloroform and allow it to stand overnight in the dark over lump calcium oxide. Distill through a still, using all-glass connections into a glass-stoppered amber bottle containing absolute alcohol (about 1% of capacity of bottle).

Apparatus.—Pyrex glassware should be used throughout; containers should all be glass-stoppered. The extractions are most conveniently carried out in Squibb-type separatory funnels, 150 c.c. capacity, graduated at 5 c.c., 10 c.c., and 10 c.c. intervals to 100 c.c., using the rotary funnel racks previously described. Use white petrolatum to grease the stopcocks, since it is practically lead-free.

Any photometer which can be used with the cells described is usually satisfactory for this procedure. A glass filter with maximum transmission at 510 mμ is suitable. The neutral wedge photometer described by Clifford and Wichmann was originally used in this work.

Wash all glassware (Pyrex) thoroughly before use with hot 50 per cent nitric acid, and rinse with distilled water to ensure the removal of lead which may be present as surface contamination. Use the same procedure for silica or porcelain ware.

Isolation of Lead.—Pour approximately 15 c.c. of the ammonium citrate solution into each of the lower funnels, using the graduation marks on the funnels as guides. Add the proper aliquots of the prepared samples (equivalent to 50-200 c.c. of urine, 0.1-0.5 gm. of fecal ash, 5-20 gm. of blood, or 1/10 of a normal day's food), with 5 c.c. of potassium cyanide solution and 1 c.c. of hydroxylamine hydrochloride solution, and make the mixtures alkaline to phenol red with distilled ammonium hydroxide. In rare instances the solutions will become very cloudy upon being made alkaline, due to the presence of an unusually large quantity of calcium phosphate; in that case add sufficient ammonium citrate solution to dissolve the precipitate.

Begin the extraction of lead with 5 c.c. of dithizone extraction solution and note the color in order that the proper standard dithizone solution may be chosen in the final lead estimation. (The lead usually is not extracted quantitatively with each portion of dithizone solution because of the various salts present. Instead of 50 micrograms of lead, which is the theoretical equivalent of the dithizone, usually only 40 micrograms will be extracted by each 5 c.c. When the quantity of lead present is less than 10 micrograms this is recognized by the distinctive greenish-blue color of the dithizone.)

Add another 5 c.c. portion of dithizone solution using the graduation marks on the funnels as guides, and note the color of this combined 10 c.c. solution before it is drained into the other funnel. This color should indicate whether the quantity of lead present is greater than 50 micrograms, or greater than 100 micrograms. Continue the extraction with successive 5-c.c. portions of dithizone solution, noting the color of each portion. Drain each portion before adding the next, until the lead is completely extracted.

Wash the combined dithizone extracts with approximately 50 c.c. of double distilled water and wash the water with 5 c.c. of distilled chloroform. This chloroform washing should be green in color; if it is not, the presence of lead or zinc is indicated. If such is the case a drop of potassium cyanide solution should then be added to the water and the funnel shaken again; if the chloroform phase does not become green the water should be washed at least once with dithizone extraction solution. Add all chloroform washings to the dithizone extract and discard the water. Strip the lead from the dithizone extract by shaking with 50 c.c. of buffer solution (pH 3.4); if the dithizone solution does not return to its original green color, bismuth is present. Drain dithizone solution from the funnel; and if the sample contains bismuth, shake the buffer solution with one 5 c.c. portion of dithizone solution. After this is drained out, add 5 c.c. of distilled chloroform and shake the mixture.

In the event that the sample taken contains over 100 micrograms of lead, as indicated by the color of the separate portions of dithizone extraction solution early in the lead isolation step, discard a part of the buffer solution containing the lead before adding the 5 c.c. of distilled chloroform. The quantity discarded should be sufficient to reduce the lead below 100 micrograms; this is conveniently done by using the graduation marks on the funnel. Return the volume to 50 c.c. by adding more buffer solution and add the chloroform as indicated previously. Allow the funnel to stand unstoppered until the drop of chloroform floating on the surface of the aqueous phase has evaporated and draw off the 5 c.c. of chloroform as completely as possible without allowing water to enter the bore of the stopcock.

Final Estimation of Lead.—In the following part of the procedure direct sunlight should not be allowed to strike the solutions.

Add the proper standard dithizone solution (10 c.c. of the 0-10 microgram solution, 25 c.c. of the 0-50 or 0-100 microgram solution) to the funnel containing the lead in 50 c.c. of buffer solution. Add 7 c.c. of ammonia-cyanide mixture, and shake the funnel immediately for one minute. The pressure which develops should not be released through the stopcock; instead the stopper should be lifted in order to avoid blowing water into the funnel stem. If a number of analyses are being run, the mixed color can be developed in the whole series and photometric readings taken one after the other.

Use part of the dithizone solution (2 c.c. of the 0-10 microgram solution, 10 c.c. of the 0-50 or 0-100 solution) to flush the stem of the funnel, dry the end of the funnel stem, and allow the solution to run directly into the proper cell for the photometric reading. Use the 0-10 microgram solution with a 2-inch cell, the 0-50 microgram solution with a 1-inch cell and the 0-100 microgram solution with a ½-inch cell. The cells are cylindrical, with optically plane ends, and have an internal diameter of about 14 mm. Since the 0-10 microgram cell holds the entire 8 c.c. remaining in the funnel, it cannot be rinsed with part of the dithizone solution, but must be cleaned and dried with pure acetone after each sample. The other two cells, however, can be rinsed with dithizone solution at least twice and it is rarely necessary to wash or dry them between samples.

The photometric readings are referred to calibration curves made for each standard solution in the following way:

Make a standard lead nitrate solution by dissolving recrystallized lead nitrate in 1% nitric acid, so that each c.c. contains 1 mg. of lead. From this solution make two dilutions in 1% nitric acid, one containing 10 micrograms of lead per c.c., and the other 1 microgram of lead per c.c. All these solutions will keep indefinitely in glass-stoppered Pyrex containers.

Make a standard lead solution in the proper buffer by taking a measured quantity of the desired standard lead solution, bring it to pH 3.4 by the addition of dilute distilled ammonium hydroxide. Add the proper amount of the Clark and Lubs buffer mentioned above, and dilute the mixture to a known volume. This solution should be made fresh each time it is used.

Add measured quantities of this standard lead solution to clean separatory funnels, bring the volume in each funnel to 50 c.c. with the pH 3.4 buffer solution and add the dithizone solution which is to be standardized. Carry out color development and photometric readings as described under the heading "Final Estimation of Lead." From these readings make a standard calibration curve.

Rapid Microanalytical Test for Lead in Urine

Method of Kaye[1]

Aub and his associates showed that ammonium hydroxide quantitatively precipitates lead from urine in the form of lead phosphate. It has been shown experimentally, however, that 100 per cent recovery of lead does not occur when ammonia is added to the urine in excess. Fairhall stated that 100 per cent precipitation of lead from urine occurs with ammonia provided the reaction of the urine is brought to pH 10.0 with ammonia. This fact has been proved experimentally.

Several excellent procedures have been described for the destruction of organic matter in urine preparatory to the determination of lead. These use either dry muffle heat below 500° C. or various acid oxidation modifications. Although these methods are fairly rapid, they require more time than the phosphate precipitation method. Moreover, when the wet oxidation methods are used, the quantities of urine analyzed are so small that slight deviations become marked and significant when calculations are made on the basis of a liter of urine per day. Larger samples of urine may, of course, be digested in carrying out these tests, but this increases the time required for analysis.

Principle.—

The method is based upon the total precipitation of lead by the addition of ammonium hydroxide to urine. Lead phosphate is formed. It is very insoluble and easily separated by filtration along with the alkaline earth phosphates of calcium and magnesium. This precipitate is subsequently dissolved with hot dilute nitric acid and is heated for a short time to oxidize any organic material which may have adhered to it. Citric acid is added to keep the phosphates in solution during subsequent neutralization. Potassium cyanide is added to form complex ions with interfering metals.[2] The reaction is adjusted to pH 9.0 to 10.0 and the lead is extracted with dithizone to separate it from extraneous salts and interfering substances. Once separated, the lead is split from the dithizone and then titrated with standardized dithizone for an accurate determination. With this test, only bismuth, tin, thallium, and lead react with dithizone. Interference of bismuth and tin is eliminated by previous extraction with dithizone while the solution is still acid. Lead is not extracted in this acid solution. Thallium, as a source of interference, has not been removed, but its occurrence is rare, and it is not likely to be found.

Reagents.—

All reagents must be kept in Pyrex glass bottles. Use distilled water from an all-Pyrex still. Use ammonia water and nitric acid with low lead content.

---

[1] J. Lab. & Clin. Med. 28: 9, 1943.

[2] Cd, Zn, Cu, Co, Ni.

Phenolphthalein Indicator.—

See page 1199.

Ammonium Hydroxide (Low Lead Content).—

8% Nitric Acid.—

Add 80 c.c. of nitric acid, c.p. (low lead content) to distilled water, and dilute to 1000 c.c. with distilled water.

10% Potassium Cyanide Solution.—

Dissolve 10 gm. potassium cyanide (low in lead) in distilled water and dilute to 100 c.c. with distilled water. POISON.

40% Citric Acid Solution.—

Dissolve 200 gm. citric acid (low in lead) in distilled water and dilute to 500 c.c. with distilled water.

Standard Lead Solution.—

Dissolve 160 mg. of lead nitrate in distilled water in a liter volumetric flask and dilute to 1000 c.c. with distilled water.

1 c.c. is equivalent to 100 gammas of lead.

Dithizone 1 for Preliminary Extraction.—

Dissolve 25 mg. of dithizone in 400 c.c. of chloroform.

Dithizone 2 for Titration.—

Dilute 100 c.c. of dithizone 1
with 100 c.c. of chloroform.

Standardize against a known lead solution (see below).

The approximate value is 1 c.c. = 5 gammas of lead.

If kept in a brown bottle and in a cool place, the titer will not change for several months. This titer is sastisfactory for amounts of lead near normal values. If larger amounts of lead are apparently present, as determined by the amount of dithizone required for preliminary extraction, a solution with stronger titer may be prepared. When dithizone 1 is standardized, the titer is approximately 1 c.c. = 10 gammas lead. The titer should be calculated to at least one decimal unit.

Technic.—

Collect and measure the total 24-hour specimen of urine.

Remove an exactly measured aliquot for analysis, usually 300 c.c.

Add a few drops of phenolphthalein indicator.

Add ammonium hydroxide, a drop at a time, until the urine turns pink. The reaction is now pH 9.0 to 10.0.

Stopper, shake well, and allow the urine to stand for about 30 minutes until the precipitate which forms settles out.

Separate the precipitate by filtering through a Buchner funnel using suction. Refilter if necessary.

Wash the precipitate with several small portions of alcohol.

Invert the filter paper so that the precipitate faces the perforations of the funnel, and insert the funnel into a clean flask.

Pour approximately 30 to 50 c.c. of hot 8 per cent nitric acid over the precipitate, repeatedly, until the precipitate either dissolves or is completely transferred to the flask. This is more easily accomplished without suction.

Boil the total redissolved precipitate gently for approximately 30 minutes until the foaming stops. This indicates that the proteins are destroyed. If the volume has decreased greatly, restore it with lead-free distilled water.

Adjust the reaction to pH 3.0 to 3.5, the lower range of methyl orange, by adding dilute ammonium hydroxide a drop at a time until the proper color develops.

0.0349 mg. lead/gram ash of feces.

0.91 mg. lead/liter urine } Storage battery mfrs.

Transfer to a Squibb separatory funnel.

Shake out with 5 to 10 c.c. of dithizone 1. Discard the dithizone chloroform layer. This extracts tin and bismuth and eliminates the possibility of their appearing later as interfering substances. Lead is not extracted at this hydrogen ion concentration. If it is known that tin and bismuth are not present, the extraction at pH 3.0 to 3.5 may be omitted.

Add 15 c.c. of the citric acid solution.

Neutralize with ammonium hydroxide.

Add 2 c.c. of the potassium cyanide solution.

The material is now ready for lead extraction. In an ammoniacal solution and in the presence of potassium cyanide, dithizone has a selective affinity for lead, forming a cherry-red complex of lead dithizone which is soluble in chloroform.

Allow a small quantity of dithizone to run from a buret into the solution. Shake the solution vigorously. The rapid appearance of a cherry-red chloroform layer indicates the presence of lead. Separate the red chloroform layer and transfer it to another separatory funnel.

Continue the addition of dithizone, the vigorous shaking, and the transferring of the colored chloroform layer until all the lead has been removed. Wash the last traces of lead dithizone through several small portions of chloroform. Collect and save these washings. The proximity of the end point (complete removal of lead) may be roughly estimated by diminution of intensity of the cherry-red color. If it is very red, a larger amount of dithizone may be added. It must be shaken and separated. After each shaking, invert the funnel and open the stopcock to relieve the pressure formed, then close the stopcock.

When all the lead has been extracted, further addition of dithizone will not impart a cherry-red color to the chloroform layer, but upon vigorous shaking of the funnel a green color will form and persist, due to excess of dithizone. The presence of many extraneous salts prevents a sharp end point; that is, a distinct change from red to green. The first titration-extraction is, therefore, not a reliable indication of the quantity of lead present in the specimen.

The end point is often difficult to see because of the lingering transition of colors from cherry-red to pink to violet to blue to green when extraneous salts are present. When this occurs, collect several portions of extracted lead dithizone.

Shake these combined chloroform extracts with 15 c.c. of 1 per cent nitric acid solution. This quantitatively separates the lead into the aqueous solution. Discard the green chloroform layer.

Wash the aqueous layer by shaking with a fresh portion of chloroform to remove any residual dithizone.

Add to the solution several drops of phenolphthalein.

Add ammonia a drop at a time until the solution is alkaline.

Add 2 c.c. of potassium cyanide.

Add citric acid solution drop by drop until the solution is just faintly pink. If the end point is passed, adjust with a drop of dilute ammonium hydroxide.

Titrate the solution with standard dithizone 2. The dithizone may be added in one large portion to within 5 c.c. of the total amount required in the first extraction (when the cherry-red color began to change).

Shake the separatory funnel thoroughly, allow it to stand until the layers separate, and then remove the red chloroform layer.

Continue the titration from this point with great care.

Deliver the dithizone in successive small quantities, approximately 0.5 c.c. each.

Before each shaking add approximately 1 c.c. of chloroform in order that the volume be great enough to enable one to see the color.

Shake vigorously after each addition of dithizone, allow to settle, run out the chloroform layer, and discard it.

Continue in this manner until the end point is reached. This is a persisting light green color in the chloroform layer.

Calculation.—

For standardization, titrate a known quantity of lead solution with dithizone solution using the procedure described above. Since the lead is in pure solution, the preliminary titration-extraction is not necessary. The quantity of lead in the standard used, divided by the number of c.c. of dithizone solution required for the end point, represents the dithizone lead equivalent.

Example.—

The standard contained 20 gammas (0.020 mg.) of lead.

6 c.c. of dithizone were used in the titration.

6 c.c. of dithizone are equivalent to 20 gammas of lead.

20 divided by 6 equals 3.3. Therefore 1 c.c. of dithizone is equivalent to 3.3 gammas of lead.

In the test 21.2 c.c. of dithizone were used.

The specimen, therefore, contains 21.2 × 3.3, or 69.96 gammas of lead per sample analyzed. The aliquot daily factor is then computed.

Summary of Urinary Changes in Lead Poisoning

The urinary changes in lead poisoning are as follows: albumin; granular casts; red cells; abnormal amounts of lead (see above tests); hematoporphyrin.

Summary of Blood Changes in Lead Poisoning

The blood changes in lead poisoning are as follows: low red cell count; low hemoglobin; high blood platelet count; presence of nucleated red cells; changes in the morphology of the red blood cells; basophilia; polychromasia.

(For fuller details, see Hematology of Lead Poisoning in chapter on Hematology.)

Contamination of Samples in Process of Collection and Analysis

Kehoe* especially warns against contaminations of samples intended for chemical analysis for lead for the reason that lead is ubiquitous and reagents of the highest purity show traces of lead. All glassware contains lead and even filter paper and distilled water may have minute amounts of lead in them. Dust suspended in the air of the laboratory may contain significant amounts of lead, especially when there are any painted surfaces. Laboratory surfaces, which have not been proved by chemical test to be lead-free, may contaminate the sample. Necessarily, blanks should be carried along with every set of samwhich have not been proved by chemical test to be lead-free, may contaminate during the collection of samples. Needles and syringes sterilized in the usual manner may introduce lead into the blood or spinal fluid. Bedpans and urinals provide gross contaminations, so that urine samples are likely to be contaminated. Care must be taken to avoid contamination in collecting samples at autopsy. In general, everything that comes in contact with the specimen must be carefully cleaned and selected, and the activities of the patient during the period preceding and during the collection of the sample must be known. A dose of Epsom salts will spoil a fecal sample because of the lead content of the salt employed (Kehoe).

The Quantitative Spectrographic Determination of Lead in Blood and Urine

One of the best and easiest methods of estimating accurately the quantity of lead in blood is by use of the spectrograph. Spectrographic methods of analysis eliminate the annoying and time-consuming measures of avoiding contaminants in reagents, glassware, etc., necessary in the regulation chemical methods. The only possible objection to spectrographic methods in the clinical laboratory is the question of cost of installation. Cholak[1] described his method and views on quantitative spectrographic determination of lead in urine, utilizing a Bausch & Lomb Littrow-type quartz spectrograph. Standard spectrographic methods were used, testing several series of samples containing known quantities of lead in solutions of urine salts equivalent to one-liter samples of urine. The quantities of lead added were such that they fell below the quantity contained in the highest urine standard, that is, 0.20 mg. per liter. He found that concentrations of lead in urine as low as 1 part per 100 million could be detected. For amounts of lead up to 0.10 mg. per liter the accuracy of the method is ± 0.01 mg. per liter. This method is applicable to the measurement of lead in all kinds of biological material.

The method of making the test was the addition of suspected material into the craters of the respective graphite electrodes by the repeated addition from capillary pipettes and the subsequent evaporation of 0.1 c.c. portions. The electrodes were dried in an oven for several hours and then used as the negative poles of the arc. The spectra of the sample and standards are photographed on a 10 × 25 cm. Eastman No. 33 plate. The spectral region taken is that between 2500 and 3400 Angstrom units.

Quantitative spectrographic analysis of lead in blood will probably be the ultimate method of choice in proving lead intoxication. The method of detecting lead in blood by spectrographic analysis may be used with either the grating or the quartz prism spectrograph. Withdraw a given amount of blood, say 5 c.c., from the arm vein, with a chemically clean syringe and needle. Ash; weigh; place in arc of spectrograph. Determine the presence of lead and the quantity of lead.

The Polarographic Method for Detection and Measurement of Lead Absorption

This method was developed through the research of H. A. Cranston, of the Laboratory of Polarographic Analysis, in Chicago, using the Heyrovsky polarograph.[2] He claimed that this new procedure is sufficiently fast and economical for routine periodic examinations, in any plant, of persons subject to lead exposure. This procedure permits accurate interpretation and measurement of current voltage curves by recording all current changes occurring in the course of an analysis.

Technic for the entrainment procedure of Cranston is as follows:

Fill a Pyrex centrifuge tube with fresh urine or with urine that has been preserved with thymol.

Add several reagents in approximate quantities, stirring the solution between each addition. Shake thoroughly.

---

[1] J. Am. Chem. Soc. 57: 104, 1935.
[2] Sargent Magazine 1: No. 1, 1941.

Set samples aside.

After precipitation is complete, centrifuge, decant, wash with ammonia water and recentrifuge.

Pour off wash water and allow tubes to drain.

Then add to each tube concentrated hydrochloric acid containing tartaric acid.

Transfer dissolved precipitates to electrolytic cell and wash centrifuge tube with a few drops of distilled water (see Fig. 708).

Add the washings to the solution on the electrolytic cell. A rack which facilitates the complete drainage of the centrifuge tube is shown. Bring to volume with distilled water and note the final volume. See Fig. 709.

Polarographic Measurement of Lead.—Hydrogen, from a tank or any convenient method of generation, is now bubbled through the solution in the electrolytic cells. This may be accomplished easily by the simple rubber stopper and tube arrangement illustrated. See Fig. 710.

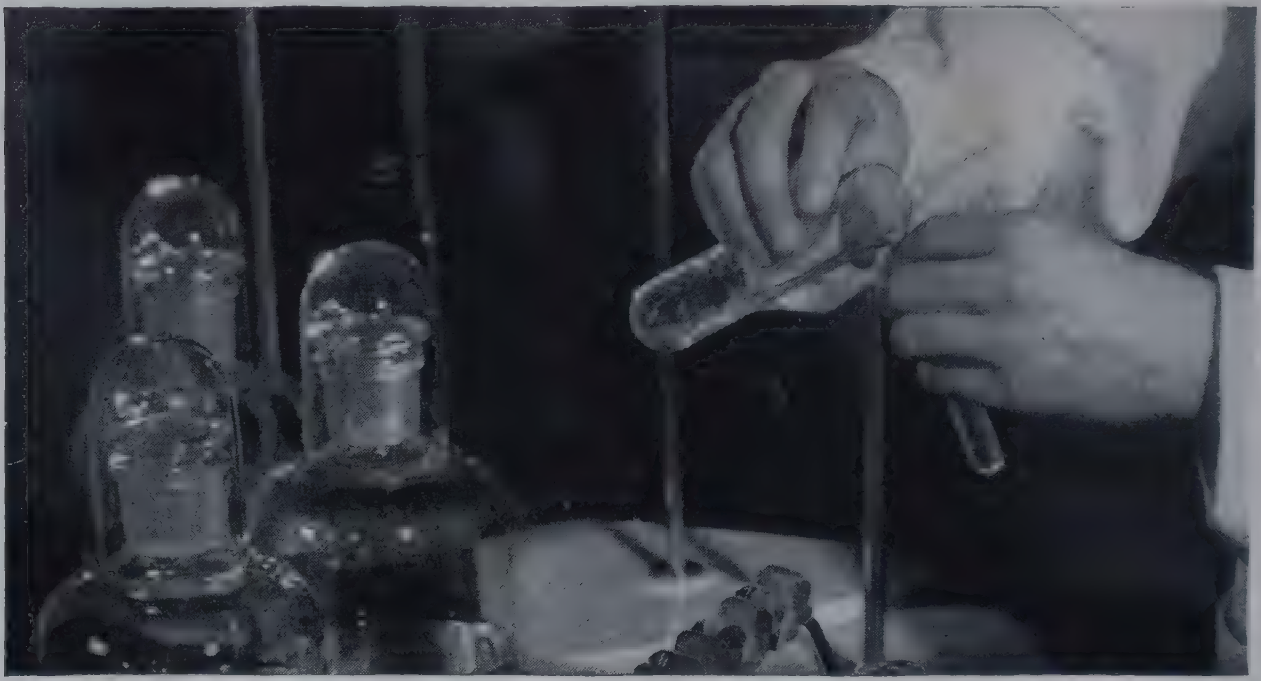

Fig. 708.—Transferring precipitate to electrolytic cell for polarographic determination of lead.[2]

Remove the stoppers and insert the dropping mercury electrode into the tube so that it is below the surface of the liquid. Connection is made through a suitable mercury pool with the lower terminal of the cell.

Adjust polarograph. The power switch of the polarograph is turned on, the potentiometer drum turned to about minus 0.2 volt, the galvanometer beam adjusted to the zero end of the deflection scale, the shutter opened and the motor started. The recording is continued to a bridge reading about minus 0.6 volt, requiring a run of about 2 to 3 minutes. The motor is then stopped, the shutter closed, and the camera drum rotated to a starting position for the next sample record. The capillary tube is shifted to the next sample tube and the operations are repeated. Ten records may be made on a single sheet without reloading the camera. See Fig. 711.

To reload, the complete drum or camera is removed from the polarograph.

Typical lead curves. After development of the photographic paper the curves are measured and compared with a similar curve run occasionally with a standard solution. See Fig. 712.

Calculation of Urinary Lead.—No attempt is made here to discuss the theoretical aspects of polarographic analysis. It will suffice for the present purpose to state that the

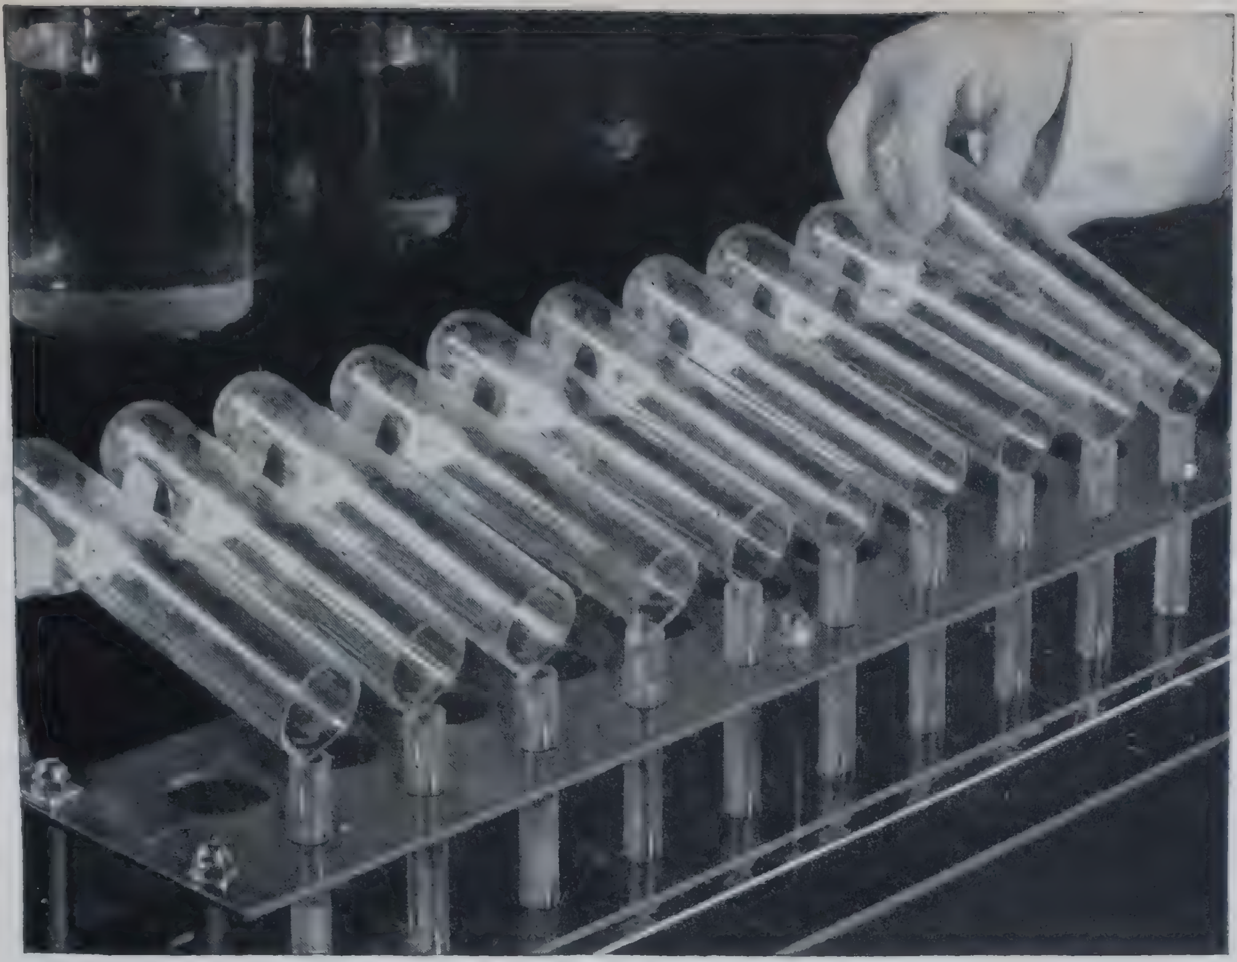

Fig. 709.—Rack to facilitate complete drainage of centrifuge tubes.

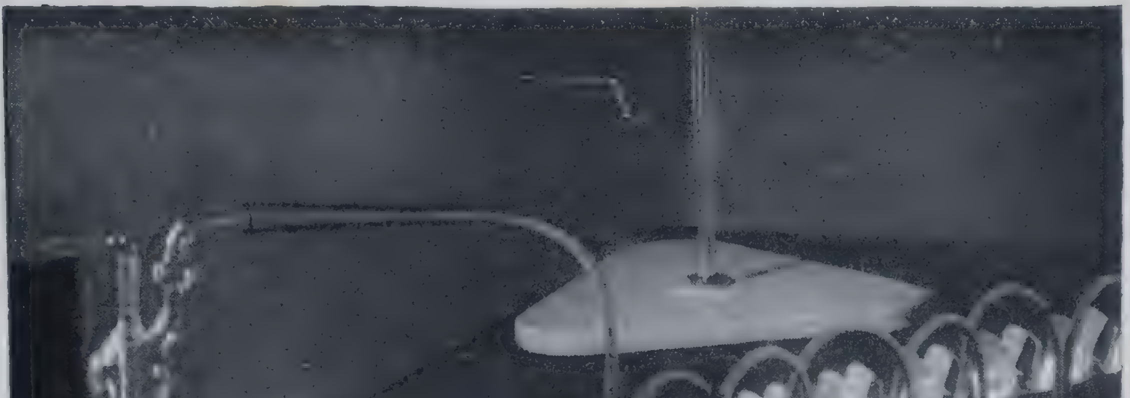

Fig. 710.—Bubbling hydrogen through solution in electrolytic cells.

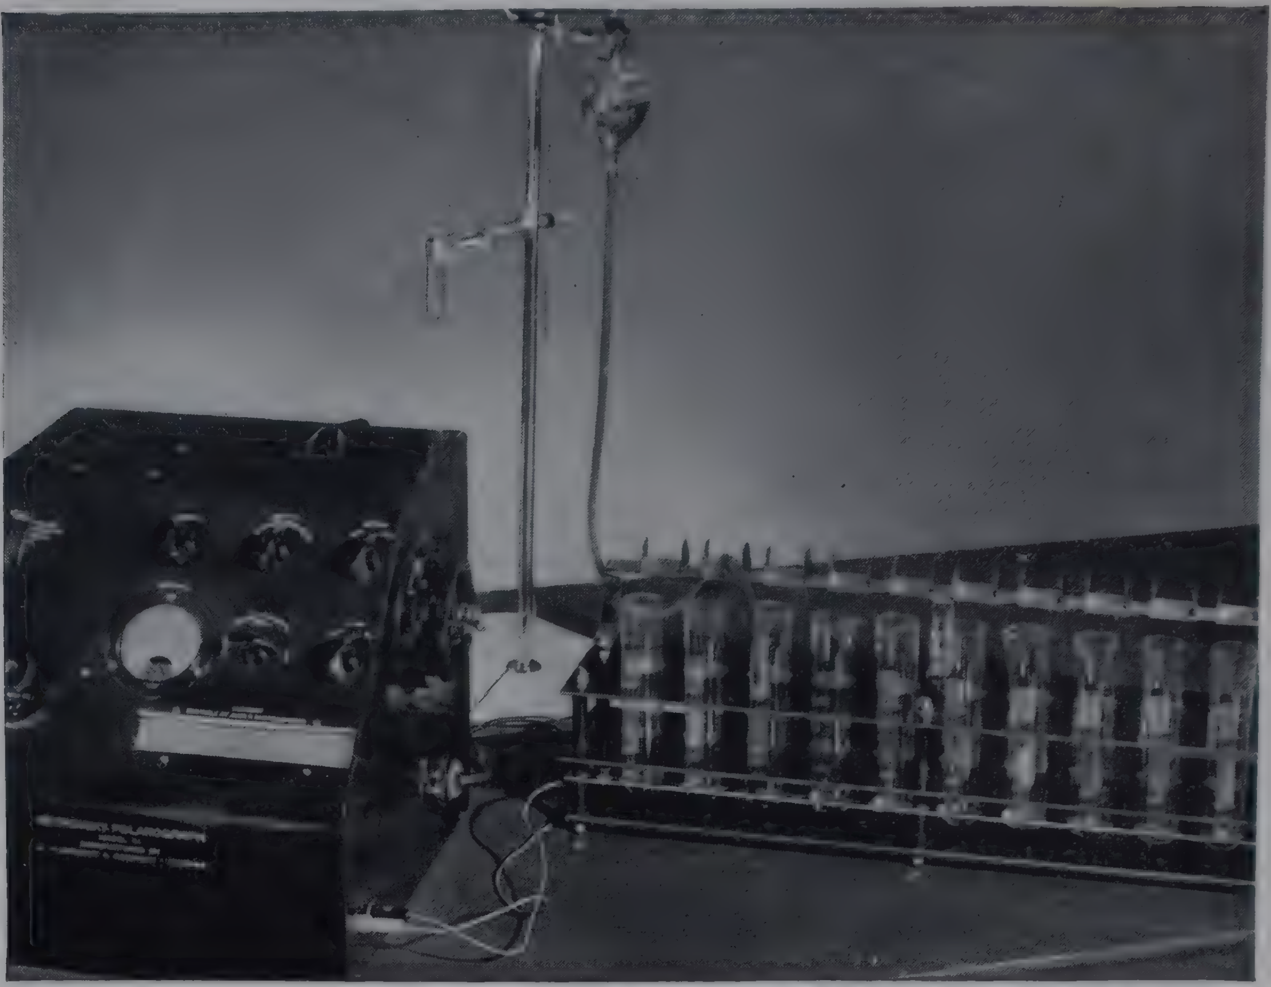

Fig. 711.—Adjusting polarograph.

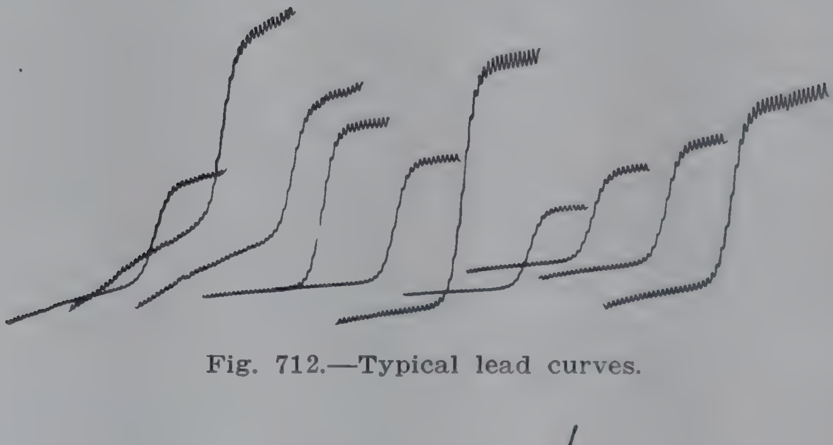

Fig. 712.—Typical lead curves.

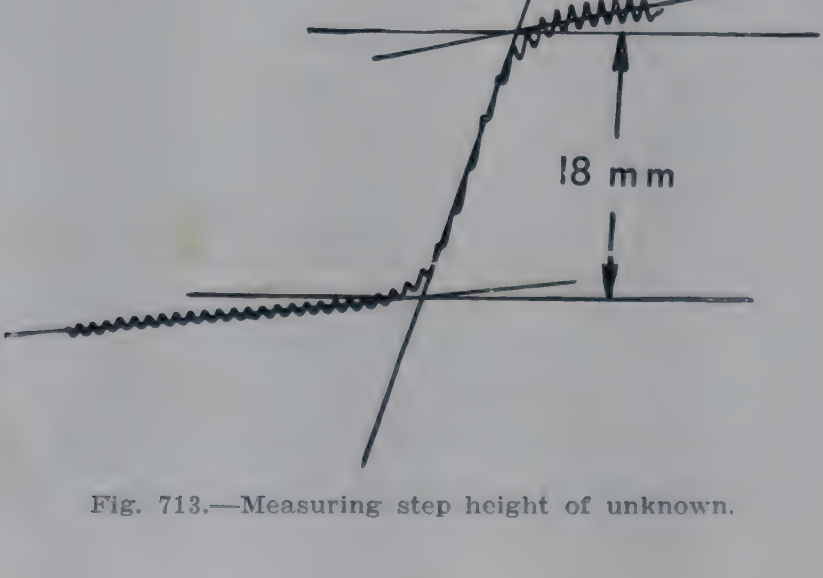

Fig. 713.—Measuring step height of unknown.

height of the step for each ion present in a solution is directly proportional to the concentration of that ion. Therefore, it is only necessary to measure the step height by the method shown, and compare it with the height of a standard solution. See Fig. 713.

Example:

Effective concentration of standard	10	micrograms/c.c.
Step height of standard	45	mm.
Step height of unknown	18	mm.
Volume of unknown	2.0	c.c.

Therefore, the concentration of the unknown is $\frac{18 \times 10}{45} =$ micrograms/c.c.; and as 2 c.c. contained the lead originally present in 80 c.c. of urine, the amount of lead present in 1 liter of urine will be $\frac{1,000}{80} \times 2 \times 4$, or 100 micrograms/liter.

Normal Urinary Lead Values

Many determinations of lead in urine have been made on individuals with no known history of exposure to lead. Gettler and Kaye found that the lead content in normal individuals varies widely. In all cases, however, the concentration was below 100 gammas* in a 24-hour specimen. Other workers have corroborated these findings.

RADIOACTIVE SUBSTANCES

Radium and Uranium

In testing for radium and uranium the bones and teeth are the tissues of choice. Gettler found that they contain more of the accumulated radium than do the soft tissues.

Ash a definite weight of bone. Test the ash for radioactivity by:

1. the Geiger-Müller counter;
2. the electroscope;
3. exposing an x-ray plate.

Place the bones or the ash on an unexposed x-ray plate which has been covered with black paper.

Allow this to stand in a dark room for a week or more.

Develop the plate.

If radioactive material was present in the material tested an exposed light space will appear on the plate in the area on which the specimen was placed. Both beta and gamma rays of radioactive substances will penetrate the black protective paper on the film and will bombard and expose the area of contact.

UNCOMMON OCCUPATIONAL METALLIC POISONS

For the detection of the more uncommon occupational metallic poisons which may be present in fair amounts in specimens submitted for analysis, reference should be made to a standard text on qualitative and quantitative analysis. A satisfactory scheme is found in Noyes textbook on qualitative and quantitative analysis. Any similar scheme may be used.

---

*0.001 milligram = 1 gamma; 100 gammas = 0.1 mg.

Group I.—

Concentrated hydrochloric acid precipitates silver (w),* lead (w), mercury (w).

Group II.—

Hydrochloric acid, hydrogen sulphide precipitates lead (bk), bismuth (bk), copper (bk), cadmium (y), arsenic (y), mercury (bk), antimony (o), tin (y).

Group III.—

Ammonia, hydrogen sulphide precipitates iron (bk), aluminum (w), chromium (gn), cobalt (bk), nickel (bk), manganese (p), zinc (w).

Group IV.—

Ammonium carbonate hydroxide reagent precipitates barium (w), strontium (w), calcium (w), magnesium (w).

To Generate Hydrogen Sulphide

Use a large test tube into which is placed a one-hole rubber stopper. One end of a piece of glass tubing, bent in a ''U'' shape, is placed through the hole of the rubber stopper so that it extends just within the test tube.

To generate hydrogen sulphide, place a small amount of sulphide of iron in the test tube and add a few c.c. of dilute hydrochloric or sulphuric acid, and tightly stopper with the rubber stopper and glass tubing. The gas which is generated passes through the glass tubing into the solution to be tested. Or use the Kipp generator (Fig. 715).

GROUP V

IDENTIFICATION OF GASES OF TOXIC NATURE IN BLOOD

Detection of Carbon Monoxide

Poisoning by a small amount of carbon monoxide may produce very few changes, or if the patient lives for a number of hours after exposure, only a careful examination of the blood will reveal the presence of the gas. Where the blood is well saturated with the gas, the surface of the body is cherry red. There are frequently red patches upon the thighs and the front of the trunk and neck. The blood is rather characteristic, being bright cherry red, usually fluid, and coagulating slowly. It should be placed in a container which is sealed immediately after collection.

Detection of carbon monoxide may be carried out by means of the spectroscope, as outlined on page 2359. Shake diluted blood with from 100 to 200 c.c. of air and examine by the spectroscope. Blood taken from persons or animals poisoned by carbon monoxide shows a characteristic absorption spectrum closely resembling that of oxyhemoglobin. The absorption occurs between the D and E lines. There are two absorption bands of nearly equal intensity and width. The one near D coincides almost exactly with that of oxyhemoglobin of the same position; the space between it and the band toward F is considerably wider than that between the two bands of the oxyhemoglobin spectrum. In making the test, the ordinary spectroscope may be used. The blood contained in the test tube is placed in the path of the rays from the lamp illuminating the spectroscope. Dilute the blood in making the test.

Other tests for carbon monoxide are as follows:

Bloods rich in carbon monoxide, when boiled, yield a brick-red mass; ordinary blood becomes brown black.

Ten c.c. of 2% solution of a blood strongly charged with carbon monoxide, with 2 c.c. of yellow ammonium sulphide, and 0.2 c.c. of 30% acetic acid, yields a bright red, while normal blood yields a green precipitate.

---

*(w) white; (y) yellow; (o) orange; (bk) black; (gn) green; (p) pink.

When blood is added to dilute hydrogen sulphide water drop by drop, it produces a bright red precipitate if carbon monoxide is present; otherwise it is bright green.

Normal blood when shaken with one or two volumes of a solution of sodium hydroxide of 1.3 specific gravity becomes black, in thin layers dark greenish brown; carbon monoxide blood remains red and appears like red lead.

Two c.c. of carbon monoxide blood with an equal quantity of water and 3 drops of a one-third saturated solution of copper sulphate when mixed produce a brick-red precipitate, while normal blood yields a greenish brown one.

Quantitative Determination of Carbon Monoxide

The method of Fodor[1] is as follows:

The method of Fodor, based on the reduction of palladous chloride by carbon monoxide, is much better for the examination of carbon monoxide in blood. The reaction is expressed by the equation: $PdCl_2 + CO = Pd + 2HCl + CO_2$. For the examination of the blood, dilute 5 c.c. with 20 c.c. of water in a large test tube of 80 c.c. capacity; add a small piece of sodium hydroxide to aid in the expulsion of carbon monoxide. A tube containing 10 c.c. of palladous chloride precedes the tube containing the blood to remove the carbon monoxide from the laboratory air. A third U tube following the tube containing the blood contains a solution of lead acetate, and a fourth tube contains dilute sulphuric acid. The chain of tubes is completed by the addition of three U tubes containing a solution of palladous chloride.[2] Heat test tube containing the blood in a water bath to 90° C., while a gentle current of air, previously drawn through the tube of palladous chloride, is conducted through the chain of tubes at the rate of 300 c.c. per hour for four hours. If carbon monoxide is present, the palladous chloride is reduced, and a black precipitate of palladium will be deposited. Collect reduced palladium on a filter paper, wash with water, and dissolve in hot nitrohydrochloric acid. The U tubes, after being washed with water, will have a small amount of palladium adhering to the sides.

---

[1] Deutsch. Vrtljschr. f. off. Gesundhtspfl. 12: 377, 1880.

[2] The commercial salt is dissolved in hydrochloric acid, with the addition of nitric acid, evaporated to dryness on the water bath, moistened with hydrochloric acid, dried, taken up with a small amount of water and again dried to free it from excess acid. The residue is then made up to volume so that 500 c.c. will contain 1 gm.

This can be dissolved in the hot nitrohydrochloric acid and added to that dissolved from the filter paper. Evaporate the solution on the hot water bath, take up with strong hydrochloric acid three or four times to remove all traces of nitric acid. Dissolve the residue in water and titrate with a solution of potassium iodide containing 1.486 gm. to the liter. Heat the diluted palladous chloride solution on the water bath before each addition of the potassium iodide solution. Filter off a brown precipitate of palladous iodide and repeat the operation until the addition of potassium iodide fails to produce a brown cloudiness. Each cubic centimeter of the potassium iodide solution represents 0.1 c.c. of carbon monoxide. In case the blood contains only a small amount of carbon monoxide, as is demonstrated by the tannic acid and other color tests, 20 c.c. of the blood are used in a small Erlenmeyer flask. When it is desired to report the saturation of the blood after obtaining the percentage of carbon monoxide by volume, one can use the relation x : 20, since a saturated blood will hold in combination 20% by volume of carbon monoxide.[3]

A Simple Method for Carbon Monoxide in Blood

Method of Gettler and Freimuth[4]

This method was devised to serve as a simple and rapid procedure for the routine analysis of carbon monoxide in blood. The determination can be completed in 15 minutes, excluding the preparation of standards, and requires no personal attention during the test.

Principle.—

The carbon monoxide is liberated from carboxyhemoglobin by potassium ferricyanide, and by aeration it is passed through a disk of palladium chloride paper. The carbon monoxide produces a dark stain on the filter paper, due to the reduction of palladium ions to metallic palladium according to the reaction $CO + PdCl_2 + H_2O \rightarrow Pd + CO_2 + 2HCl$. The depth of stain is proportional to the amount of carbon monoxide present.

Apparatus (See Fig. 716).—

3 potato tubes, 5 to 6 inches long, ¾ inch wide
1 glass flange (see Fig. 572)
1 2-liter Marriott flask, or a larger flask
2 screw clamps
Glass beads

Reagents.—

Palladium Chloride Solution.—

Dissolve 0.5 gm. palladium chloride
in 0.5 c.c. concentrated hydrochloric acid and
dilute to 50 c.c. with distilled water.

Ferricyanide Solution.—

Dissolve 3.2 gm. potassium ferricyanide ($K_3Fe(CN)_6$)
and 0.8 gm. saponin in distilled water and dilute to
100.0 c.c. with distilled water.

Lactic Acid Solution.—

Place 0.8 c.c. lactic acid, sp. gr. 1.20, in distilled water in a 100 c.c. volumetric flask, and dilute to 100 c.c. with distilled water. Mix well.

Ferricyanide-Lactic Acid Solution.—

Mix equal parts of each.

[3] See Florentin and van den Bergh: Compt. rend. Acad. d. sc. **172**: 391, 1921; Nicloux, M.: Bull. soc. chem. biol. 2: 171, 1902; Micromethod for Estimating Carbon Monoxide, Ibid. 3: 286, 1921.

[4] Am. J. Clin. Path. **13**: 9, Sept., 1934.

Lead Acetate.—

Dissolve 10 gm. lead acetate ($Pb(C_2H_3O_2)_2.3H_2O$) in distilled water in a 100 c.c. volumetric flask, and dilute to 100 c.c. with distilled water.

Caprylic Alcohol.—

Technic.—

Tube "A."—Place 5 c.c. of palladium chloride solution in tube "A."

Tube "B."—

Place 2 c.c., accurately measured, of the blood to be analyzed, in tube "B."
Add 4 c.c. of the ferricyanide solution
and 2 drops of caprylic alcohol.

Tube "C."—

Place a 1½ -inch layer of glass beads in tube "C."
Add 5 c.c. of the lead acetate solution.
Set up the apparatus as indicated in Fig. 716.

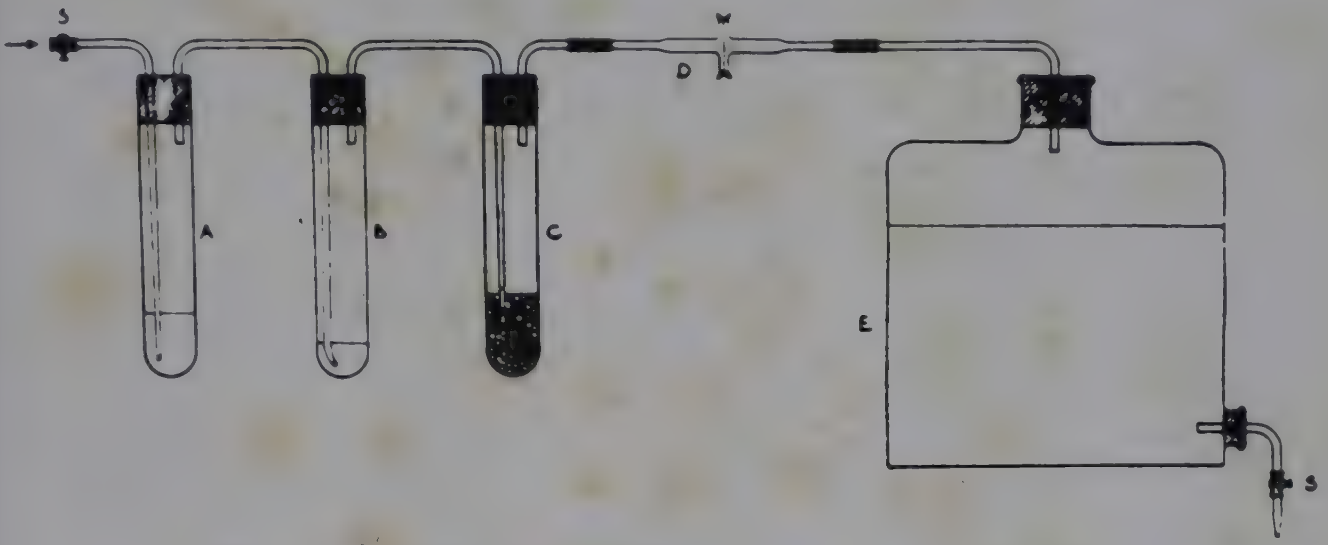

Fig. 716.—Apparatus for estimating carbon monoxide in blood.

Place between the two glass flanges "D" a moist disk of *palladium paper* prepared as follows:

Palladium Paper.—

Cut, from a piece of Whatman No. 3 filter paper, a disk just slightly smaller in circumference than the ground glass surface of the flange. Then moisten the disk with a few drops of palladium chloride solution. Any excess solution must be removed by pressing the disk between two pieces of blotting paper. Then place the moist disk between the flanges and fasten together by means of rubber bands. They must be fastened tightly to prevent leakage at this part of the apparatus.

The *Marriott flask* "E" contains a large volume of tap water.

Begin the aeration by slightly releasing the screw clamp "S" on the rubber tube connection of the outlet tube of bottle "E," which allows water to flow out slowly. So regulate the rate of flow, with either one of the screw clamps "S," that 400 c.c. of water will run out in about 15 minutes. As a result of the removal of this amount of water, 400 c.c. of air will have been slowly drawn through the entire apparatus. Air is drawn first through the palladium chloride solution "A" to remove from it any carbon monoxide which might be present. This washed air then passes through the blood in "B" and carries any carbon monoxide present in the blood along with it. The stream of air containing the carbon monoxide next passes through the lead acetate solution in "C."

Here any hydrogen sulphide that may be present in the blood due to putrefaction is removed, and the carbon monoxide passes through unaffected. The stream of air containing the carbon monoxide passes along and is carried through the flanges where it meets the disk of moist palladium chloride paper. The carbon monoxide reduces the palladium ions to metallic palladium, and as a result a dark circular stain is produced. The depth of stain is proportional to the amount of carbon monoxide present.

Discontinue aeration after 15 minutes.

Remove the disk of palladium chloride paper from the flange, and wash it thoroughly with distilled water to remove all unchanged palladium chloride. Then compare the stain with a series of standard stains in order to estimate the per cent of carbon monoxide saturation of the blood.

Standard Stains.—

Prepare standard stains in a similar manner by saturating normal blood with carbon monoxide gas for about 15 minutes. Then assuming this to be 100% saturation, make various dilutions of this blood with other normal blood samples to produce the desired per cent of saturation. For example, a mixture of 1 part of 100 per cent saturated blood and 1 part of normal blood will produce 50 per cent carbon monoxide saturation. Lower carbon monoxide-containing samples may be prepared by mixing the 50 per cent carbon monoxide blood with normal blood.

After preparing, washing, and drying these standard stains, mount them on a cardboard. Keep them away from fumes, heat, or direct sunlight, and they will remain in good condition for several months.

The carbon monoxide content of the blood of patients who have been removed from a carbon monoxide atmosphere and brought to a hospital has never been found to be higher than 50 per cent saturation.

It is evident that an approximate estimation only may be made by this method. For more accuracy a correction must be made. Determine the per cent of hemoglobin in the blood and correct as follows:

$$\frac{100}{\%\text{ of hemoglobin}} \times \text{carbonyl hemoglobin saturation} = \begin{array}{c}\text{per cent saturation with}\\ \text{carbon monoxide.}\end{array}$$

Example.—

If the per cent of hemoglobin is 90 and the carbonyl hemoglobin saturation is 20, then $\frac{100}{90} \times 20 =$ per cent saturation with carbon monoxide.

For a more accurate quantitative determination of carbon monoxide, the manometric technic of van Slyke should be used.

For a rapid qualitative indication and semi-quantitative estimation of carbon monoxide, use the following methods. These tests are not sensitive, however, below 15 per cent carbonyl hemoglobin saturation.

Dilution Test.—

Add 1 drop of blood to 10 c.c. of distilled water. Compare with normal blood treated in a similar manner. Blood containing carbon monoxide will be cherry-red while the normal blood will be brownish red.

Alkali Test.—

Add several drops of 10% sodium hydroxide solution to blood diluted 1 drop to 10 c.c. of water. Blood containing carbon monoxide remains a cherry-red whereas normal blood turns a yellow-green.

Welzel Test.—

Add a solution of tannic acid to the diluted blood. A brick-red precipitate forms in the presence of carbon monoxide.

Sayer-Yant Pyrotannic Acid Test.—

Dilute 1 c.c. of blood with 9 c.c. of distilled water.

Add 10 c.c. of pyrotannic acid solution.

Stopper the tube, shake, allow to stand 15 minutes.

Normal blood is gray-brown; blood containing carbon monoxide retains a pink color.

Pyrotannic acid solution is made by dissolving 1 gm. of pyrogallic acid and 1 gram of tannic acid in 100 c.c. of distilled water.

Note.—Both the Welzel test and the Sayer-Yant test may be used as a rough estimation of the quantity of carbon monoxide present, since the color intensities produced are proportional to the concentration of carbon monoxide.

Gettler and Freimuth reported carbonyl hemoglobin saturation of blood of 30 to 90 per cent in deaths due to carbon monoxide poisoning.

Postmortem absorption of carbon monoxide is very small; the quantity absorbed after death is practically negligible, less than 2 per cent.

Carbon monoxide is not produced by putrefaction.

Embalming fluid interferes with CO determination.

It seems reasonable to assume, therefore, that carbon monoxide found in the blood was absorbed during life.

Hydrogen Sulphide

Hydrogen sulphide may be isolated by steam distillation. Distill over steam *fresh* organs or body fluids. During this distillation the very characteristic hydrogen sulphide odor of rotten egg is detectable, if hydrogen sulphide is present.

Add a small aliquot of the distillate to a solution of lead acetate. If a black precipitate of lead sulphide forms, hydrogen sulphide was present in the original specimen.

A spectroscopic examination for sulfhemoglobin may be made. This spectroscopic test is unreliable if the individual has recently been treated with sulfa drugs.

Cyanide in Blood and Tissues

Micromethod of Gettler and Goldbaum

The micromethod of Gettler and Goldbaum for detection of cyanides in blood and tissue combines the simplicity of a spot test with the specific Prussian blue reaction. By the use of an impregnated paper and a special flange arrangement, it is possible to detect micro quantities of cyanide and to estimate the concentration by comparison with spots similarly prepared from cyanide solutions of known concentration.

Ferrous Sulphate Impregnated Paper.—

Dissolve 10 gm. hydrated ferrous sulphate in 100 c.c. of distilled water. Remove insoluble material by filtration.

Pour the clear solution into a large Petri dish.

Immerse Whatman No. 50 filter papers in the ferrous sulphate solution for 2 to 5 minutes. Remove and suspend in the air to dry.

Place 20% solution of sodium hydroxide in another Petri dish.

Dip the dry ferrous sulphate papers in this solution for a few seconds, remove, and suspend in the air until they are only slightly moist.

Prepare fresh papers on the day of the analysis.

Flanges.—

Use the flanges made by Eck and Krebs of New York. See Fig. 691. These are of varying diameters, 8 mm., 4 mm. Place the moist paper disk in the flange and close by means of a rubber band.

20% Trichloroacetic Acid.—

20 gm. trichloroacetic acid dissolved in distilled water and diluted to 100 c.c. with distilled water.

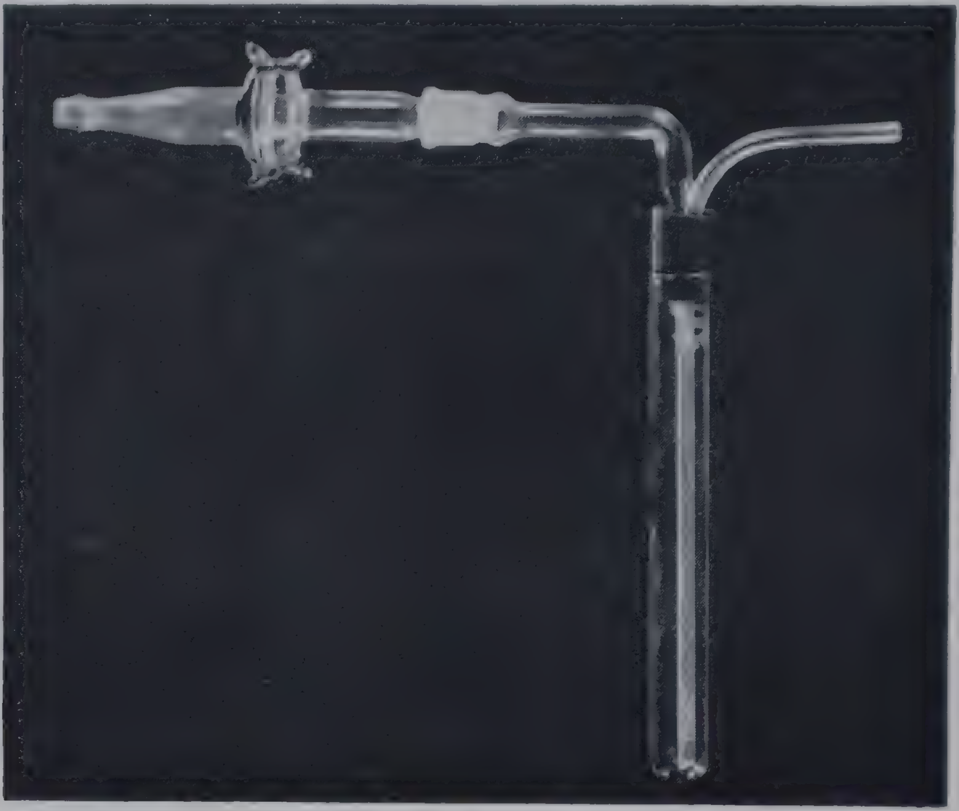

Fig. 717.—Apparatus for the Gettler-Goldbaum spot-test for cyanide.

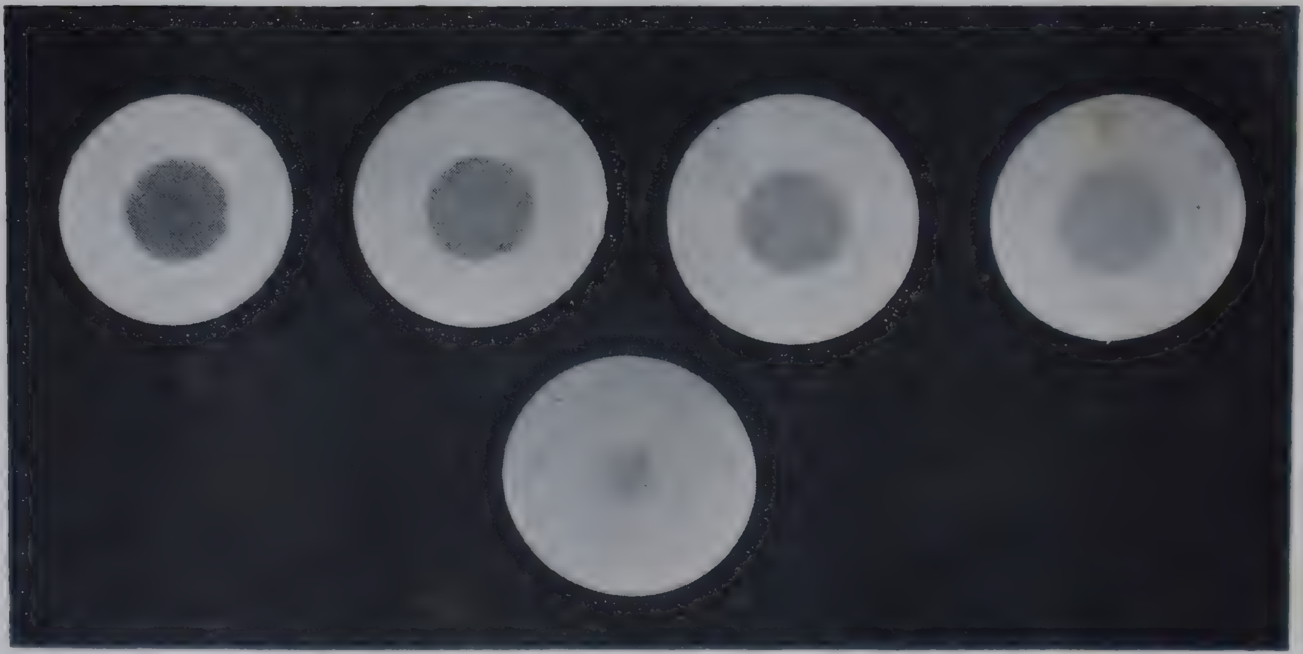

Fig. 718.—Gettler-Goldbaum cyanide spot-test. Standards containing 5, 4, 3, 2, and 1 microgram of cyanide.

Technic.—

Transfer 1 c.c. of blood or 1 gm. of tissue to a 20 c.c. test tube.

Assemble the apparatus as shown in Fig. 717 with the moistened paper disk in place.

Place the test tube in a boiling water bath and apply suction gently while running 2 c.c. of 20% trichloroacetic acid through the inlet tube into the test tube. The trichloroacetic acid helps prevent foaming by precipitating the proteins. It also helps liberate hydrogen cyanide.

Now apply suction at full force.

If water droplets condense around the joint of the apparatus, turn the suction down to keep the water from wetting the paper.

Stop the suction at the end of 5 minutes.

Remove the paper and dip it into a small beaker containing warm 1:4 hydrochloric acid. An insoluble precipitate of Prussian blue develops in the center of the paper and soluble iron salts are formed if cyanide is present. The iron salts may be removed by washing the paper with water. This leaves the insoluble Prussian blue impregnated filter paper.

To make a quantitative determination, compare the blue color with spots prepared from cyanide solutions of known concentrations treated in a similar manner. See Fig. 718.

With the 8 mm. flange, concentrations of cyanide as low as 1 microgram can be detected. Quantities of 1 to 5 micrograms can be estimated within 0.5 microgram by comparison with a series of standards containing, respectively, 1,2,3,4, and 5 micrograms of cyanide.

Sensitivity may be increased to detect concentrations of 0.2 microgram of cyanide by using 4 mm. flanges.

The Spectroscope

Spectroscopic Tests for Carbon Monoxide and Other Substances.—

The discovery of Hoppe-Seyler in 1862 of the spectrum of oxyhemoglobin led to the introduction of the spectroscope into forensic medical practice. Later the spectrum of carbon monoxide hemoglobin was worked out and its irreducible character demonstrated so satisfactorily that no examination for this substance is complete without a spectroscopic control. (See pages 2352 ff. for detailed examination for carbon monoxide.)

A prism is a triangular piece of transparent glass. When light is projected on a prism, two results are brought about.

1. The rays of light are divided from the plane and an **angle of deviation** is formed.

2. The rays of light are divided into their component parts, giving a **band of colors** ranging from red to violet. This phenomenon is called **dispersion.** When this band of colors is focused upon a screen, a **spectrum** is formed.

The **spectroscope** is an instrument used to view the spectrum. There are two general types of spectroscope; namely, the direct vision, and the single prism.

Description of the Instrument

The **Direct Vision** spectroscope consists of a cylindrical tube provided with an ocular, and containing a prism, a draw tube with adjustable slit, and a telescope or collimator tube with a convex lens to render the rays parallel. At the end of the collimator is a slit. When a beam of light enters through the slit, it is dispersed and a band of colors can be seen through the instrument.

The **Simple Prism** spectroscope consists of a prism and two telescopes directed toward the prism. The light is allowed to enter one tube, or telescope, called a collimator, through a narrow slit at its distal end, while at the other end a convex lens serves to collect the light into nearly parallel beams. These rays pass through the prism where dispersion and deviation are brought about. The spectrum is observed through a second telescope.

The second telescope is equipped with a simple microscopic device. There is in the instrument a third telescope equipped with a scale for measurements of light at different points on the spectrum. The measurements are in microns. The prism is located in the instrument in such manner that it will rotate at different points on the scale. The scale is photographed above the spectrum, the divisions being placed so that the measurement of bands of light can be recorded. A direct reading of bright line spectra or absorption bands can be made. (See below.)

A luminous Bunsen flame, or an electric light serves as the source of illumination.

Principle

When a luminous flame of a candle, oil, or gas is examined spectroscopically, it shows **a continuous spectrum**; that is, this white light has been decomposed into its component parts.

If a metal or its salt is burned on a nonluminous flame, the spectrum is not continuous, but, instead, bright lines, close together, will appear at different colors of the spectrum. These lines are called **bright line spectra**. For example, if a platinum wire is dipped into sodium chloride, and placed in a flame, and this light allowed to shine through the spectroscope, two bright lines very close together in the yellow portion of the spectrum are seen. Since this spectrum is specific, sodium can be identified by it. The other colors are very dim. All other metals and their salts, such as, potassium, lithium, calcium, strontium, can be identified by spectroscopic examination. These spectra can be seen only when the substance is heated to a point where volatilization takes place, because gases alone show the property of giving **discontinuous**, or **bright line**, spectra. **No two gases give the same spectra**. In setting up the instrument, the scale is put in position by means of the spectra from sodium and strontium. Luminous flames give a continuous spectrum because the luminosity is due to light emitted by particles of **solid** carbon floating in the burning gas.

If it can be so arranged that a continuous spectrum is produced from a strongly luminous flame, and a gaseous compound placed between the light and the slit in the spectroscope, there is no longer a continuous spectrum. A **black line** intercepts it. When portions of light are absorbed by vapors, in the manner just described, the spectrum is **an absorption spectrum**. When light passes through solutions of blood, light absorption spectra are produced.

In studying different solutions of blood, the specimen is diluted so that the density is not very great. A portion of diluted specimen is placed in a glass absorption cell which has a width of about 2 to 3 mm. The cell containing the specimen is held in place in front of the source of light. The source of light is a very strong electric light. There will be formed different absorption bands (dark bands) for different substances in the blood specimen; such as, hemoglobin, oxyhemoglobin, methemoglobin, carbon monoxide, cyanide, etc.

Examples

Bright Line Spectra

Sodium	0.5896 and 0.5893.
Potassium	0.7699 and 0.7666.
Lithium	0.6708
Hydrogen	0.6563 and 0.4867 and 0.4308
Thallium	0.5351
Magnesium	0.5184 and 0.5173
Strontium	0.4608

Absorption Spectra

Hemoglobin	0.5896 to 0.5305 and 0.8100 to 0.76 and 0.451 to 0.456.
Oxyhemoglobin (very weak dilution)	0.84 to 0.815 and 0.583 to 0.575 and 0.5525 to 0.53 and 0.4225 to 0.4215.
Methemoglobin	0.72 to 0.70 and 0.641 to 0.635 and 0.62 to 0.6125 and 0.595 to 0.5875.
Carbon Monoxide Hemoglobin	0.72 to 0.6975 and 0.5825 to 0.5625 and 0.549 to 0.5289 and 0.4425 to 0.4375.
Acid Hematin	0.7125 to 0.70 and 0.6525 to 0.62 and 0.56 to 0.5267.

Acid Hematin in alcoholic solution,	0.7175 to 0.70 and 0.6533 to 0.62 and 0.588 to 0.58 and 0.555 to 0.5267 and 0.51 to 0.496 and 0.46 to 0.4533.
Acid Hematoporphyrin	0.7175 to 0.73 and 0.61 to 0.586 and 0.562 to 0.5575 and 0.54 to 0.536 and 0.4575 to 0.45.
Alkaline Hematoporphyrin	0.722 to 0.7067 and 0.6345 to 0.61 and 0.572 to 0.56 and 0.542 to 0.53 and 0.515 to 0.51 and 0.4925 to 0.4875 and 0.449 to 0.445.
Hemachromogen	0.825 to 0.80 and 0.57 to 0.5633 and 0.555 to 0.55 and 0.535 to 0.515 and 0.469 to 0.466.

Cyanide—The blood should be diluted 1:100. Normal blood is also diluted 1:100. To both specimens, add some neutral hydrogen peroxide, taking care to avoid an excess. The normal blood retains its red color and its oxyhemoglobin absorption bands. The cyanide blood changes in color from red to brownish red, brown, yellow, and finally white. Spectroscopically, during these color changes, the absorption bands of the oxyhemoglobin are changed into those of methemoglobin, and these finally disappear, leaving no absorption bands at all.

GROUP VI. MISCELLANEOUS METHODS

FLUORIDES

Fluoride compounds have been used in various insecticides. Fluoride poisoning is not too uncommon an occurrence. Symptoms are similar to the general symptoms of acute metallic poisoning—cramps, abdominal pain, purging, etc.

Etch Test

Using sodium hydroxide solution, alkalinize a small aliquot of either tissue or body fluid.

Ash at low heat.

Transfer the ash to a small *lead* dish.

Coat a small glass plate with paraffin. Carefully scratch several small characteristic markings through the paraffin in such manner that the glass surface is exposed through the scratches.

Add several c.c. of concentrated sulphuric acid to the contents of the lead dish in order to liberate hydrofluoric acid.

Quickly place the glass plate, paraffin side down, over the opening of the lead dish so that the entire dish is covered.

Leave the glass plate in this position for 30 to 60 minutes.

If the specimen contains fluorides, the exposed glass will be etched.

When the reaction is complete, remove the slide or glass plate, wash off the paraffin by means of an organic solvent, and observe the exposed areas for etching. They should correspond to the characteristic markings originally scratched through the paraffin.

To increase the sensitivity of this test, use a lead cover with an opening small enough to allow only a small area in the dish to liberate the hydrofluoric acid. Place the slide over this area.

This test is specific for fluorides.

Gettler Test

Alkalinize 1 to 3 c.c. of stomach contents or urine with several drops of sodium hydroxide solution.

Dry at low heat in a small glass container or porcelain crucible.

To the dry residue add a small amount of powdered glass and mix thoroughly.

Acidify the mixture with several c.c. of concentrated sulphuric acid.

Cover immediately with a small glass plate from the under surface of which is hanging a drop of 5 per cent sodium chloride.

Heat the crucible gently. To prevent evaporation of the drop of sodium chloride hanging down from the under surface of the slide, place a small piece of ice, or a small container of ice, on top of the slide.

After 3 to 5 minutes, carefully remove the slide and examine the drop.

If fluorides are present in the specimen, silicon tetrafluoride is formed. This very volatile substance rises and combines with the sodium chloride drop to form typical crystals of sodium fluosilicate.

Examine under the microscope. The crystals are usually found along the rim of the drop. They are very small, approximately one-twentieth the size of the larger square-shaped sodium chloride crystals. Sodium fluosilicate crystals are small, hexagonal, and under subdued light have a light pink hue. The test is sensitive to approximately 20 gammas of fluoride.

DETERMINATION OF DEATH BY DROWNING

The expert must often determine whether a person whose body is found in water met death by drowning or by some other cause. There are a number of tests described but none at present has any specific or reliable value. The surface signs of drowning have been suggested as means of proving this question.

1. Excessive coldness of corpse (of no value).
2. Extreme whiteness (of no value).
3. When the body is brought into contact with the air, it changes from brown to dark green more quickly on the breast than on the abdomen. The reverse occurs in all nondrowning cases (this sign is of no value).
4. Wrinkling of the skin (of no value because this may happen to a body thrown into the water after death).
5. Goose skin (this is not specific, because it is found in other conditions; it may also form after death).
6. Contraction of penis, scrotum, and breast (these may contract if the body is thrown into the water after death).
7. Foam in mouth and nose (this is found very often, although it is not a constant sign; it may, however, occur from other causes, as in pulmonary edema).
8. Ecchymoses in the conjunctivae and in the skin of the face (a rare finding).

The following interior signs have been suggested:

1. Dark and fluid blood (this is found in many other conditions).
2. Dilated thorax and distended abdomen (of no value).
3. Epiglottis relaxed (this is found in many other conditions).
4. Bladder empty (of no value).
5. Congestion of all organs (of no value; characteristic of all forms of asphyxia).
6. Excessive oozing of blood when skull cap is removed (of little value; characteristic of asphyxia in general).
7. Drowning fluid in stomach (Liman proved that water can get into the stomach after death, but in a small amount).
8. Large, pale red ecchymoses on surface of lungs (this is not a constant finding).
9. Drowning fluid in duodenum, jejunum, and even in the ileum (Kolisko). This finding is more specific than water in the stomach. There are numerous drowning cases, however, in which the water does not get into these parts of the alimentary tract. The presence of fluid in the ileum is typical of drowning because it cannot get there after death except by enormous pressure. However, it must not be overlooked that the absence of drowning fluid in the ileum does not mean that the case is not one of drowning, because in many cases the water does not reach the ileum.
10. The presence of fluid in the middle ear is significant only if the ear drum is intact; it has, however, been proved that this may happen after death.

11. Drowning fluid and foam in the trachea and lungs.[1] The fluid does not seem to get into the lungs until the third stage; then it goes to the bronchi and alveoli. The amount depends on the length of the terminal inspirations (there are exceptional cases in which there is no third stage). It is important in this connection to bear in mind the presence of foamy fluid in the lungs in cases of pulmonary edema.

12. Balloon-like lungs, increased in volume (this is not a constant finding).

13. Pieces of lungs sinking when thrown into water (of no value).

14. Inflation of lungs with colored liquids or gases to determine whether they will penetrate throughout (nondrowned lungs) or only partially (drowned lungs). This contention has been proved erroneous.

15. The presence of foreign bodies (present in the water) in the alveoli (Lesser). This is not a constant finding in drowning cases.

As Gettler[2] well states: "Most conditions named above are misleading and useless." The following three conditions will aid in deciding the cause of death; namely, (1) foamy fluid in the trachea, bronchioles, and lung cells; (2) microscopic finding of foreign bodies (from the water) in the bronchioles and alveoli; and (3) water in the stomach, duodenum, jejunum, and ileum.

Gettler and others turned their attention to chemical and physical methods for proving the question. They based their investigations on the well-known physiologic fact that blood from the lungs passes to the left heart and then through the organism, whereupon it goes to the right heart, and then back to the lungs. Water entering the lungs will quickly reach the left heart and dilute the blood therein, while the blood of the right heart remains relatively undiluted. Wachholz has proved experimentally, both in man and in animals, that no water can get into the left heart if the individual is thrown into the water after death. A number of methods have been suggested, but none has been so well proved as that reported by Gettler. He suggests the determination of the chloride content of the blood to determine the question at issue, since sea water contains a large amount of chloride and fresh water a negligible amount and that the chlorides of the inorganic constituents of the body are not likely to be affected by postmortem changes. Furthermore, the microchemical methods for chlorides lend themselves admirably to this work.

Chloride Test of Blood to Establish Drowning As Cause of Death

The method in detail advocated and used by Gettler very successfully as Pathologic Chemist for the Chief Medical Examiner of New York is as follows:

The pathologist should be supplied with two clean, dry glass bottles of about 30 c.c. capacity, labeled, respectively, right and left (no anticoagulant is used); two clean, dry 25 c.c. pipettes from which the tips have been broken off and the ragged edges rounded in a flame (the object of this is to have a large opening so that there is less chance of a small clot obstructing the opening); also a rubber tubing with glass mouthpiece for attaching to pipettes when drawing up the blood. The heart, while still in place in the cadaver, is wiped dry with a clean towel, and a small slit is made with a clean, dry knife in the right ventricle. The pipette with rubber attachment is then inserted into the heart, through the incision, and careful suction is applied. If the blood does not enter the pipette readily, the latter is carefully moved into different positions within the heart chamber until the end of the pipette rests within the blood. When from 5 to 10 c.c. of blood are in the pipette and while suction is still being applied, the rubber tubing attached to it is pinched tightly to prevent the blood from returning to the heart. The pipette is then drawn from the heart, and the contents are emptied into the vessel marked "right." This vessel should be stoppered, labeled, and sealed. With another dry knife, the left chamber of the heart is opened and the contents are put into the bottle marked "left," exactly the same technic being used.

---

[1] The time interval between submersion and death in cases of drowning may be divided into three stages: First, the period in which respiration is held back. This lasts only a few seconds and is instinctive; it may be reflex and may result in prolonged respiratory suspension. Second, the stage of dyspnea, which consists in short but deep inspiration, quickly followed by expiration. This is followed by convulsive expiration. Third, the stage of asphyxiation. Here we have unconsciousness and lost reflexes and deep inhalation at long intervals.

[2] J. A. M. A. 77: 1650, 1921.

The Analysis in Detail.—

Pipette carefully 3 c.c. of the blood into a clean, dry Erlenmeyer flask; if the blood is badly clotted, accurately weigh 3 gm. Add 27 c.c. of distilled water and 30 c.c. of saturated picric acid. Mix well and let stand ten minutes; then filter through dry filter paper. Pipette accurately 40 c.c. of this filtrate into another dry Erlenmeyer flask and add 10 c.c. of M/29.25 silver nitrate solution. Mix thoroughly and allow to stand, preferably overnight. Then filter and pipette 20 c.c. of this filtrate into a clean casserole. Add 4 c.c. of the starch-citrate mixture and titrate with the standard M/117 potassium iodide solution. (Austin and Van Slyke.)

Calculation.—

$$125 \times \left(8 - \frac{\text{c.c. KI used}}{2}\right) = \text{mg. sodium chloride in 100 c.c.}$$

The **silver nitrate solution** contains, per liter, 5.812 gm. of $AgNO_3$ + 250 c.c. of concentrated nitric acid.

The **starch-citrate** solution is made as follows: Dissolve 2.5 gm. of soluble starch in 500 c.c. of warm water; then add 446 gm. of sodium citrate and 20 gm. of sodium nitrite and heat until all are dissolved. Filter while still hot through cotton; allow to cool and make up to 1 liter.

The **M/117 potassium iodide solution** contains 1.419 gm. in 1 liter.

Alternate Method

For precipitating the protein and formed elements, tungstic acid is used, and the technic of Folin and Wu is followed. This method is as accurate as the picric acid method:

Pipette 5 c.c. of blood into a dry Erlenmeyer flask; add 35 c.c. of water; mix thoroughly. Then add 5 c.c. of 10% sodium tungstate, mix well, and add 5 c.c. of $\frac{2}{3}$ normal sulphuric acid. Stopper with a well-fitting rubber stopper and shake vigorously for five minutes. Filter through dry paper into a dry beaker. Pipette 20 c.c. of the filtrate into another clean, dry beaker, add 10 c.c. of M/29.25 silver nitrate solution, mix well, and let stand, preferably overnight. Then filter through dry paper and pipette 15 c.c. of this filtrate into a casserole. Add 4 c.c. of the starch-citrate mixture, and titrate with M/117 potassium iodide solution.

Calculation.—

$$100 \left(10 - \frac{\text{c.c. KI used}}{2}\right) = \text{mg. sodium chloride in 100 c.c.}$$

The chloride content in the blood of the right and left chambers is the same in the various pathologic conditions so far examined, the greatest difference being 5 mg. in 100 c.c. of blood. In some cases the left is higher and in others the right; but the difference is never greater than 5 mg. In all those cases in which the drowning occurred in salt water, the chloride content is higher in the left heart chamber; the difference between the chloride content in the left and right heart chambers was marked by Gettler as plus. In those cases in which drowning occurred in fresh water, the left heart chamber always showed the lower chloride content and the difference is marked minus in his table.

Some cases have as high a difference as 294 mg., while others have only from 25 to 50 mg., depending on the amount of water going into the lungs and also on the time interval between the entrance of water into the lungs and death. The longer this time interval, the more water passes to the left heart chamber. Whenever the chloride content in the two chambers is so close as to give a difference of only 25 mg., it is advisable to repeat carefully the determination. If the same results are obtained a second time, one can safely assume that the case is one of drowning. It must be borne in mind, however, that it is possible in an exceptional case, for a person to die through shock as soon as he hits the water, or he may die in the first of the three drowning stages. If this is the case, then the chloride content is not altered.

DETECTION OF SILICON IN LUNGS

Of increasing importance is pneumonoconiosis, which is a disease due to breathing air containing silica (silicon dioxide). This disease, also called ''silicosis,'' shows anatomically generalized fibrotic changes and miliary nodulation in both lungs.

Crystalline and amorphous silicon compounds, comprising rock crystal, quartz, quartzite, flint, and sandstone, are the chief producers of silicosis. Lemon and Higgins[1] emphasize the point that more than 10 million particles of silica per cubic foot of air and a size of less than 10 microns are essential to any appreciable silicosis hazard. As high as 92 million particles have been determined. It has been shown that following inhalation the particles are engulfed by macrophages or ''dust cells'' which enter and block the lymph spaces. Mavrogordato believes that silica kills the dust cells and dissolves in the alkaline tissue juices forming a poisonous hydrosol jell ($Si(OH)_4$). The sharp edges of the silica particles are of very little importance in producing the changes in the lungs.

In the final analysis of proof that a given case is or is not silicosis at the autopsy table, resort must be made to a chemical analysis of the lungs for silica. According to McNally,[2] silica is a normal constituent of the human body but any lung containing more than 2 mg. of silicon dioxide per gm. has had undue exposure to a dusty atmosphere. In an investigation of a number of cases he found an average of 1.13 mg. of silica per gram of dry lung in non-silicotic persons. He found from 2.4 to 26.0 mg. of silicon dioxide per gram of dried lung in workers in various dusty trades. Stone and granite cutters showed the higher amounts. Church found the ash of potters' lungs to contain 47.78 per cent silica. Gardner[3] found almost universal microscopic but no gross evidence of silicosis in a study of 15 tunnel rock drillers and sand blasters and pulverizers, 12 of whom died of pulmonary infections within nine to eighteen months after short exposures. Sixty-one per cent of the bronchial lymph nodes were silicotic. The nodules varied from 0.3 to 0.4 mm. in diameter as compared with 3.0 to 4.0 mm. sizes found in hard rock miners and lead miners with many years' exposure. A maximum of 3.1 per cent silica content in the lungs was found.

Test for Silicon in Lungs, McNally Method[2]

Weigh and dry fresh material, pulverize, and determine a second moisture content on 20 gm. of the ground sample. Ash, weigh, and digest the sample with hydrochloric acid, evaporate to dryness, and repeat the process. Take up the residue with hydrochloric acid and water, filter, and incinerate the insoluble residue in a platinum dish.

This is recorded as the hydrochloric acid insoluble.

This ash is nearly always white. Residue is treated with hydrofluoric acid.

The loss of weight is recorded as silicon dioxide.

In the majority of instances, a faint to a weighable residue of iron-stained material is likely to be noticed. This is dissolved in hydrochloric acid and added to the original filtrate.

The percentage of moisture in the lung, the percentage of ash, and hydrochloric acid insoluble of ash are found in Table 233, below, from McNally's article.

TABLE 233.—PERCENTAGE OF MOISTURE IN THE LUNG, PERCENTAGE OF ASH, AND HYDROCHLORIC ACID INSOLUBLE OF ASH

Case	Moisture, Per Cent	Ash, Per Cent	Weight of Lung, Gm.	Mg. of SiO_2 per Gram of Dried Tissue
312	85.72	5.61	600.5	0.92
311	89.15	6.71	729.5	1.86
317	3.96*	4.51	----	1.22
325	86.28	5.61	306	1.06
324	89.55	7.19	785	0.90
323	77.15	4.66	652	0.85
333	88.04	6.23	518	1.10
332	83.34	5.35	893.2	3.28
39	88.42	5.67	402	2.21
41	73.96	3.75	619	1.65
35	85.31	---	388	1.40
42	84.21	6.58	602	1.50
34	89.13	5.52	561	4.60
350	89.98	5.14	707	0.92
352	86.20	7.51	708	2.40
349	82.57	3.82	1,048	0.73
267	86.08	8.13	468	7.06
359	81.99	5.24	543	0.79
356	87.18	5.39	397	1.41
357	89.37	5.77	416	1.25
360	89.87	5.98	304	2.66
358	81.82	3.66	122	0.13
368	85.84	3.36	312.5	1.51
361	84.49	5.97	321	2.37
337	81.79	5.68	756	9.75
389	89.13	6.51	310	0.64
431	90.06	5.15	780	0.71
441	86.03	6.17	378	1.21
455	----	4.76	---	1.80
459	----	4.10	---	0.40

*Moisture on dried sample.

The following example is of a specimen received in our laboratories.

Weight of crucible plus wet sample of lung	43.593 gm.
Weight of crucible empty	17.073 gm.
Weight of wet sample	26.520 gm.

---

[2] J. A. M. A. **101**: 584, 1933.

Sample was then dried.

Weight of dried sample plus crucible	23.593 gm.
Weight of crucible empty	17.073 gm.
Weight of dried sample	6.520 gm.

Sample was then pulverized, dried and reweighed.

Weight of pulverized sample plus crucible	23.526 gm.
Weight of crucible empty	17.073 gm.
Weight of pulverized dried sample	6.453 gm.

Sample was then ashed.

Weight of crucible plus ash	17.379 gm.
Weight of crucible empty	17.073 gm.
Weight of ash	0.306 gm.

Ash treated with hydrochloric acid, filtered, and ashed on filter paper.

Weight of insoluble residue plus paper ash plus crucible	17.156 gm.
Weight of paper ash	0.002 gm.
Weight of residue plus crucible	17.154 gm.

Weight of crucible plus residue	17.154 gm.
Weight of crucible empty	17.073 gm.
Weight of hydrochloric insoluble	0.081 gm.

Residue treated with hydrofluoric acid, diluted with water, filtered, and ashed.

Weight of residue plus paper ash plus crucible	17.078 gm.
Weight of paper ash	0.002 gm.
Weight of residue plus crucible	17.076 gm.

Weight of crucible plus residue	17.076 gm.
Weight of crucible empty	17.073 gm.
Weight of residue	0.003 gm.

Weight of insoluble hydrochloric acid residue	0.081 gm.
Weight of hydrofluoric acid residue	0.003 gm.
Weight of SIO_2	0.078 gm.

Calculations and Results.—

26.520	gm.—weight of lung
6.453	gm.—weight of dried lung
20.067	gm.—loss of water.

$\frac{20.067}{26.520} = 75.66\%$ of water.

Weight of dried tissue	6.453 gm.
Weight of ash	0.326 gm.

$\frac{0.326}{6.453} = 5.05\%$ ash in dried lung tissue.

$\frac{0.078}{6.453} = 0.0121$ gm. of silicon dioxide per gram of dried lung tissue

or

12.1 mg. of silicon dioxide per gram of dried lung tissue.

Spectrographic Test for Silicon

Once more may we suggest the superiority of spectrographic determination of silicon over previously described chemical methods. They are simple and exact.

DICHLORO-DIPHENYL-TRICHLORETHANE (DDT)

Smith and Stohlman[1] reported a method of testing for dichloro-diphenyl-trichloroethane (DDT) which may be applied in cases of possible poisoning with DDT. The method is applicable to the original powder and to blood, urine, feces, and tissue.

Extract a definite weight of DDT powder with several portions of acetone.

Collect the extracts and evaporate to dryness on a water bath.

Dissolve the residue in 10 c.c. of absolute alcohol and transfer quantitatively to a reflux condenser.

Add 1 gram of metallic sodium, cut into small bits.

Reflux for one-half hour.

Transfer the contents of the flask quantitatively with the aid of distilled water to an Erlenmeyer flask.

Acidify with 3 c.c. of concentrated nitric acid.

Decolorize with 1 gram of chlorine-free Nuchar (charcoal).

Filter.

Titrate the filtrate for chlorides using either the Volhard-Arnold or the Schales method (pages 433 and 435).

Calculations.—

Calculate the chlorine (*not* the sodium chloride). Multiply the result by 2 to convert to DDT, since 50% of the weight of DDT is Cl.

Example.—

The specimen contained 6 mg. of chlorine by this test.

2 × 6 = 12 mg. of DDT present.

DDT in Body Tissues or Fluids

Extract body tissues or fluids by means of steam distillation (page 2243).

Treat the residual mash for purification in the same manner as for the barbiturate group (page 2285), substituting for the acid-ether extraction an extraction with several portions of acid-petroleum ether (benzine).

Evaporate the combined petroleum ether extracts.

Pick up the residue with acetone.

Proceed as for testing for DDT above.

The general opinion regarding toxicity of DDT is that from 150 to 200 mg. of DDT per kilogram body weight is toxic for man. The few cases of fatal poisoning due to DDT which have been reported in the literature were all due to accidental ingestion or inhalation of the substance. These accidents occurred during the process of applying DDT in an effort to exterminate insects.

BENZEDRINE

Since benzedrine does not undergo deamination in the human body, a direct determination may be made in body fluids. Benzedrine is chemically akin to ephedrine and adrenaline.

In Urine and Viscera

Acidify the urine or an extract of the viscera with tartaric acid.

Carry out steam distillation as described on page 2243.

---

[1] Pub. Health Rep. 59: 984, 1944.

Collect the distillate into 10 c.c. of N/1 hydrochloric acid.

Distill for approximately 1 hour.

Add sodium hydroxide solution to the benzedrine-hydrochloric acid mixture until it is alkaline.

Extract with several small portions of ether.

Collect the extracts, and add to the combined extracts a few drops of concentrated hydrochloric acid and 5 c.c. of alcohol.

Evaporate to dryness on a steam bath. Carry out the tests below.

In Benzedrine Tablets

Crush the tablet. Mix with it a little solid barium chloride and 1 c.c. of N/1 hydrochloric acid.

Add 25 c.c. of absolute alcohol.

Heat on a water bath for several minutes.

Filter.

Wash the residue with absolute alcohol, and save the alcohol extracts.

To the combined alcohol extracts add 1 c.c. of N/1 hydrochloric acid.

Evaporate with gentle heat to almost dryness on a steam bath.

Dissolve the residue with a small quantity of N/1 hydrochloric acid.

Filter and transfer quantitatively into a separatory funnel.

Make the filtrate slightly alkaline with 10% sodium hydroxide solution.

Extract with chloroform.

Separate off the chloroform layer and add a few drops of N/1 hydrochloric acid, then evaporate the chloroform extracts to dryness. Carry out the tests below.

Tests for Benzedrine

Benzedrine and Pervitin (n-methyl benzedrine) give the general reactions for alkaloids.

Dissolve the residue (above) in 20 drops of water. Place 2 drops of the solution on each of several slides. Carry out tests on known benzedrine samples simultaneously.

(A) Add 1 drop of 5 per cent chloroplatinic acid solution. Typical pale yellow crystals will form if benzedrine is present. Examine under the microscope. Compare with control crystals.

(B) Add 1 drop of Marquis reagent to the drops on the slide. If benzedrine is present a brick red precipitate will form, which persists approximately only 30 seconds. A dirty brown colored precipitate forms and persists approximately 1 hour. A dirty olive green precipitate forms.

(C) Benzedrine gives the usual precipitation reactions with Mayer and Dragendorff reagents below.

Marquis Reagent.—

Several drops of formaldehyde in 5 c.c. of concentrated sulphuric acid.

Mayer Reagent for Alkaloids.—

Dissolve 13.55 gm. mercuric chloride
and 50 gm. potassium iodide in distilled water and dilute to 1000 c.c. with distilled water.

A white precipitate forms with most alkaloids in acid solution.

Dragendorff Reagent for Alkaloids.—

Dissolve 8 gm. of bismuth subnitrate in 20 c.c. of nitric acid.

Add the solution gradually to a concentrated solution of 22.7 grams of potassium iodide in a small amount of water.

Cool. Decant the fluid from the potassium nitrate crystals and dilute to 100 c.c. with distilled water.

Most alkalies give a reddish flocculent precipitate with this reagent.

Morgan[1] stated that benzedrine can be detected in urine for three to four days after a fairly large injection of the substance. It is eliminated slowly in the urine; thus the unit concentration may be low. Approximately 50 per cent is eliminated in the first 48 hours. Highest recoveries may be obtained within the first one to eight hours after injection.

CHAPTER XVI

BASAL METABOLISM

The terms "Basal Metabolism" and "Basal Metabolic Rate" mean the heat production of an organism measured from twelve to eighteen hours after the ingestion of food with the organism at complete muscular rest. This may be determined directly by actual measurement by means of the calorimeter or indirectly by calculating heat production from an analysis of the end products which result from oxidation within the organism, or from the amount of oxygen used.

There are certain well-known facts about metabolism which must be considered. We know that food is taken into the gastrointestinal canal, there prepared for absorption, thence carried to the tissues either to be directly consumed or else to be stored away. Waste products are formed and excreted from the body. By comparison of the products excreted with those taken in as food, we know how much is retained or lost. This constitutes general metabolism. Special metabolism entails the study of the chemical changes which each of the foodstuffs undergoes in passing through the phases of absorption and excretion.

The methods of determination of basal metabolism are: first, gas analysis; second, the estimation of oxygen used and carbon dioxide eliminated; and third, the estimation of the amount of oxygen used, at a given time, or the length of time necessary to use a given amount of oxygen.

General Instructions for Basal Metabolism Patients

The patient is instructed to eat a light dinner, to have a good night's rest, and to report to the laboratory in the morning without breakfast. If the patient is in the hospital, either the apparatus is taken to the bedside, or the patient is wheeled into the basal metabolism room. Undue exercise is avoided.

If the patient reports to the laboratory for the test, he is allowed to rest for thirty minutes to one hour. During this time, he is not to be disturbed by conversation or loud noises. The room in which the patient is resting should be away from those parts of the building in which any disturbances or noises may occur.

The basal metabolism apparatus is prepared away from the patient and taken to the side of the bed after preparation. Do not set up the machine before the patient.

The patient should be told something about what is expected of him before beginning the test. It is necessary only to explain to him that he is to breathe naturally into the apparatus, and that the technician is simply going to measure the quantity of oxygen that he is consuming. Frequently it is necessary to make one or two preliminary tests to acquaint the patient with the apparatus.

The mouthpieces and the nose clamp should be washed with hot water and soap, thoroughly rinsed, and disinfected before beginning the test. Place them in alcohol for fifteen minutes before using. Rinse many times with tap water before using on the patient.

The soda lime (4-8 ''Wilson'' soda lime, if the Collins machine is used, or Baralyme for the Sanborn Metabulator) in the apparatus should be changed from time to time, and should never be used up to the point of becoming wet. About 50 tests can be made without changing the lime.

An extra tank of oxygen should be kept on hand. Be sure to read both the outside and inside labels of the tank to make certain that you are using an oxygen tank. Other gases, such as nitrous oxide, have been sent to laboratories by mistake with serious consequences.

Basal Metabolism

Basal metabolism determinations are very important in a wide range of diseases. The basal metabolic rate is, of course, most important in diseases of the thyroid gland. Extremely high rates are seen in cases of toxic goiter, both in adenomata with hyperthyroidism and exophthalmic goiter. The more severe the thyrotoxicosis, the greater the rate will be. It is generally accepted that a basal metabolic rate of over +40 is sufficient grounds for postponing operation until this rate has been materially reduced.

The highest rates are seen in cases of exophthalmic goiter. In certain cases of thyrotoxicosis of a borderline type, it is necessary to conduct a therapeutic test on iodides in order to establish the diagnosis. We make two or three determinations of basal metabolic rate before any iodide is administered. If any degree of thyrotoxicosis is present, subsequent tests done after five to ten days with patient on iodides will show lowering of basal metabolic rate of 15% or more.

In cases of nontoxic goiter, it is necessary to control these cases by basal metabolic rate determinations so as to know when the transition takes place from nontoxic to toxic goiter. In cases of nontoxic goiter due to adenomata without any symptoms of hyperthyroidism, if the basal metabolic rate is 10 to 20 per cent above normal, hyperthyroidism should be suspected. This enables us to control the case long before the heart and the nervous system become damaged. In cases of nontoxic colloid goiter, the basal metabolic rate is usually within normal limits. In myxedema, where there is a partial or complete atrophy of the thyroid gland, the basal metabolic rate is between –35 and –45. In cases of cretinism, the basal metabolic rate is low.

The basal metabolic rate is useful in differentiating cardiorenal disease from myxedema with which it is often confused. In myxedema the rate is always below –20, whereas nephritis does not cause these low rates.

Dyspnea causes an increase of the metabolic rate; when edema exists with cardiorenal disease, the basal metabolic rate falls after the initial rise caused by the dyspnea itself.

There are a number of cases in which the basal metabolic rate serves to establish the case as a thyrotoxic one rather than primarily a cardiac case.

Toxic goiter causes many forms of irregularities of the heartbeat, especially auricular fibrillation. In these cases the basal metabolic rate will furnish the necessary evidence by showing a plus rate. In the so-called "effort syndrome" the basal metabolic rate is usually normal. However, a primary test on such a case may show a rate of +10 to +25 because of the extreme nervousness of the patient, but subsequent tests will show the rate to approach normal limits.

Dysfunction of all the endocrine glands affects the basal metabolic rate. In anterior lobe pituitary disease, resulting in acromegaly or gigantism, the basal metabolic rate is slightly increased in the early stages of the disease. In disease of the posterior lobe, the basal metabolic rate is either normal or slightly increased. In lesions of the pituitary alone, or in combination with lesions in the sella turcica, causing Fröhlich's syndrome, the basal metabolic rate is usually decreased.

In atrophy of the adrenal glands, seen in Addison's disease, the basal metabolic rate is low.

In gonadic disturbances where there is loss of the ovarian hormone, due to ovariectomy or to the onset of menopause, there is a low basal metabolic rate.

In certain types of leukemia of myelogenous or splenic origin, the basal metabolic rate is increased. Polycythemia shows an elevated basal metabolic rate. Pregnancy shows a basal metabolic rate as high as +30% after the fifth month.

In certain types of obesity, resulting from disturbance of the endocrine glands, the basal metabolic rate is low. The test serves to distinguish between incipient tuberculosis and certain diseases resembling this condition. In diabetes of a severe type the rate is lower than normal.

In general, it may be stated that fever increases the basal metabolic rate and that if a patient has fever, the normal for that patient should be increased about 7.2 per cent for each degree of fever.

THE COLLINS (BENEDICT-ROTH) APPARATUS

Description of the Apparatus

The apparatus is placed on a table or a stand by the bedside. Adjustment of the mouthpiece to the proper height is obtained by raising or lowering the horizontal support. The metal mouthpiece assembly slides on the horizontal bar, and can be easily removed for sterilization.

The thermometer may be removed when carrying the apparatus. It should be kept in place in the oxygen bell during the test, and the temperature recorded before and after each test.

A high-grade clockworks revolves a drum on which is placed the graph used in recording the test. On the upright arm of the apparatus in front of this drum is a pen. The pen is detachable. After using the pen, it is first washed thoroughly in water, then dried in alcohol and ether. The pen should be kept clean.

There are two rubber breathing tubes below the apparatus. The shorter piece of tubing is connected to the upper metal, and the longer piece to the lower metal connection below the apparatus.

There are two petcocks below the apparatus; one is for oxygen inlet, the other for the removal of the water from the apparatus after use. Each petcock is labeled.

To Use the Apparatus

Remove the oxygen bell. Fill the soda lime container with 4-8 "Wilson" soda lime and screw the container in place. Place the metal top on the can and seal with the wide rubber band supplied.

Fill the outside container with water up to within two inches of the top. This provides a seal against the escape of oxygen from the apparatus.

Fill the apparatus with oxygen.

Place the pen in position and fill with kymograph ink.

Place the kymograph paper around the drum. The bottom of the paper should be about ¼ inch above the bottom of the drum. Before placing the drum in position, be sure that the clock has been wound.

The vertical lines on the kymograph paper are placed at one minute intervals; the horizontal lines indicate mm. for detecting rise in O_2 line.

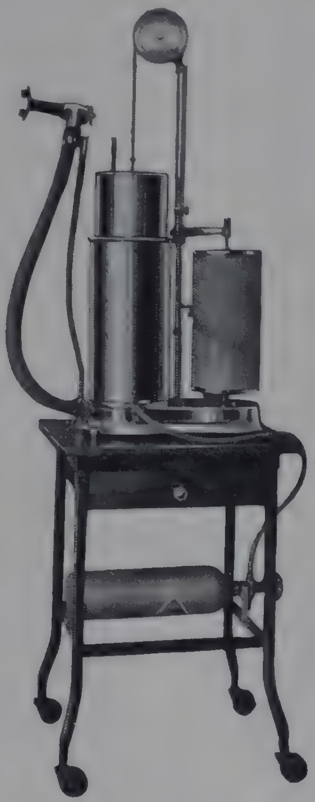

Fig. 719.—Collins (Benedict-Roth) basal metabolism apparatus. (Courtesy Warren E. Collins, Inc., Boston.)

The apparatus should be tested for leakage before attaching to the patient. This is accomplished by placing a few inches of oxygen in the apparatus and closing the mouthpiece with a rubber stopper. Next place a 200-gram weight on the bell. The pointer against the millimeter scale must remain stationary for a minute or more if there is no leak. Remove the oxygen and refill the oxygen bell with fresh oxygen for the test.

Test for obstructions in the breathing apparatus by breathing through the mouthpiece. If there is an obstruction, drain the absorber in the lower breathing tube.

Place the rubber mouthpiece on the apparatus, and instruct the patient how to put it in his mouth. Be sure that no oxygen or carbon dioxide can escape from the mouthpiece.

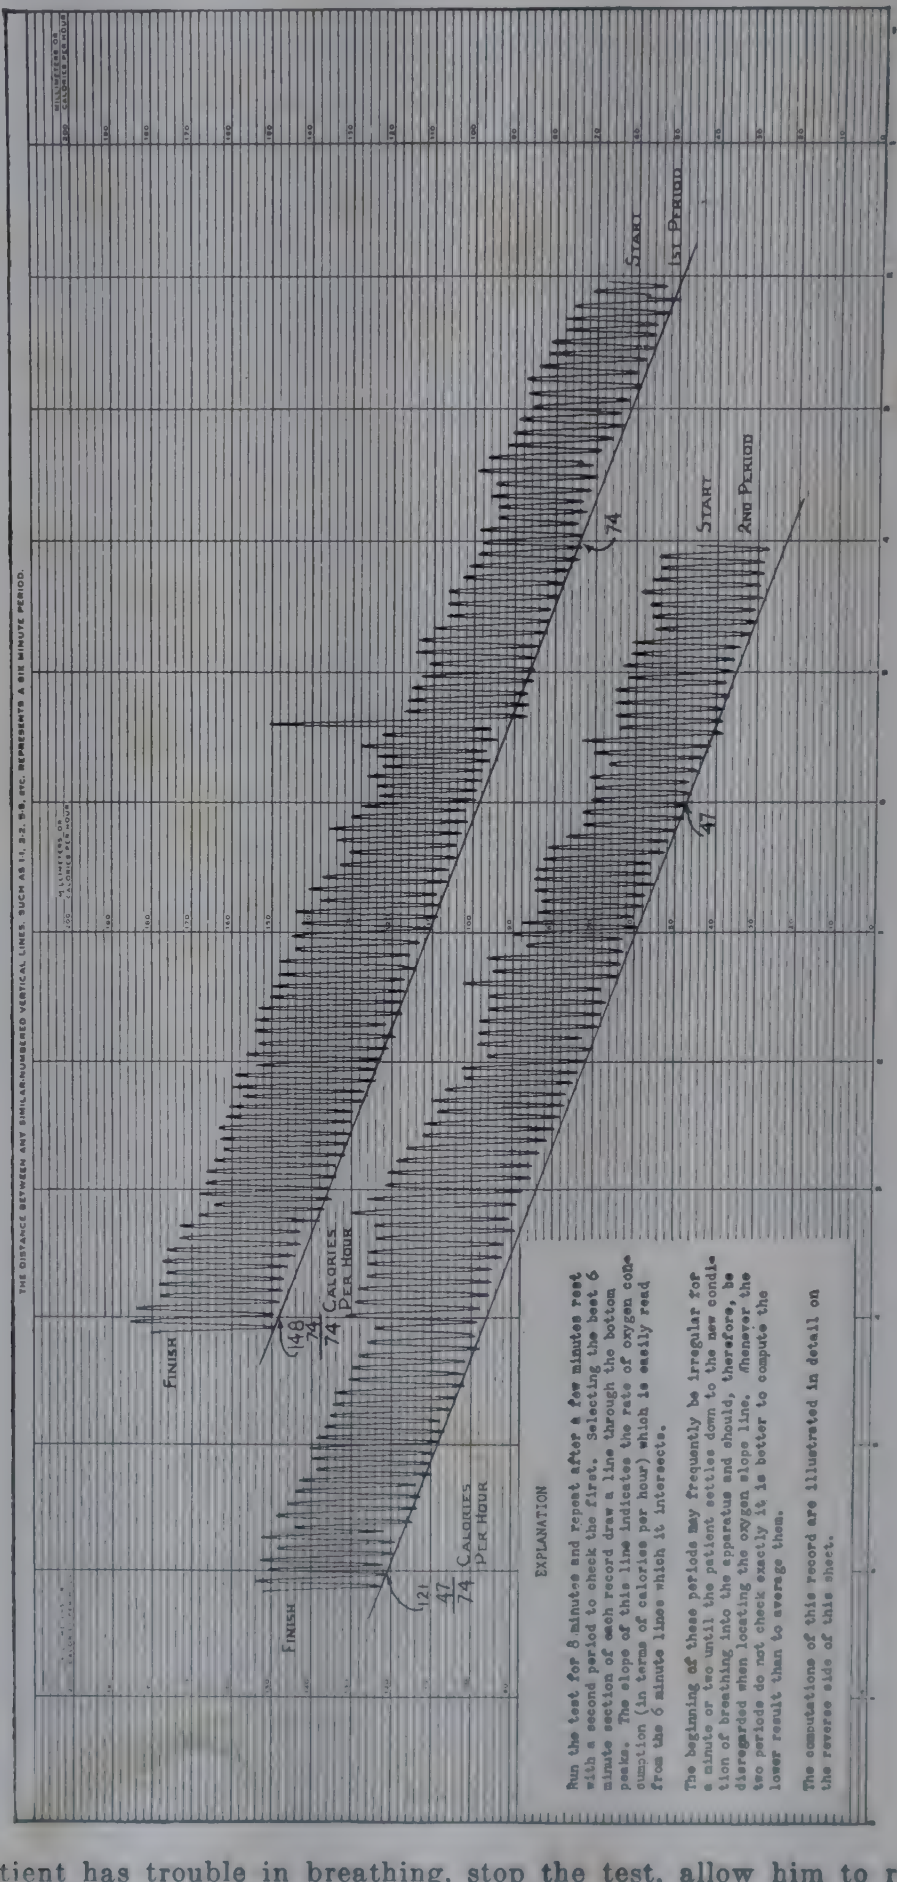
Apply the noseclip, and ask the patient to make a slight effort to breathe through his nose. If he can breathe through his nose, the clamp must be replaced in correct position.

Record the reading of the thermometer in the apparatus.

Swing the kymograph attachment around until the pen touches the paper, and allow the patient to breathe into the apparatus for about eight or ten minutes. The test requires six minutes' breathing, but it is sometimes necessary to make longer tests to accustom the patient to the apparatus.

If there is a leak of oxygen from the oxygen bell or any of the connections, the graph on the kymograph chart will rise very rapidly.

If the patient is breathing outside air, and not the oxygen in the tank, the line made by the pen will be almost horizontal.



Run the test for 8 minutes and repeat after a few minutes rest with a second period to check the first. Selecting the best 6 minute section of each record draw a line through the bottom peaks. The slope of this line indicates the rate of oxygen consumption (in terms of calories per hour) which is easily read from the 6 minute lines which it intersects.

The beginning of these periods may frequently be irregular for a minute or two until the patient settles down to the new condition of breathing into the apparatus and should, therefore, be disregarded when locating the oxygen slope line. Whenever the two periods do not check exactly it is better to compute the lower result than to average them.

The computations of this record are illustrated in detail on the reverse side of this sheet.

Fig. 720.—(Courtesy Warren E. Collins, Inc., Boston.)

If the patient has trouble in breathing, stop the test, allow him to rest, and renew the effort to obtain regular breathing after a few minutes. Occasionally it may be necessary to make many tests before obtaining regular breathing.

TABLE "A"

DUBOIS BODY SURFACE CHART

(As prepared by Boothby and Sandiford of the Mayo Clinic)

DIRECTIONS

With the computation tables on this sheet it is possible to compute the Basal Metabolic Rate of any patient from 5 to 80 years of age according to the DuBois method, as modified by Boothby and Sandiford of the Mayo Clinic.

To determine the NORMAL use Table A and draw a line through the patient's height found in column I and through the weight in column II. Using a straight edge (ruler) draw a line between these two points and read the BODY SURFACE AREA where this line intersects column III. Transfer this body surface figure opposite "Column III" in the space for computations. Then refer to table B and using the patient's age (nearest birthday) and sex read the calories per square meter per hour. Transfer this figure beside "Table B" in space for computations. Multiply III x B which will give the total NORMAL CALORIES PER HOUR—the exact normal for a person of this height, weight, age and sex.

To determine the ACTUAL TEST, transfer the difference in height of the 6 minute test period (from kymograph tracing on the reverse side) to the space provided for it opposite O line. Next record the temperature of the oxygen bell (from the thermometer) and the prevailing barometric pressure in millimeters. Using table C draw a circle around both the temperature and the barometer readings and at the intersection of these two columns you will find the correction factor. Transfer this figure opposite "Table C" in space for computations. Multiply O line by table C which will give the total ACTUAL TEST CALORIES PER HOUR.

Now you have the NORMAL oxygen consumption determined from the tables and the ACTUAL oxygen consumption as found by the TEST both in terms of calories per hour.

To find the BASAL METABOLIC RATE from these two figures (i.e. the relation of one to the other in terms of per cent) simply subtract the smaller figure from the larger then divide the difference ALWAYS by the normal. This will give you a decimal fraction which when multiplied by 100, or by moving the decimal point two figures to the right, gives the Basal Metabolic Rate in per cent. To determine whether this per cent is plus or minus, simply note whether the ACTUAL TEST is greater or less than the NORMAL. If greater than the Normal the result is plus and if less than the Normal the result is minus.

THIS CHART FOR USE WITH BENEDICT-ROTH RECORDING METABOLISM APPARATUS, MADE BY WARREN E. COLLINS INC. 555 HUNTINGTON AVENUE BOSTON

Fig. 721.

NOTE: Table "C" is given here only to illustrate the method of obtaining the correction for temperature and pressure. This table will be found on the reverse side of all Collins kymograph sheets. (Courtesy Warren E. Collins, Inc., Boston.)

When the test is completed, again read the thermometer.

Obtain the patient's age, sex, weight without clothing, height without shoes.

Read the barometric pressure. All these facts are necessary for calculating basal metabolic rates.

At least two tests must be made on each patient, and the average used.

Calculation

Connect the majority of the **bottoms** of the kymograph lines by ruling a line between the **lowest** of these lines, and the bottom of the last kymograph line six minutes removed. If more than a six-minute test has been made, select the six minutes in the test which give evidence of the most regular breathing. The line is always drawn for a six-minute test.

The rise in millimeters of the O_2 line is the difference between the end of the line after six minutes and the beginning. For example, if one end of the line cuts the vertical line at 121 mm., and the other end at 47 mm., the rise in the O_2 line is $121 - 47 = 74$.

Figs. 720 and 721 give methods of computing basal metabolic rates of all patients from five to eighty years of age according to the method of Du Bois modified by Boothby and Sandiford of the Mayo Clinic.

To determine the **Normal***: Use Table A (Fig. 721). Rule a line to connect the ''patient's height'' found in Column I with the ''patient's weight'' found in Column II. The point at which this line intersects Column III is the *body surface area.* Record this in the computation space allotted to it. Now, using Table B, find the calories per square meter per hour by using the patient's age (nearest birthday) and sex, and record in space for computations. Multiply III by B to obtain total *normal calories per hour,* the exact normal for a person of this height, weight, age, and sex.

To determine the **Actual Test:** Record difference in height of the 6 minute test period from the kymograph tracing in the space called ''O_2 line.'' Record the temperature of the oxygen bell from its thermometer, and the prevailing barometric pressure in millimeters. Obtain correction factor for pressure and temperature from Table C (the intersection of the two columns representing the temperature and pressure for this test). Record in proper computation space. Multiply O_2 line by Table C to obtain *total actual test calories per hour.*

To find the **Basal Metabolic Rate:** Use the *Normal* and the *Actual* consumption of oxygen per hour. Subtract the smaller from the larger figure. Divide the difference by the *Normal.* Move the decimal two places to the right to obtain *Basal Metabolic Rate* in per cent. If the *Actual Test* is greater than the *Normal,* report as plus; if less than the *Normal,* report as minus.

SANBORN METABULATOR[1]

The Sanborn Metabulator is the latest equipment (1947) made by the Sanborn Company for making basal metabolism tests. (See Figs. 722 and 723.) Before attempting to cope with an actual patient it is a very sound policy to run trial tests on normal subjects.

Preparation of the Patient.—The patient is prepared in the usual manner. He must be completely at rest mentally and physically, and 14 hours must have elapsed since his last meal. He should lie down for one-half hour immediately preceding the test made with this equipment. (This is true of all equipment.)

Preparation of the Apparatus.—With the patient comfortable and resting, wheel the metabolism tester to a convenient position beside the bed and plug its power cord into the AC outlet. Place the chromium-plated leak tester in a glass of cold water and allow it to remain there while the patient is being prepared. Place a sterilized rubber mouthpiece on the mouthpiece connector. Open up the plexiglass window over the writing stylus. Turn the breathing valve to the ''test'' position, thus connecting the bellows with the outside air, and then collapse the bellows by pushing the bellows carriage toward the absorption chamber as far as it will go. With the bellows in this position, turn the patient valve back to ''fill,'' thus closing off the bellows. Now admit oxygen by carefully turning the handwheel on the oxygen tank to the left. Continue filling until the writing stylus is about an inch from the top edge of the paper; then close the valve on the oxygen tank tightly by turning it to the right.

---

*These calculations are compiled from data furnished by Warren E. Collins, Inc., Boston, Mass.

[1] These data are compiled from facts furnished by the Sanborn Co., Cambridge, Mass. For further information, refer to the brochure supplied with each Metabulator.

Adjusting the Noseclip.—The instrument is now ready for the test. Connect the patient to the apparatus. Adjust the noseclip before inserting the mouthpiece. The sponge rubber pads are used to apply pressure against the soft sides of the nostrils. Loosen the thumbscrew so that the clip will fit loosely when first applied, and then take the noseclip between thumb and finger of both hands and, placing it over the nose near the bridge, slide it downward parallel to the patient's face until the pads are at the right level. Now tighten the thumbscrew until the patient finds he can no longer breathe out through his nose. Make sure of this by asking him to close his mouth and try. The noseclip must not be uncomfortably tight, for the patient will have to wear it for nearly ten minutes, but on the other hand, it must be tight enough to prevent any possible leakage. When the adjustment is satisfactory, remove the noseclip again by springing its arm outward slightly without changing the adjustment of the thumbscrew.

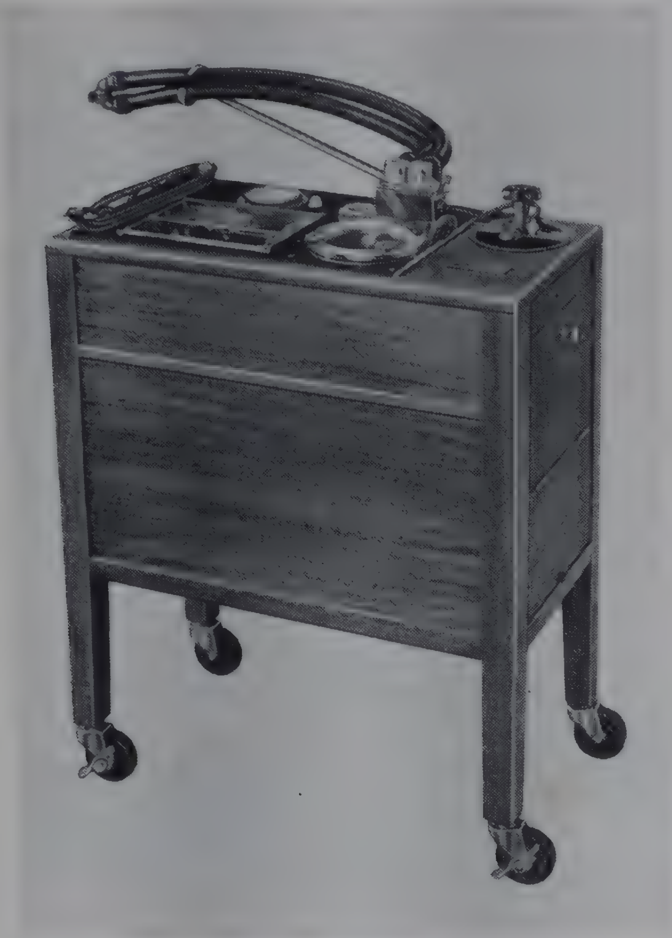

Fig. 722.—Sanborn basal metabolism apparatus. (Courtesy Sanborn Company, Cambridge, Mass.)

Placing the Mouthpiece.—Adjust the portion of the tester and of its flexible arm until the rubber mouthpiece is just in front of the patient's mouth, with its long axis pointing across the face. Insert the mouthpiece so that the two small projections lie between the upper and lower teeth while the flange of the mouthpiece lies between the lips and the teeth. See that the lips are not folded under, for this may permit leakage.

False Teeth.—False teeth will not cause trouble, especially if the teeth fit well. Since there may be an air passage over the plate, however, it is doubly important with patients wearing artificial teeth to see that the lips make a good seal over the outside of the rubber mouthpiece. It is a mistake to remove the teeth, for this may allow the mouthpiece to fall inward, away from the lips.

With patients with few or no front teeth, the problem is apt to become more difficult. This problem is solved, however, by having a good seal made by the lips. It may be necessary to draw the lips over the flange of the mouthpiece and hold them in place with adhesive tape.

Ruptured Eardrums.—If the patient has a ruptured eardrum and a patent auditory (eustachian) tube, air is likely to escape through the ear. If this occurs, the external ear canal is sealed with a cotton swab impregnated with petrolatum. The operator may have to hold the plug in place while the patient is being tested for leaks at the nose, for otherwise the plug may be blown out.

Making the Test.—With the patient ready and breathing room air comfortably, start the record by turning on the motor switch. The stylus should now be tracing a horizontal line near the top of the record. The actual test is started by flipping the breathing valve to the ''test'' position, preferably at the end of an expiration. As soon as it is clear that the test is proceeding normally, check the seals at the patient's nose and mouth (and ears also, if necessary) with the leak tester. To do this, take it out of its glass of cold water, wipe it dry, and then hold it under the nose and at the corners of the mouth while you watch for any condensation on the polished surface of the metal. The test should not be allowed to proceed unless all leaks have been eliminated, for a leak will spoil the accuracy of the oxygen-consumption measurement.

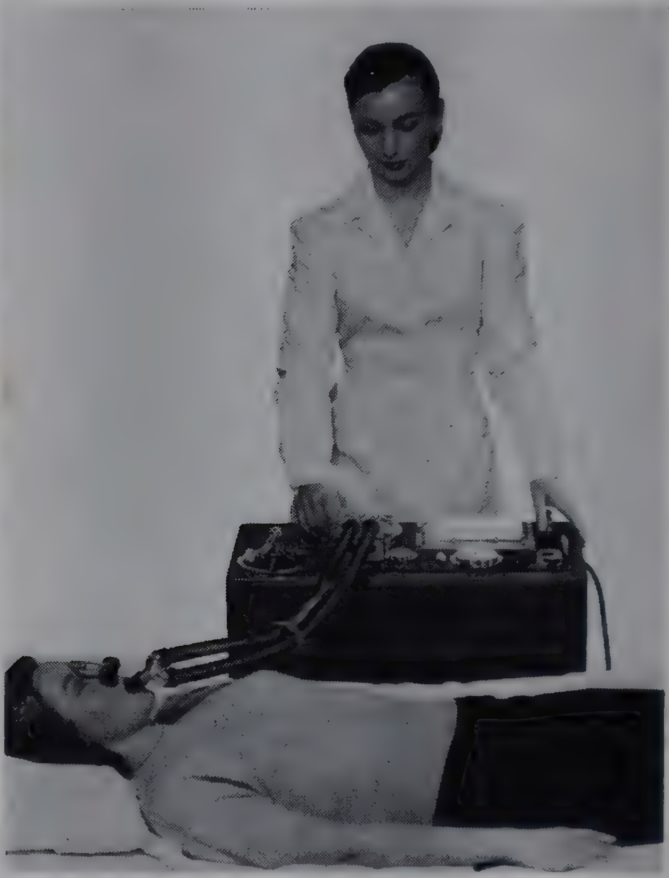

Fig. 723.—A basal metabolism test using the Sanborn instrument. (Courtesy Sanborn Company, Cambridge, Mass.)

Run the test six minutes or more unless the bellows become collapsed earlier. If a duplicate test is desired, turn the breathing valve to the ''fill'' position at the end of the first test, readmit oxygen from the tank as before, and when the bellows has been adequately filled close the valve on the tank and return the breathing valve to the ''test'' position. If the patient shows any signs of discomfort or reluctance at the end of the first test, however, remove the mouthpiece and noseclip and allow him to rest before making a second run.

At the middle of each test record the *temperature,* as read from the instrument's dial thermometer, and the *barometric pressure,* directly on the record. Tap the barometer gently before making the reading. With the test completed, throw the breathing valve to the ''fill'' position again and disconnect the patient. Pull carefully on the protruding paper in order to bring the remainder of the record out of the machine, then bend the paper sharply back over the barometer dial and move the free end a little to one side, whereupon a quick pull will tear off the protruding portion of the paper. Be sure the motor switch is turned off. Write the date, and the patient's name, height, weight, age, and sex on the record, and also the temperature and barometer readings if this has not already been done.

Measurement.—Since the volume occupied by a given amount of gas depends on the temperature and pressure, the statement that a patient's oxygen consumption is so many cubic centimeters per minute means little unless the conditions under which the volume measurement was made are specified. However, temperature and pressure are likely to be different in each test, so that it has become accepted practice to refer all gas-volume measurements to ''standard temperature and pressure,'' or ''STP'' for short. Standard temperature is 0° C. or 32° F., standard pressure is 1 atmosphere, or 760 mm. of mercury. The actual volume measurement is made under the conditions prevailing during the experiment, and then the operator calculates, using the gas laws, the volume that *would have been found* if the measurement had been made under STP conditions. This is what is meant by an oxygen-consumption rate as ''x c.c. per minute, STP.''

A measuring scale has been provided that eliminates the STP calculation.

The purpose of this test is to determine the patient's rate of oxygen consumption, expressed in cubic centimeters per minute at standard temperature and pressure. This is done by estimating the *average downward trend* of the patient's respiratory tracing. To do this, draw a ''slope line'' through the top peaks of the record. The top peaks are chosen because they represent the expiratory position of the patient's lungs, which is usually a little more regular than the inspiratory position. The slope line can be drawn through the top, bottom, or the middle of the record as long as it represents the average downward trend. If the record is regular, the slope line can easily be drawn through the top peaks. If the record is jagged, the operator must exercise some judgment in deciding what represents the average slope. If the respiratory tracing is very irregular, it is useless to attempt to place a slope line, and the test must be repeated.

Lay the record on a flat surface and, with a long ruler and a dry pen, pencil, or other scratching device, draw a straight slope line to represent the average downward trend of the tracing. Extend this slope line to the edges of the record.

L-scale.—A measuring device has been designed to enable the operator to read the oxygen consumption, in STP per minute, directly from the record. The L-scale will be found among the accessories in the case with the ''Slide-Rule Calculator.'' Hold the long arm of the ''L'' horizontal, with the lettering right-side up, and slide the shorter arm (pointing upwards) over the left-hand end of the long one. The small slider will already be in place at the right-hand end of the arm. The scale now consists of a horizontal bar carrying two sliders, each with a vertical hairline lying over a correction scale (see Fig. 724). One of these scales is for temperature and the other for barometric pressure. Adjust the sliders so that the hairlines mark the temperature and barometer readings taken during the test. Note that each slider also carries a *horizontal* hairline, lying a little above the upper edge of the long arm of the ''L.'' The line on the right-hand slider has a vertical hairline crossing it, and the L-scale is to be applied to the respiratory tracing in such a manner that the intersection of these two hairlines on the slider lies exactly over the intersection of the previously drawn slope line and one or other of the horizontal lines printed on the record (see Fig. 724). When this has been done, adjust the ''levelling'' of the ''L'' until the horizontal hairline on the *left-hand* slider also coincides with the horizontal line which has been chosen. Check the position of the intersection on the right-hand slider again, to be sure that it has not moved, and then read the oxygen consumption directly at the point where the slope line strikes the right-hand margin of the vertical arm of the ''L.'' The reading on this latter scale is the patient's oxygen consumption in cubic centimeters per minute, reduced to standard temperature and pressure.

T-scale.—While this new L-scale represents a considerable improvement over the T-scale that has been supplied with the Sanborn Waterless Metabolism Tester, it is perfectly permissible for any operator who wishes to do so to use the T-scale on the records produced by the present machine. It is applied to the tracing exactly as in the case of the waterless testers, using a vertical line for the alignment and reading the oxygen consumption along the horizontal arm. Corrections for the temperature and pressure are made, of course, by adjustment of the sliders before the scale is applied.

Conversely the L-scale may be used to measure a slope line produced on one of the older waterless machines. Since alignment of the L-scale depends on a *horizontal* line, it will be necessary to draw in a base-line on the Waterless chart, which can be done most conveniently before the chart is removed from the machine. Simply inflate the bellows to the point where the writing stylus will cross the respiratory record near its end and then, maintaining the bellows at this volume, give the drum one full turn by hand. This will provide a horizontal base-line for the L-scale. If it has been placed correctly, as suggested above, the base-line and the slope line will cross near the right-hand edge of the record. If the base-line is too high or too low, it can easily be drawn in a more appropriately placed line parallel to the original.

Basal Metabolic Rate.—The Metabulator will provide the operator with a measurement of the patient's oxygen consumption in STP c.c. per minute. The BMR goes a step further—it is a measure of how nearly normal the determined oxygen consumption is for the particular patient concerned, taking his height, weight, age, and sex into account. The BMR is expressed as a figure (with a prefixed plus or minus sign) showing the *percentage* by which the patient's oxygen consumption is above or below normal. Thus a BMR of +42 indicates an oxygen consumption 42 per cent too high; while -17 indicates one 17 per cent below normal, etc. The problem now is how to convert the figure found for oxygen consumption into a BMR for the patient concerned, thus telling by how many percentage points the oxygen consumption differs from the normal.

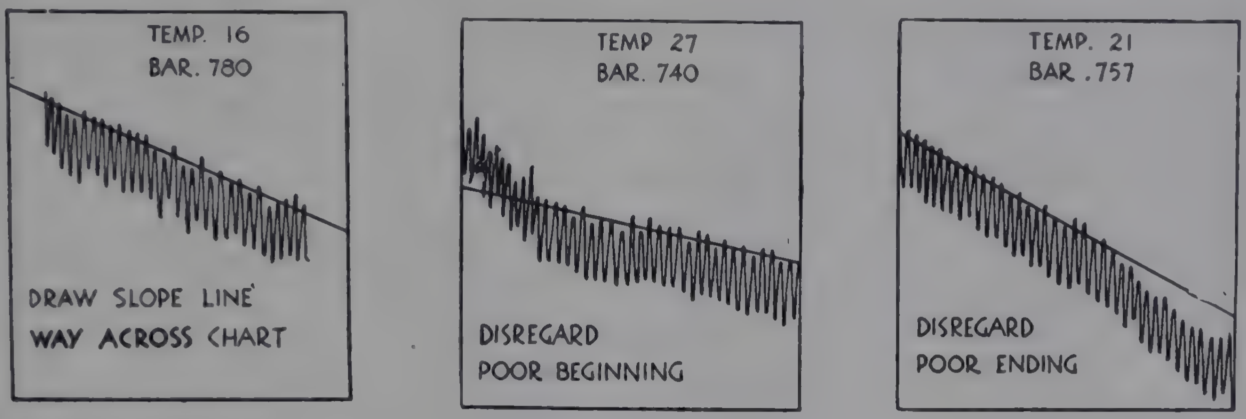

Fig. 725*A*.—How to draw slope lines, Sanborn basal metabolism test. (Courtesy Sanborn Co., Cambridge.)

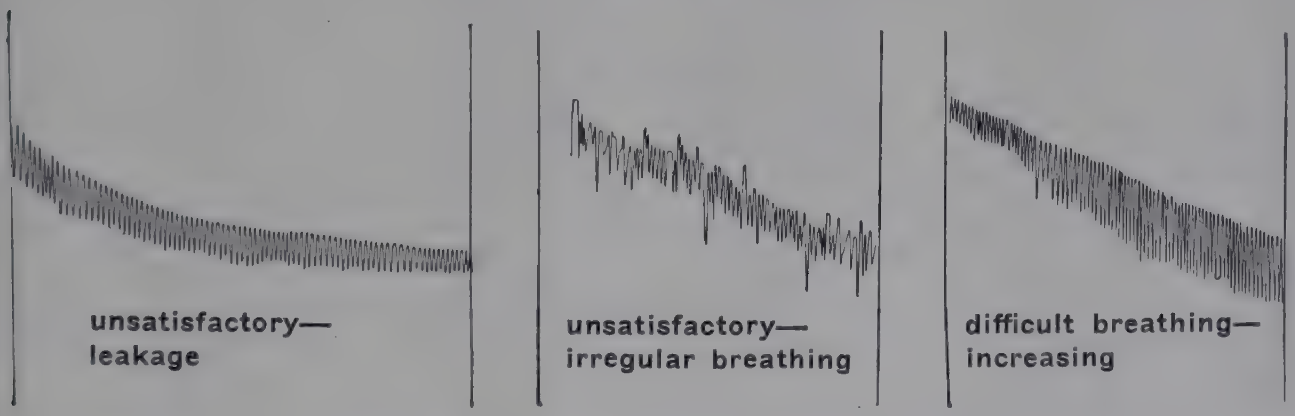

Fig. 725*B*.—Types of slopes that are to be discarded in making Sanborn basal metabolism tests. (Courtesy Sanborn Co., Cambridge.)

This conversion may be accomplished either by the "Slide-Rule Calculator" supplied with the accessories or by using metabolism tables. The former is more rapid; the latter more accurate. The metabolism tables also cover more extreme cases, and can be used with either English or metric units for height and weight.

Slide-Rule Calculator.—Set the hairline on the slider to the figure found for oxygen consumption.

Move the central scale until the male or female age, as the case may be, lies under the hairline.

Move the hairline again until it lies over the correct height.

Slide the central scale until the weight lies under the hairline.

Finally read the BMR opposite the black arrow at the top edge of the central scale.

Metabolism Tables.—The tables formerly used with Sanborn metabolism testers are perfectly adequate to convert oxygen consumption to BMR. The new set of tables will greatly facilitate the calculation involved. The printing on the recording paper is designed so that the whole computation can be carried out on the original record.

The quantities concerned in the calculations are: (1) the patient's height, (2) his weight, (3) his rate of oxygen consumption (L-scale reading), (4) his age and sex.

The newer tables give a factor for each of these four measurements, and a column is provided on the chart for the factors found, so that they can be put down one above the other. They are then added together and the sum is converted directly to a BMR through the use of a final conversion table.

English or Metric Units.—The principle involved in this method of calculation makes it possible to use the same tables whether the heights and weights are in pounds and inches on the one hand or in kilograms and centimeters on the other. The difference is taken care of by the addition of a ''metric conversion factor'' if the metric units are used. Examine the printed box on one of the charts. The tabulations are set up so that if the bodily measurements are taken in English units the left-hand section is used, with no conversion factor; whereas if the measurements are in centimeters and kilograms the right-hand column is used, and the metric conversion factor is printed at the bottom of the factor column so that it will be added in along with the other factors. The sum in line 6, obtained by the addition of all the figures in the factor column, will be the same whether the left-hand section with English units is used, with no conversion factor to add in, or whether the right-hand section with metric units is used, and the conversion factor ''0295'' added in. Since the sum in line 6 is the same for either system of units, the BMR in line 7 will also be the same, as it should be.

Height Factor.—Measure the patient's height to the nearest inch or centimeter. In the column at the left-hand side of Table 1 on the recording paper will be found the heights arranged in steps of ten. Suppose the patient's height is 67 inches. Since 67 = 60 + 7, follow the left-hand column down to ''60,'' then follow that horizontal line across to the column headed ''+7.'' This factor, 0750, is the correct one for a height of 67 inches. Other values will be treated in exactly similar fashion. If the height is 182 centimeters, follow the height column down to ''180'' and then follow the horizontal line across to the column headed ''+2,'' where the factor 0121 will be found, etc.

Weight Factor.—Measure the patient's weight without clothing in pounds or kilograms.* Find the weight factor in Table 2 on the recording paper. For example, if the patient's weight is 145 lbs., follow the weight column down to ''140'' and then trace that horizontal line over to the ''+5'' column, where the factor 0765 will be found.

Oxygen-Consumption Factor.—Use Table 3 on the recording paper to find the factor for oxygen consumption. The procedure is the same as for the other two. The figure to start with is the number of STP c.c. of oxygen per minute as determined from measurements of the patient's record. For a consumption rate of 217 c.c. per minute, for example, find ''210'' in the left-hand column and then follow that line across to the column headed ''+7.'' The factor is 1275.

Normal Standard Factor.—Since the basal metabolic rate depends on a comparison of what the patient actually does with what a normal person of his age and sex ought to be doing, a factor must be found representing ''normal'' behavior. Table 4, showing the factors for the normal standard, will be found on the back of the tables card. The column for the age is in the middle, and the factors for male patients are found at the left, while those for females are to the right. Some of the factors are the same for a number of different ages. This is all right, for that is the way normal people behave. The groupings also differ between males and females.

Find the patient's ''normal standard'' factor and put it down in line 4; e.g. for a female patient, aged 29, it would be 1208. For a male of the same age, it would be 1114.

Conversion to BMR.—When all the factors have been added (including the metric conversion factor if the height and weight were in centimeters and kilograms) the total is converted directly to BMR through the use of Table 5 on the recording paper. Reduce the sum to three figures by discarding the fourth, increasing the third figure by 1 if the fourth is 5 or more. Thus, if the total is 4316, call it ''432''; while if it is 4312 it becomes ''431.'' Using the conversion table just as the others were used, it will be seen that ''431'' gives a BMR of +43. Insert the result in line 7 on the chart.

---

*Needless to say, heights and weights must be either *both* English or *both* metric; do not try to mix a metric height with an English weight, or vice versa.

JONES METHOD

This method was devised by Dr. Horry M. Jones, of Chicago. The machine is a portable instrument, consisting of a bellows mounted on a strong metallic stand with a standard liter measuring device which automatically corrects its oxygen volume with the barometer and thermometer without the use of a barometer and thermometer.

The metabolism test is a quantitative determination, and therefore requires more than ordinary precision in technic. Results should be within from 1 to 5 per cent of the patient's true metabolic rate, otherwise the technic is being very crudely performed.

Set up the apparatus, as illustrated. Carry out each step in the exact sequence as given.

Connect oxygen tank in place using wheel wrench to tighten it against leather gasket. Place the tracing sheet on the clock plate with the lettered end of the clock plate up.

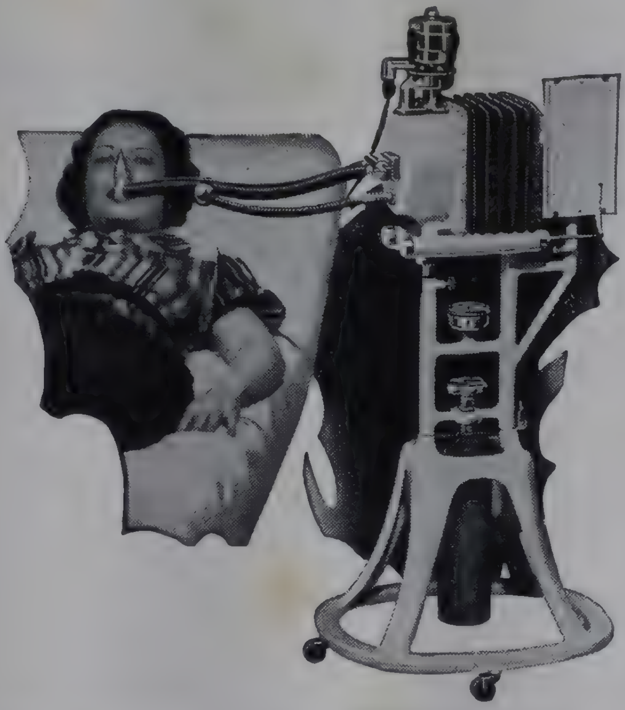

Fig. 726.—The Jones basal metabolism apparatus. (Courtesy Middlewest Instrument Co., Chicago.)

Adjust clock plate so that its geared bar fits in the slot of clock housing and then slide plate down into slot until it comes to rest against geared wheel inside of housing. If the clock starts, stop it by snapping switch to OFF position. If it does not start with switch in ON position, lift clock plate about ½ inch and bring it down with slight downward jerk. Then see if the clock can now be started by turning on switch. If this has succeeded in getting geared bar and geared wheel to mesh, stop clock until it is to be started as directed later.

Keep the pen tip free of dried ink or lint by drawing a pinpoint through it so that the pen will write with a fine, sharp line. Fasten the pen to its bar and rotate the clock in its seat until the pen traces evenly across the entire width of the clock-plate. The mouthpiece (disinfected, not by boiling, but by briefly immersing into wide-mouthed jar of 50 per cent alcohol, and then rinsed with water) is now attached to the breathing tubes, so rotated that it faces the patient's mouth squarely without twisting the tubes.

Stand the apparatus at exactly the correct distance (move apparatus to patient, not the patient to the apparatus) so that the mouthpiece will just reach the patient's mouth without bending the breathing tube.

Turn the three-way valve so that its pin is parallel to the floor. Pull on the bellows until the point of the pen is at the air position on the graph. Holding the bellows in that position, turn the three-way valve perpendicular to the floor, and keep the bellows at the air position.

Close the needle valve. This retains the oxygen in the measuring chamber.

Admit an unknown amount of oxygen into the bellows. The black needle on the oxygen gauge below the bellows should point around 10° to 20°.

Open the needle valve and admit enough of this oxygen into the bellows to push the pen point to S, M, or L on the paper (Small, Medium, or Large, depending on the size of the patient.)

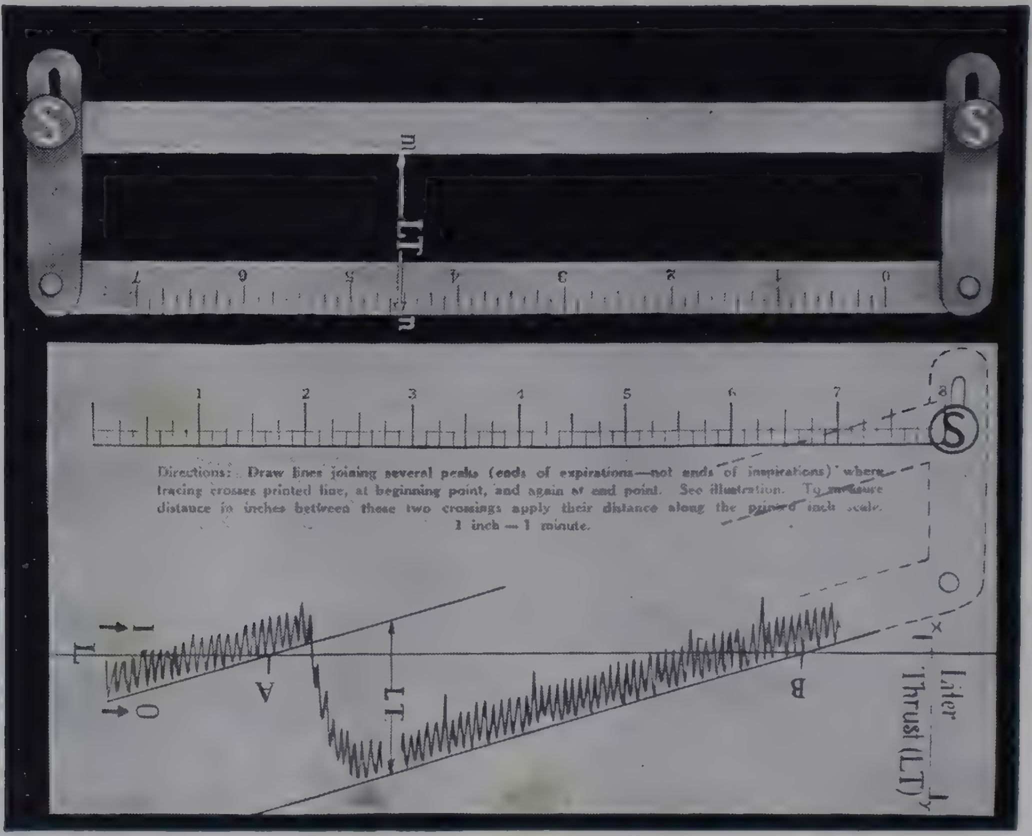
Admit an exact liter of oxygen into the measuring chamber by turning the wheel wrench on the oxygen tank until the black needle is superimposed on the red needle of the gauge.

Attach the nosepiece to the patient. Connect the mouthpiece to the apparatus. Instruct the patient how to use the mouthpiece, and insert it into the patient's mouth.

Start the motor of the apparatus.

At the extreme end of the patient's expiration turn the three-way valve parallel to the floor, thus connecting the patient to an unknown quantity of oxygen in the bellows.

After a few respirations, start the clock, and make the pen write on the graph.



Directions: Draw lines joining several peaks (ends of expirations—not ends of inspirations) where tracing crosses printed line, at beginning point, and again at end point. See illustration. To measure distance in inches between these two crossings apply their distance along the printed inch scale. 1 inch — 1 minute.

Fig. 727.—Jones basal metabolism protractor and sample test chart. (Courtesy Middlewest Instrument Co., Chicago.)

When the tracing has crossed the base line at A (receded within the black line on the paper), open the needle valve and admit the known liter of oxygen from the measuring chamber into the bellows. This will push the pen out beyond the black line. When the pen recedes within the black line again at B, the test is ended.

Testing for Nose Leak.—After the noseclip has been placed in position, instruct the patient to try to breathe through his nose. If he is able to breathe through his nose while the clip is in place, adjust it to make it airtight. If there is a nose leak, the tracing will be concave instead of a straight line slope.

Testing for Mouth Leaks.—If there is a mouth leak due to improper adjustment of the mouthpiece, the tracing will be a back and forth movement of the pen instead of a slope.

Calculation of Basal Metabolic Rate.—Use the protractor to determine the time required to consume one liter of oxygen, as follows: Apply the top edge of the top ruler of the adjusted protractor along the long or "liter" slope of the tracing on the paper to line up with the highest peaks. Do not allow more than one or two peaks to project above the ruler edge. Holding the upper rule in this position, swing the connecting arms to such position that either edge of the connecting arm lies PARALLEL to the edge of either end of the

tracing sheet. The shorter slope peaks should now line up with the upper edge of the lower ruler. If they do not, it indicates (1) that a full liter was not admitted to the breathing chamber; or (2) that part of it was lost through a nose leak or mouth leak; or (3) that soda lime has been used for more than a hundred tests; or (4) that a full minute preliminary breathing period was not given; or (5) that the patient was not made to relax for even breathing by taking a full, deep inspiration.

Draw a line along the top of the two edges of the protractor. A is the point where the shorter, or first slope crosses the printed line; B is the crossing of the longer slope. The distance between them, in inches, is the time in minutes required by the patient to consume the standard liter of oxygen.

Obtain the age of the patient, his weight without clothing, height without shoes, and sex.

Read off the basal metabolism rate on the automatic calculator.

Determine the Liter Thrust of the Pen.—When a liter of oxygen is discharged into the bellows, the pen moves outward by the amount of the expansion of the bellows. This we call the liter thrust of the pen. Measure up a liter in the usual way. Do not have the apparatus connected to a patient for this part of the procedure. Next open the three-way valve and pull the bellows carried by the hand to a point such that the pen tip is about ¾ inch inside of the printed line of the tracing sheet, then close three-way valve to hold the bellows at that point. Let the clock-plate run to trace a short line (X) to show this position of the pen tip. Stop the clock-plate. Discharge the liter of oxygen now in the measuring chamber, making sure the indicator swings from the room temperature point on the gauge scale backward all the way to within ⅛ inch of the self-verifying zero of the gauge. The self-verifying zero is a short, black calibration mark somewhere near and slightly above the word ''caution'' at the edge of the gauge dial. If the indicator does not make this full swing, you have not delivered a liter of oxygen to the bellows. After all of the oxygen has gone into the bellows, that is, after the pen has been thrust out as far as this liter pushes it, again let the clock run to trace another short line (Y) to show its new position. The distance between (X) and (Y) is the ''liter thrust.'' This part of the procedure should be done independently of the test, that is, any time after or before the test. It is done only for the purpose of adjusting the rulers of the protractors and occasionally as a check-up to see if the protractor rulers are still adjusted to equal the distance of the liter thrust.

To adjust the rulers of the protractor to fit this liter thrust, release the knurled nuts of the short arms of the protractor, then move the rulers closer in, or farther apart, until the upper edge of one ruler coincides with (X) and the upper edge of the other ruler coincides with (Y). Adjust both ends of the protractor so that the upper edges of rulers equal the distance from (X) to (Y) throughout the entire length of the protractor, then tighten the knurled nuts to hold the rulers to that adjustment. At sea level and 25° C., this liter thrust of the pen is approximately 1½ inches, and for each thousand feet of elevation above sea level, this liter thrust is increased about 1/12 inch. For example: At about 6,000 feet above sea level, the liter thrust would be 1½ inches plus 6/12, or 2 inches. This serves as a means of determining whether or not you are actually delivering the standard liter regardless of the barometric pressure changes caused by changes in elevation above sea level.

Having determined the liter thrust of your machine for the sea-level elevation of your locality, this thrust is approximately constant, and thereafter it is unnecessary to adjust the rules of the protractor to equal the liter thrust, except as an occasional check-up.

THE JONES DOUBLE BELLOWS MOTOR-BASAL

This apparatus differs from the Jones MOTOR-BASAL in that there are two bellows instead of one (one inside the other). The larger of the two bellows has exactly twice the cross-section area of the smaller bellows.

By means of a conversion valve, a single turn converts the apparatus to either a small bellows or a large bellows hook-up.

The smaller bellows hook-up is used on a small sized patient, who would be connected to the apparatus for an unnecessarily long period if a large capacity bellows were used. The large bellows hook-up is used on a large sized patient who would be connected to the apparatus a relatively short time if a small bellows were used. Thus, the capacity of the apparatus is adjustable to the size of the patient.

CHAPTER XVII

ELECTROCARDIOGRAPHY

By Julius Elson, M.D.*

The frequency with which disorders of the cardiovascular system are encountered in the practice of medicine and the importance of the electrocardiograph in the diagnosis, treatment, and prognosis of these disturbances has made it desirable to include a discussion of this important subject in this book.

It is not within the scope of this chapter to undertake an explanation of the theories underlying electrocardiographic interpretation and all the patterns which present themselves in clinical practice. These subjects are covered thoroughly in standard texts devoted solely to the subject of electrocardiography. This chapter will present the principle and the use of the electrocardiograph, and will point out the more important patterns, clinical applications, and pitfalls of electrocardiography.

THE USE OF THE ELECTROCARDIOGRAPH

Because the terms *electrocardiograph* and *electrocardiogram* are so often confused, it is well to point out that *electrocardiograph* refers to the recording instrument, whereas *electrocardiogram* refers to the record itself. The electrocardiograph is an instrument by means of which a visible record is made of the many minute electrical or electrochemical changes occurring in the *heart muscle* associated with its contraction. It is important to stress the point that the electrocardiogram is a reflection merely of electrical activity of heart *muscle* so that one will recognize the limitations of the clinical application of this means of diagnosis.

For instance, in valvular disease, or in certain congenital malformations where the heart muscle is not primarily involved, the electrocardiogram cannot be expected to be of help except in those cases where secondary heart muscle changes occur, usually in the form of hypertrophy of the auricular or ventricular musculature. These secondary effects on the musculature give a clue to the primary valvular disease; but until these effects do occur the electrocardiogram is often normal in the presence of valvular disease.

The electrocardiogram may be normal even in the presence of myocardial involvement if the site of the lesion is not in the proper axis with regard to the electrocardiographic "leads."

All laboratory tests must be interpreted in the light of the clinical picture. Laboratory tests alone should rarely if ever be relied upon for making a diagnosis or determining treatment and prognosis. This is an extremely important point, and must constantly be borne in mind. In the experience of many electrocardiographers, patients are often referred for electrocardiographic tracings in the belief that such tracings may give the answer to the whole question of diagnosis. Actually, so many factors can affect electrical action currents in the heart that even experienced electrocardiographers may not be able to make proper electrocardiographic diagnoses without ample clinical data. Even with this information it may be impossible to make a decision in borderline electrocardiograms because of the many variations of the normal electrocardiogram.

---

*Instructor in Clinical Medicine, Washington University School of Medicine; Associate in Medicine, Ward Service, Jewish Hospital of St. Louis; Associate in Medicine, Cardiac Clinic, Jewish Hospital of St. Louis; Cardiac Consultant to Christian Hospital.

While a normal electrocardiogram does not necessarily exclude the presence of cardiac disease, an abnormal tracing surely indicates some disorder. This disorder may be organic in nature, or it may involve disturbances in the cardiac mechanism; or it may merely reflect an abnormal psychosomatic effect on the heart. Many extracardiac influences can alter the electrocardiogram. Toxic substances, either bacterial or nonbacterial, and disturbances in other organs which might affect the position of the heart in the thoracic cavity, are among the factors which sometimes alter the tracing. Drinking cold water, emotional disturbances, and smoking may also alter the normal electrocardiographic pattern.

VALUE OF THE ELECTROCARDIOGRAPH

The greatest value of the electrocardiograph lies in the field of coronary artery disease in which the myocardium is involved acutely or by progressive degenerative changes. The electrocardiograph in these conditions is of great value since in many instances there are no objective positive clinical findings.

Often in acute myocardial infarction the electrocardiogram will present a pathognomonic picture, especially if serial electrocardiograms are taken and these electrocardiograms are found to undergo characteristic changing patterns. While acute myocardial infarction without significant electrocardiographic abnormality does occur, such a diagnosis should be made with reservation. Although the diagnosis can often be made clinically, it is a great comfort to the clinician to have the added assurance of the electrocardiographic diagnosis. This may be of vital importance to the patient also, since on occasion the symptoms may be confusing and may simulate those of an acute surgical abdominal condition or dissecting aneurysm. Patients have been operated upon for perforated peptic ulcer, when in reality they were suffering from myocardial infarction; others have been spared needless surgery by making an electrocardiogram which disclosed the cardiac nature of the patient's symptoms.

In addition to its value in coronary artery heart disease, electrocardiography is very useful in the positive recognition of certain cardiac arrhythmias and disturbances of conduction, the exact nature of which could not be ascertained without recourse to cumbersome methods of recording venous pressures, arterial pulses, and the apex impulse. The electrocardiograph has made the certain identification of these abnormal mechanisms a simple matter.

This instrument can sometimes be of aid as a guide to treatment. Recognition of characteristic alterations of certain segments of the tracings or of clinically obscure disturbances in rhythm and conduction which have occurred in the course of treatment with certain drugs, most commonly digitalis, is often the signal for discontinuation or more cautious administration of such drugs.

From a prognostic standpoint, conclusions from an electrocardiogram alone are most precarious. Prognosis should be made from an evaluation of the clinical aspects of the case. For instance, the presence or absence of heart failure, which is not indicated by the electrocardiogram, is very important. If such disturbances as complete heart block or bundle branch block are found in the tracing, the prognosis is usually poor; not infrequently, however, a patient with bundle branch block may live for a number of years. A patient with myocardial infarction may, on the other hand, show an electrocardiogram approaching a normal pattern, yet he may die of cardiac rupture, embolism, ventricular fibrillation, or heart failure.

The characteristic alterations of the electrocardiogram caused by digitalis have led to another field of usefulness for the electrocardiograph; namely, in the standardization of digitalis glycosides, using human subjects.

PRINCIPLE OF ELECTROCARDIOGRAPHY

The science of electrocardiography was first made possible in the middle of the 19th century when it was discovered that the contraction of the frog's heart was accompanied by an electric current. By connecting the outside surface of the human subject by means of electrodes to a capillary electrometer, Ludwig and Waller in 1887 demonstrated that the electrical currents in the heart could be recorded. Because of the nature of the instrument, records at that time were inaccurate, and the method was not practicable. It was not until 1903, when Einthoven applied his string galvanometer to the study of the human heart, that electrocardiography was put on a firm, clinically reliable basis. Only with an understanding of the electrocardiogram in electrical terms can one appreciate the magnitude of Einthoven's contribution to medicine.

The electrocardiogram, as recorded by electrodes placed upon the body surface, consists of a series of impulses, each of which is of relatively short duration. The baseline above and below which these impulses fluctuate is known as the *isoelectric level.* Some of these impulses may rise from the isoelectric level to their peak in a time interval as short as 0.02 second while the amplitude may represent as little as one millivolt.

Furthermore, the resistance of the circuit within the patient, the *patient circuit,* as measured between a pair of electrodes, averages under good conditions about 2,000 ohms. On the basis of one millivolt amplitude and 2,000 ohms resistance offered by the patient, the peak power which the body generating the electrical impulses can deliver to the recording instrument would be only one-eighth of one-thousandth of one-millionth of a watt.

String Galvanometer.—The string galvanometer is based upon the fundamental principle that a conductor which carries an electric current, and which is suspended in a magnetic field, will tend to be deflected from its original position by a force acting on that conductor. This force is produced by the reaction between the current and the magnetic field.

String Shadow.—In the usual electrocardiograph the current-carrying conductor is a quartz "string" about one five thousandth of an inch in diameter (5 μ), covered with a metal such as platinum. This string is suspended between the north and south poles of an electromagnet. Without stretching this platinum-coated quartz string very tightly one may time this light fiber to a sufficiently high natural frequency of vibration to produce a moving system capable of following the details of the human electrocardiogram with a satisfactory degree of accuracy.

The actual motion of the "string" through which the current from the patient passes is so small that it must be magnified from 500 to 1,000 times. This is accomplished by means of a microscope through which light is thrown by an electrical source and condenser. The magnified shadow of the "string," with all its movements, is thus projected on a camera. The recording medium, usually bromide paper, is pulled through the camera at a constant speed. A timing device is provided by a spoked wheel rotating in the path of light and periodically interrupting the light to produce timing coordinates, thus allowing measurement of the various events of the cardiac cycle.

With most timers using a rotating wheel, the fifth spoke is wider, so that every fifth vertical time line is broader than the other four. The distance between each fine line represents 0.04 second; that between each wide line, therefore, represents 0.20 second.

A piece of glass with parallel lines ruled on it is mounted just in front of the paper so that it casts fine horizontal shadows on the sensitized paper at one-millimeter intervals. The resulting horizontal lines are the coordinates by means of which the amplitude of the electrical deviations is measured.

This combination of the string shadow, the light interruptions produced by the timer, and the ruled scale for the amplitude coordinates results in a completed record in which the string movements and the time and amplitude coordinates appear as white lines on a dark background.

Leads.—There are three main types of leads in general use today: (1) the bipolar or conventional leads, (2) the unipolar leads, and (3) the augmented unipolar leads.

Bipolar leads are obtained by placing metal electrodes on two different points of the body. By convention, and because experience has justified it, these leads are recorded from the right arm, left arm, and left leg, as well as from various positions on the chest.

The lead taken from the right and the left arm is known as **Lead I**; that from the right arm and the left leg is called **Lead II**; and that from the left arm and left leg is called **Lead III**. These are the conventional bipolar leads universally used.

The chest leads are designated in a variety of ways, depending on the position of the chest electrode, or *exploring electrode*, and the limb electrode, or *indifferent electrode*. For further clarification of certain complexes of the electrocardiogram even esophageal leads have been used; in these a specially designed electrode is passed down into the esophagus and electrocardiograms are taken with this electrode held at various levels.

In recent years, the method of unipolar lead electrocardiography has been widely adopted. These leads more nearly record the absolute potential at each of the extremities as well as at the exploring electrode on the chest wall.

Unipolar Leads.—There are two types of unipolar leads: (1) the Wilson type, and (2) the augmented unipolar limb leads. Unipolar leads are described on pages 2407 ff.

The use of ''unipolar limb leads'' has become general. The connections are made as for the ''central terminal'' (V) leads of Wilson, described on page 2405. Three records are then made, with the precordial electrode placed on the right arm, on the left arm, and on the left leg, respectively. A discussion of the theoretical considerations and clinical applications of the unipolar leads can be found in *Unipolar Lead Electrocardiography* by Emanuel Goldberger* and many other publications devoted to this subject.

The choice of the lead or electrode pair to be recorded is made by a *lead selector* switch on the panel of the instrument.

Other Currents.—In addition to the currents caused by the action of the heart there are other currents, such as those arising in the skin, which cause deflections in the string. These currents are relatively constant, but unless counteracted they will produce a movement of the string away from the center or zero position which will make the recording of the heart action current impossible.

To compensate for, or to neutralize the effects of these currents, there is incorporated in the electrocardiograph an ordinary dry cell such as is used in a simple flashlight. This necessitates another switch, the *compensating switch,* which is adjusted in a manner to keep the string centered despite the fluctuations of the extracardiac currents.

Standard Records.—Records made at different times, or by different instruments, in order to be comparable, must record the same electrical quantity according to the same scale. The unit of measurement is the millivolt, and the scale of recording is one centimeter, which corresponds to one millivolt developed at the electrodes.

To standardize an electrocardiograph, the sensitivity of the string is so adjusted that it responds to a one millivolt current by deviating one centimeter from the base line or zero level. The one millivolt standardizing current is introduced from a source built into the instrument. If the sensitivity of the string is such that it deflects more than one centimeter, the tension of the string must be increased; that is, the string must be tightened by means of a screw attachment until the deflection or ''jump'' of the string is exactly one centimeter. If the sensitivity is such that the string ''jump'' is less than one centimeter, the string is then accordingly loosened by the screw attachment.

Before standardizing a string galvanometer type of electrocardiograph it is necessary that the patient, the galvanometer, and the standardizing circuit all be connected. Resistance in the patient circuit varies from time to time and from lead to lead; for this reason it is necessary to restandardize the instrument for each lead while the string and patient circuit are connected and the string is responding to cardiac action currents.

---

*Goldberger, Emanuel: Unipolar Lead Electrocardiography, Philadelphia, 1949, Lea & Febiger.

Skin Resistance.—The patient circuit resistance derived from the skin must be kept low, two thousand ohms or less. Too high resistance necessitates ''loosening'' the string to such an extent, in order to make it jump one centimeter, that ''overshooting'' of the string results. ''Overshooting,'' or string fling, results in distortions in the tracings which make it difficult or even impossible to evaluate the electrocardiogram properly.

Skin resistance is lowered by the application of some form of electrode paste or jelly to the skin at the site of the electrode. This paste contains an electrolyte; when rubbed into the skin with a little excess on the electrode, it reduces the resistance between the electrode and the tissues beneath the skin from a value of many thousands of ohms to about one thousand ohms.

Electron Tube Amplifier.—Another type of electrocardiograph was later developed and is now in common use. It employs the electron tube amplifier principle. This type of instrument makes use of an amplifying circuit which greatly magnifies the tiny cardiac currents, and includes a very large resistance to prevent overshooting. The most popular of this type instrument employs a very small mirror attached to the movable element or coil in the magnetic field. This mirror is so arranged that by its motion it swings either a spot of light or a field of light with a shadow in it across the face of the recording camera.

An advantage of this type of apparatus is that it is not necessary to standardize the instrument with the patient switched in. This enables the operator to make the tracing without any disturbance to the recording beam other than that caused by its response to the standardizing pulse. Still another advantage is that standardization need not be repeated after the patient is switched in, nor for each of the leads, as in the case with the string electrocardiograph. These advantages are possible because of the relatively high resistance and current in the amplifying circuit as compared with the slight resistance caused by the skin or by polarization. All of these electrocardiographs require the use of photographic paper or film for recording the electrocardiogram.

Direct Writing Electrocardiographs.—Direct writing electrocardiographs have in many places supplanted the photographic types of instruments. These apparatus, by use of high-power radio tube amplifiers, have made possible direct, immediately visible recordings of the electrocardiogram. In addition to this very real advantage, the need for photographic materials and a dark room is obviated.

Vectorcardiography

This method of electrocardiographic study is not new, but in the past few years has been studied with greatly renewed interest and emphasis. There are two ways of analyzing electrocardiograms. One is the conventional or ''pattern'' method, with which we are largely concerned in this chapter, and the other is the ''vector'' method of analysis. In the former, we learn by experience and correlation with pathologic specimens the various electrocardiographic patterns associated with disease entities, whereas in the latter the many electrical forces developing and receding in the cardiac cells are represented by an arrow, the length of which measures their resultant magnitude and the tip of which their direction at any given instant. These arrows, representing the magnitude, direction, and sense of this force at a given intent, will vary from moment to moment as the impulses travel through the heart fibers in the various directions. These "instantaneous vectors" can be constructed from the conventional electrocardiogram taken to include the three bipolar limb leads, the three unipolar limb leads, and the six unipolar chest leads. By connecting the tip of each arrow representing the vector of electrical potential from moment to moment, a "loop" is formed, graphically depicting the direction of the vectors throughout the cardiac cycle. These vector loops can be much more accurately depicted by means of an oscillograph connected with the body by means of specially placed electrodes.

This method of interpretation has the advantage of not requiring memorizing of the numerous patterns with their wide range of normality; one merely visualizes abnormalities in direction and magnitude in the electrical potentials.

There are serious disadvantages to the routine adoption of spatial vectorcardiography as a routine method of study in clinical practice. The chief of these perhaps is the impossibility at this date of determining time relationships of the various phases of the cardiac cycle, and the inability to identify accurately arrhythmias. Vectorcardiography should still be regarded as an experimental method and until the objections mentioned above are obviated, and until some standard method of lead placement is generally agreed upon, it perhaps should not be adopted as a routine method in clinical practice.

The Ballistocardiograph

While a discussion of this relatively new instrument which is being found increasingly useful in the study of cardiac dynamics is not strictly within the province of this chapter, nevertheless it is of value to at least mention in a general way the nature of this type of device and its scope.

In contrast to the electrocardiograph which is an instrument that records the *electrical* events during the heart cycle, the ballistocardiograph records the movements transmitted to the body by the mechanical effects of the contraction of the heart. These movements occur in well-recognized patterns with each heartbeat, and, magnified many times by the instrument, are recorded in repeatedly reproducible patterns.

The value of the instrument lies in the fact that, since it records the certain phases of the mechanical action of the heart, it is related to the heart's efficiency as a pump. It has been shown that the ballistocardiogram changes with age, hypertension, coronary disease, has a characteristic pattern in coarctation of the aorta, and is altered by smoking. Indeed, in some instances it will show changes indicative of coronary disease before any other methods of study can reveal them. It must not, however, be inferred from this that the opposite does not happen. There certainly are instances in which the ballistocardiogram is normal and other methods of study show unmistakable evidence of abnormality. There are many types of ballistocardiographs, none entirely satisfactory. Much work is being done to evolve an instrument that will meet all basic objections. Up to this time, not even the origin of all the waves of the lead ballistocardiogram is understood.

GENERAL DIRECTIONS FOR USING A STRING-TYPE ELECTROCARDIOGRAPH (CAMBRIDGE)

Detailed descriptions of all the electrocardiographs on the market and their step-by-step operation will not be given here, since they vary in certain respects from each other. Complete information can be found in the brochures which each manufacturer supplies with the instrument. The method of taking an electrocardiogram with a standard string electrocardiograph, the Cambridge instrument, is described below.

Preparation of the Patient.—The room temperature should not be too low, because a cold room may cause quivering of muscles which results in artefacts in the tracings. The patient should preferably not have partaken of excessively cold drinks and should not have smoked immediately prior to the taking of the tracing, since cold drinks and smoking sometimes modify the tracing. The patient is instructed to bare the forearms, the chest, and the left leg, and to lie down. The supine position is preferred to the sitting position for making tracings because alterations of the electrocardiogram may occur in some individuals in the upright position.

Preparation of the Electrodes.—Some electrode jelly is rubbed rather briskly into the skin of each forearm. The massaged areas should be somewhat larger than the size of the electrodes. Massaging into the skin should be to a point of slight erythema to minimize the effects of skin resistance.

Electrode jelly suitable for electrocardiographic purposes is made by several manufacturers. The purpose of this jelly is to lessen skin resistance, improve contact, and to conduct the cardiac current through the skin to the electrode. The basic ingredients are salt, glycerine, pumice powder, gum tragacanth, potassium bitartrate, and water. A small amount of the electrode jelly is spread over the surface of the electrode which is to be in apposition to the skin. The site of application of the electrodes may be anywhere on the arm, but for convenience the anterior surface of the forearm just above the wrist and the lateral surface of the left leg just above the ankle are used.

Care must be exerted in massaging the electrode jelly so that areas of skin disease or marked varicosities are avoided.

It makes little difference where the electrode is placed with respect to the limb leads, but it is very important that the chest electrode be placed in the exact manner prescribed. Slight changes in position are likely to cause significant effects on the electrocardiogram.

If the skin in the areas where the electrodes are to be placed is hairy, use the jelly more freely and rub it into the skin more briskly than usual.

The electrodes are strapped onto the arms and the left leg in the prepared areas. It is of utmost importance that the electrodes be in complete contact with the skin since occasionally tension on the wires by movement of the patient will cause partial separation of the electrode from the skin. If the electrode is strapped on too loosely, artefacts may be caused in the record by slipping of the electrodes; if applied too tightly, artefacts due to muscle tremor may be produced.

The standard type of chest electrode has an insulated handle which may be held in place on the chest wall by the patient or by an assistant.

Lead Wires.—The lead wires are connected to the limb electrodes, care being taken that the right arm lead wire is connected to the right arm electrode, the left arm wire is connected to the left arm electrode, and the left leg lead wire is connected to the left leg electrode. The lead wires are designated in various manners; by letters, such as RA for right arm, LA for left arm, and LL for left leg; by using colored terminals, red for the right arm wire, blue for the left arm wire, and white for the left leg wire; or by wires colored in the same manner as the colored terminals.

After recording electrocardiograms of the limb leads, it is necessary to rearrange the lead wires and electrodes for taking the precordial leads. The left leg lead wire is connected to the chest electrode, which is then placed in the proper position on the chest wall. Then the left arm lead wire is connected to the left leg electrode which is still in place. The lead switch is turned to the Lead III position and the chest lead is recorded.

Electrical Interference.—All sources of electrical interference must be eliminated or minimized. Electric fans, electric pads, electric refrigerators, which may be in the room or near by, may cause marked interference with the records, and should be turned off.

The electrocardiograph should be grounded by means of a wire leading from a water pipe, a radiator, or bedspring to the suitable ground wire connecting post in the machine. A water pipe is most desirable for grounding purposes. The electrocardiograph, in the case of the electric type of machine, is connected to an electric light outlet. Be sure to check the type of current available; most instruments require AC current. Some machines are supplied with special bulbs which indicate whether the current is proper for that instrument. If the wrong current is used and the electrocardiograph is switched on, a fuse blows, thus protecting the instrument.

The Room.—The room should be darkened during the actual recording process so as to prevent fogging of the bromide paper by extraneous light. Enough light should be left so that the dials are visible during the operation.

Operating the Electrocardiograph.—The machine is prepared by switching on the electrical current. In the electrical string instrument this starts the timer and throws a beam of light onto the string and the camera. The shadow of the string is seen lying on the zero mark on the scale. This shadow should be focussed so that its outlines appear as sharp as possible.

If the string lies on either side of the zero mark on the scale it must be centered.

Always check the camera box to make sure that the paper is in proper position and that the container which receives the exposed paper is in the open position. If one inadvertently fails to replace the receiving box or if the box has not been opened, the paper may become jammed and stop feeding into the receiving box. This also may occur at times when the paper or film has slipped out of its proper position in the slot.

After the instrument has been connected to the electrodes on the patient and the current has been turned on, it is necessary to ''compensate'' for the skin currents. These currents may be of sufficient magnitude actually to deflect the string shadow completely out of the visual field on the camera, or actually to break the string. This current varies both in direction and in strength in each lead, with different patients, and even with the same lead in the same patient from time to time. The effects of this current can be neutralized by gradually introducing a counteracting current into the system by means of a ''compensating'' dial. In some instruments neutralization of skin currents is accomplished by condensers.

The skin current may cause the string shadow to move to either side of the scale. Many electrocardiographs have the compensator so arranged that by turning the knob clockwise the shadow will move forward, and by rotating it counterclockwise the string shadow moves in the opposite direction. In this way it is easy to determine the direction in which the skin current of the patient deflects the string, and then, by means of the compensator knob, to bring it back to the center.

With the electrodes on the patient connected to the proper lead wires, and the light and timing device turned on, turn the lead selector knob on the control panel to Lead I. Then slowly rotate the ''protector'' knob which shields the string from the current from the patient by means of a large resistance. This gradually reduces the resistance and permits the current from the patient to enter the string. At this time the string shadow will begin to move away from the center line in either direction. During this procedure the string shadow can be brought back and kept on the center line of the camera until finally the protecting resistance is zero and the current from the patient then enters freely into the string. The string shadow then moves in uninhibited response to each contraction of the heart. Now standardize the string by introducing one millivolt current from an independent source of electrical energy such as a Weston cell. If the string jumps more than one centimeter, tighten it by means of a screw or wheel adjustment until the one centimeter deflection is produced. If the string jumps less than one centimeter, loosen it by turning the screw or wheel in the opposite direction until the one centimeter deflection is produced. If the skin resistance is too great, the string must be loosened excessively thus producing overshooting. Under these circumstances the protecting resistance knob must be turned on again and the electrodes reapplied after rubbing more jelly into the skin. It may also be necessary to recleanse the electrodes or lead wire contact points.

With the string standardized, focused, and centered, Lead I can now be recorded. Turn on the camera switch lever. This starts the bromide paper moving at a constant rate, the movements of the string shadow being recorded upon it. The standardization impulse should be recorded while the record of each lead is actually being made.

After photographing the desired number of cycles, usually about ten, turn off the camera lever and again turn on the protector resistance. Rotate the compensator knob to ''zero'' and shift the lead switch to Lead II. Repeat the entire procedure for Lead II, taking care to restandardize and record the standardization for this lead and all subsequent leads. Now take Lead III. It is common practice to have the patient take a deep breath during the recording of Lead III to determine the influence of deep breathing on the electrical axis of the electrocardiogram. With the machine turned off and all the knobs turned to zero readjust the electrodes and the lead wires for recording the chest leads, as indicated above. Now take the chest lead.

Turn the lead selector switch and the compensator switches to zero after the desired leads are recorded. Tighten the string so that it will not be broken by accidental jarring of the instrument. This is done by turning the lead selector switch to zero or to the position marked *4* in some of the electrocardiographs. The string is thus out of the patient's circuit and unprotected by resistance. Tighten it by turning the string tension adjusting wheel until 1 millivolt of current causes only about a 0.3 centimeter deflection. Turn the lever on the record receiver box to the closed position, cutting off the record from the unexposed paper. If more electrocardiograms are to be taken before developing this tracing, turn the lever on the record receiver box to the open position, allowing a new strip of paper to enter the box. Turn off the switch controlling the source of power to the machine and remove the electrodes from the patient. Clean them thoroughly with water, and dry. Remove the electrode jelly from the patient.

With the lever in the closed position, remove the record receiving box and take it to the darkroom for the development of the records.

Developing the Tracings.—Remove the paper from the container in the darkroom and place it in the developing solution. Agitate and examine it from time to time until it shows complete development and proper contrast. With fresh developer and proper temperature of the solution this should take about four minutes. If the temperature of the solution is too low or if the solution is old, more time is required for development. Solutions should be kept at about 68 to 70° F.

Remove the paper from the developer bath, wash it thoroughly in clear water, and then place in the fixing solution. Allow it to remain for about ten or fifteen minutes in this bath. The fixing solution and the developer should be the same temperature.

The white light may now be turned on in the dark room. Remove the electrocardiogram from the fixing bath and wash it thoroughly in running water for about one-half hour. Hang it up to dry. If the developer is too old, the record becomes stained and yellow, and it is necessary to prepare fresh solutions.

Preparing the Tracing for Examination.—Ferrotyping the electrocardiogram will produce a glossy finish and will prevent the records from curling and cracking when they are straightened.

Use a ferrotype plate, 18 by 24 inches, and a squeegee roller. The plate should always be kept clean and glossy. Cut the electrocardiogram into sizes to fit the length of the ferroplate taking care to mark the leads properly so that they will not become confused with each other or with those of other patients. Shake the surplus water from the paper strip and place the strip face downward on the plate. Run the roller firmly over the paper until excess water and air bubbles are forced out and the record lies in perfect contact with the plate. Allow them to dry; the records will of themselves separate from the plate.

The electrocardiogram is now ready to be interpreted by an electrocardiographer. This interpretation is written in special form as directed by the electrocardiographer. Next cut and mount the record, taking care to mark the leads properly and not to mount them upside down.

History.—The date, the patient's name, sex, age, pertinent facts in the history, and type of medication should accompany the electrocardiogram when it is presented for interpretation. Retain the unmounted portions of the tracings, mark them properly, and file them for future reference. Present the mounted record to the referring physician.

THE SANBORN CARDIETTE

Another instrument commonly used is the Sanborn Cardiette. A brief description of this instrument is included as an example of the electron tube amplifier type of electrocardiograph. For complete operating details, consult the brochure which is supplied with the Cardiette.

Be sure that there is enough sensitized paper in the camera and that the batteries are fully charged. Check the camera to see that it is operating. Do not wear a watch while operating the instrument. See that the patient removes his watch.

Prepare the patient and attach the electrodes as directed on pages 2396, 2403, 2405, 2406, 2407 ff.

Turn the voltage knob to the right until the needle on the circular dial, the voltmeter, comes to the position marked 1 MV. The needle must be maintained at exactly 1 MV mark throughout the taking of the tracing. Turning this knob illuminates the left-hand corner of the control panel. If it is not illuminated, start the camera for an instant, then turn it off.

In less than a minute a dark line will slowly move across the scale and out of sight. It soon returns and stops in a visible position on the scale. This is the beam shadow. Turn the beam knob to center this shadow.

Press down on the 1 MV button to cause the beam to deflect. It should "jump" 1 centimeter on the glass scale. If the deflection is over or under the standard centimeter, turn the sensitivity knob clockwise to increase, or counterclockwise to decrease, the deflection, until the 1 centimeter jump is attained. The machine is now standardized.

Attach the lead wires to their respective electrodes, and check them to make sure that they are properly placed.

Turn the lead switch to Lead I. Check the instrument to make sure that the beam is centered and that it jumps the standard 1 centimeter. Turn on the camera, press the lead marker once, and record the first lead, pressing the deflection button once during the recording of this lead to show that the machine is standardized. The average length of a lead is 8 inches, which requires 8 seconds to record.

Turn the camera knob to the "off" position. Turn the lead indicator switch to Lead II. Check the beam for centering and standardization, then turn on the camera and record Lead II. Press the lead marker twice at the beginning of this lead in order to identify it. *Press the beam deflector button once during each lead to show that the instrument is standardized.*

Turn off the camera. Turn the lead indicator switch to Lead III. Center the beam and check the deflection. Instruct the patient to take a deep breath and then to let it out. Turn on the camera and record Lead III. Mark the lead by pressing the lead marker three times. Turn off the camera.

Turn off all switches. Attach the left arm lead wire to the left leg electrode, and the left leg lead wire to the chest electrode. Leave the right arm electrode in place. Put the chest electrode in proper position, turn the lead indicator switch to Lead III, check the beam, turn on the camera, and record Lead IV. Mark by pressing the lead marker button four times. Turn off the camera.

Detach the lead wires and take the instrument or the camera box to the darkroom. Develop the tracing as directed on page 2398.

While making the tracing, if the beam shadow is not in focus, attach the ground wire to eliminate any interfering electric circuits from the outside. If the beam is still not in focus it may be due to skin resistance. Adjust the electrodes so that they are neither too tight nor too loose, or apply more electrode jelly.

Clean the electrode jelly from the patient. Clean and dry the electrodes before returning them to storage.

THE SANBORN INSTOMATIC CARDIETTE

The Sanborn Instomatic Cardiette differs from the Sanborn Cardiette in several details. To operate, turn the main switch to ''STD'' and wait one minute for the amplifier to reach operating stability. Standardize the beam deflection as for the Cardiette. To test the deflection, press down the same knob used to center the beam.

Draw back the autographic slot cover and write the patient's name or identifying number. The camera may be run for a moment if more room is needed for writing. Run a few inches of the paper into the receiving box to prevent ''striking'' the paper with light.

Prepare the patient as directed on page 2403. Plug the patient cable into the rectangular socket at the upper left corner of the panel. Attach the patient cables to the electrodes in the usual manner.

Set the lead length indicator at ''0.'' Each small white mark on the dial represents six inches of exposed paper, or six seconds of recording.

Check the machine for standardization. Be sure that the beam is deflected one centimeter per millivolt. No further adjustment of the sensitivity knob during the test is ordinarily necessary.

The beam deflector button must be pressed once during the taking of each lead to show that the instrument is standardized.

Press and hold down *Instomatic* button at the left of the sensitivity control. With the button depressed, turn the *Lead Selector Switch* to Lead I. Release the Instomatic button. Turn the camera on and record Lead I. Press the lead marker once during taking of this lead. Then turn off the camera.

Repeat for Lead II, pressing and holding down the Instomatic button while turning the main switch to Lead II. Press the lead marker twice for Lead II. Turn the switch to Lead III and repeat for this lead. Press the lead marker three times for Lead III. Turn off the camera between each lead.

To take Lead IV F disconnect the right arm terminal and attach it to the chest electrode. Leave the other connections in place. Apply the chest electrode at the outer border of the apex. Hold down the Instomatic button and turn to Lead IV, then take Lead IV F. Mark by pressing the lead marker four times.

To take Lead IV R, turn the main switch to ''STD.'' Attach LA terminal to the chest electrode. Press and hold down the Instomatic button while turning the main switch to Lead I.

To take Lead IV L turn the main switch to ''STD.'' Attach the LL terminal to the chest electrode. Press and hold down the Instomatic button while turning the main switch to Lead III. Proceed as for other leads.

Run the camera about 4 seconds then turn it off. Turn off all switches. Take the removable record container to the dark room and develop the tracing in the usual manner.

Mounting the Electrocardiogram

Electrocardiograms may be mounted with ordinary photographic mounting tissue. Cut the tissue to desired length and breadth. Attach one corner to the electrocardiogram which has previously been trimmed to desired proportions. Put the tracing on the paper which is to be the permanent record with the mounting tissue beneath the tracing. Cover with a towel or several thicknesses of paper and press with a hot electric iron. Take care not to burn the tracing. Now label each lead. Be sure that leads are not interchanged while mounting them and that they are not mounted upside down.

Maintenance of the Instrument

All electrocardiographs are delivered in proper working condition and are accompanied by a pamphlet giving complete detailed instructions for operating the instrument. Since maintenance and care of the instrument vary with the type of apparatus used, it is best to refer to these pamphlets for such information. In choosing an electrocardiograph it is advisable to bear in mind the availability of service for it.

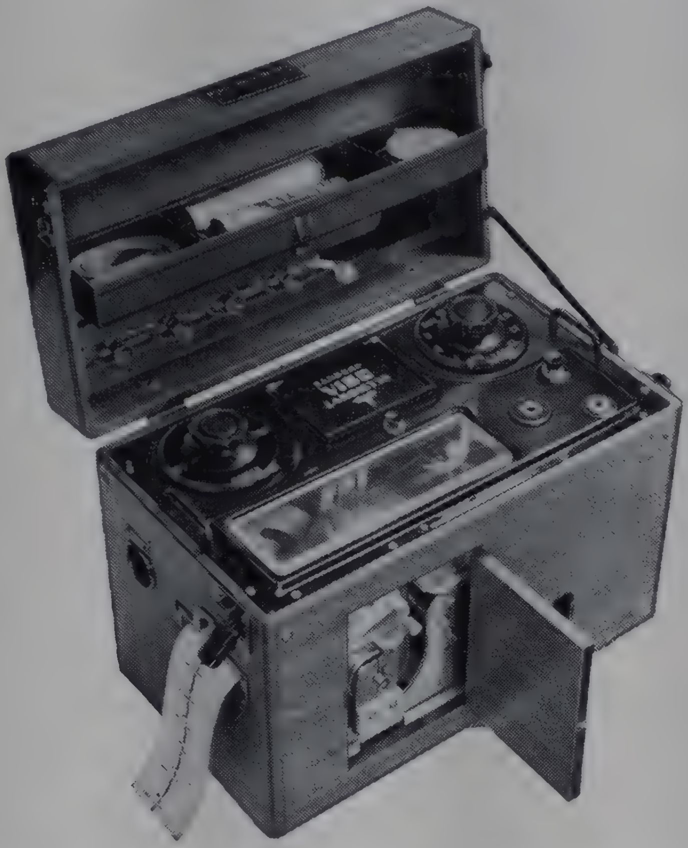

Fig. 729.—Sanborn Model 51 Viso-Cardiette. (Courtesy Sanborn Company, Cambridge, Mass.)

THE SANBORN VISO-CARDIETTE Model 51*

One of the most commonly used types of direct writing instrument is the Sanborn Viso-Cardiette. The Viso-Cardiette produces an electrocardiogram or graphic record of the electrical waves (action potentials) generated by the beating of a patient's heart. The record reads from left to right to represent the passage of time, the standard speed being 25 millimeters per second. The paper is ruled in 1-millimeter squares. The light vertical lines on the graph mark off twenty-fifths of a second, or 0.004 second, per square, and the heavy lines fifths of a second (0.20 second).

The vertical deflections of the recorded tracing show the electrical changes taking place in the heart. Each millimeter square, the lighter lines, represents 1/10 millivolt; each square within the heavier *horizontal* lines represents ½ millivolt. The short lines above the graph printing indicate 3-second intervals.

Complete operating instructions, including checking of the shipment and the instrument, accompany the purchase of such an instrument and will not be repeated here.

---

*This section is an abstraction of a pamphlet furnished with the Viso-Cardiette by the Sanborn Company, Cambridge, Mass., and is reproduced with their permission. All cuts courtesy of Sanborn Company.

Operation of the Viso-Cardiette.—

The Viso-Cardiette must not be operated on direct current nor on alternating current having a frequency different from that marked on the serial name plate. While 50-cycle current will not damage a 60-cycle instrument, it will make the recording paper run at a speed equal to 5/6 of the rated value. Direct current will blow the fuse in the instrument.

Remove all watches from the patient and the operator unless they are of the nonmagnetic variety. Watches may be easily demagnetized by gradual withdrawal from the center of an aircore coil carrying alternating current.

Do not expose the instrument unduly to outdoor winter temperatures. It takes some time for the instrument to warm up properly and condensation invites temporary electrical abnormalities.

Technic.—

(1) **Control Tests on Instrument:**

Plug in the power cord and check for proper grounding, as follows:

Make sure the power switch is in the OFF position.

Insert the round plug of the power cable firmly into the power cable socket.

Automatic grounding can occur only if the polarity of the power cord is correct. The grounding indicator is the neon lamp in the grounding disk. Connect the instrument to the line and then touch the gold-plated metal band on the disk with one hand, avoiding contact with any other part of the instrument (so as not to destroy the value of the test; there is no danger of shock), and look at the indicator lamp. If the lamp glows, the polarity is wrong, and the grounding can be corrected by pulling out the power plug and inserting it again the reverse way around. No glow should be obtained now when the metal band on the grinding disk is touched.

Since the grounding can be changed by reversing either end of the power cord, avoid the mistake of marking the power plug at its round end to show which way it should presumably go in.

Turn the power switch to ''ON,'' and observe the writing arm, noting that it wanders here and there, finally becoming stable when the amplifier is fully warmed up. This is normal, and may last for 90 seconds. Prepare the patient while warming up the instrument.

Check the stylus temperature. Locate the stylus temperature control in the covered compartment in the control panel and set the record in motion by turning the power switch to RUN. Lower and raise the stylus temperature by turning this knob to the left and then to the right until the point is reached at which the top and bottom edges of the base line on the record become sharply outlined.

A dull red glow of that part of the stylus ribbon projecting beyond the paper while the record is being run is a good approximate indicator of the recommended stylus temperature.

Check the lead marker, while the record is running, by depressing the lead marking button in the center of the control panel once or twice. Small black marks will appear at the top of the record, above the printed scale. Stop the record by returning the power switch to the ''ON'' position. The amplifier will remain in operation until the switch is turned to ''OFF.'' An automatic switch reduces the stylus temperature while the record is not running, preventing the stylus from burning a hole in the paper.

Adjust the position of the writing arm approximately to center by the centering control in the small compartment.

If the sensitivity has been adjusted when the instrument is first set up, it will seldom need correction. The universal standard is 1 centimeter per millivolt. While the 1MV button at the right end of the control panel is being depressed and released rapidly, observe the writing arm. Adjust the sensitivity control until the deflection sweeps through 10 of the small squares (2 large squares) on the recording paper.

By turning the control counterclockwise, the deflection is decreased; turning it clockwise increases the deflection.

Check the final standardization performance while the record is running. Measure deflections from one edge of the base line to the same edge of the deflection. If the vertical portions of the standardizing deflections are not visible, increase the stylus temperature until they are.

All routine tests must show standardization, so that 1 centimeter of deflection represents 1 millivolt of electrical potential at the patient's electrodes.

Try to apply the millivolt pulse standardization immediately after the T wave.

(2) **Preparation of the Patient.—**

The patient should be warm, comfortable, and relaxed, not apprehensive.

All three standard limb leads must be connected for all patients, even if only a chest lead or a single limb lead is to be recorded.

It is important to have good contact between the skin and the electrodes. Use the Redux electrode paste, or any suitable electrocardiographic jelly. Apply it sparingly and only where needed. Remove bracelets and wrist watches and exposed clothing as a general precaution.

Expose both forearms and the calf of the left leg. If chest leads are required, arrange the clothing so that an electrode can be applied to the chest.

Spread a moderate amount of electrocardiographic jelly on the skin on the inner side of one forearm, about half way between wrist and elbow.

Holding the electrode so that one long edge can make contact with the patient's skin, scrape the edge upward gently but firmly, along the patient's arm, for a distance of about 2 inches.

With the opposite edge of the electrode, scrape downward on the patient's arm. Using about 10 or 12 strokes, continue with a stropping motion until the jelly is well distributed, and the skin slightly reddened. This improves electrical conductivity.

Make sure there is a slight, moist residue of jelly remaining.

Fasten the electrode in place with one of the rubber straps, the concave surface being lengthwise on the arm and the thumbscrew nearest the patient's hand.

Hook the strap over the central pin on the electrode.

Draw the strap tightly enough to produce firm contact between the electrode and the skin, but not so tightly that it is uncomfortable.

No metallic particles should be trapped under the electrode and the skin should be clean. If necessary, swab down the electrode sites with 70% alcohol.

Place a second rectangular electrode on the other arm, using the same method. Place a third on the left leg, with the thumbscrew pointing upward.

If AV leads or V (''Wilson'') chest leads are to be taken, apply an electrode also to the right leg. This is essential to eliminate automatically AC interference when AV and V leads are being taken.

Place the leg electrodes to one side of the calf. More friction must be used on the legs than on the arms. Do not remove hair; simply rub thoroughly.

The small disk electrode is provided for chest leads. The edge of this may be used for scrubbing the skin, as with the limb leads. No surplus paste should extend beyond the disk, for the chest leads are essentially *point contacts,* and an excess of paste is the equivalent of a larger electrode and may distort the result.

It is best to hold the chest leads in place by means of the chest strap and not with a folded towel.

When the electrodes have been placed, plug the patient cable into its receptacle and connect the free ends of the leads to the appropriate electrodes as indicated by the markings: RA to right arm, LL to left leg, and so on. Screw the nut of each terminal down firmly onto the tip of its lead wire.

If the RL lead is not required, the wire may be unscrewed from the distributor block and stored.

(3) **Recording the Electrocardiogram.—**

After the lead wires have been connected and the patient is comfortable and relaxed, the instrument is ready for operation.

Turn the power switch to RUN for a moment, until a short length of record protrudes from the case. Check the stylus temperature and the standardization during this time, by depressing the "1 mv" button a few times and inspecting the deflections.

Return the power switch to "ON."

Write the date and the patient's name on the protruding strip of record. Record any other data desired.

With one hand, push the Instomatic switch (just below the lead selector switch) and with the other turn the lead selector switch to the first desired lead position, usually lead 1. Keep the Instomatic switch pushed for a second longer, then release it.

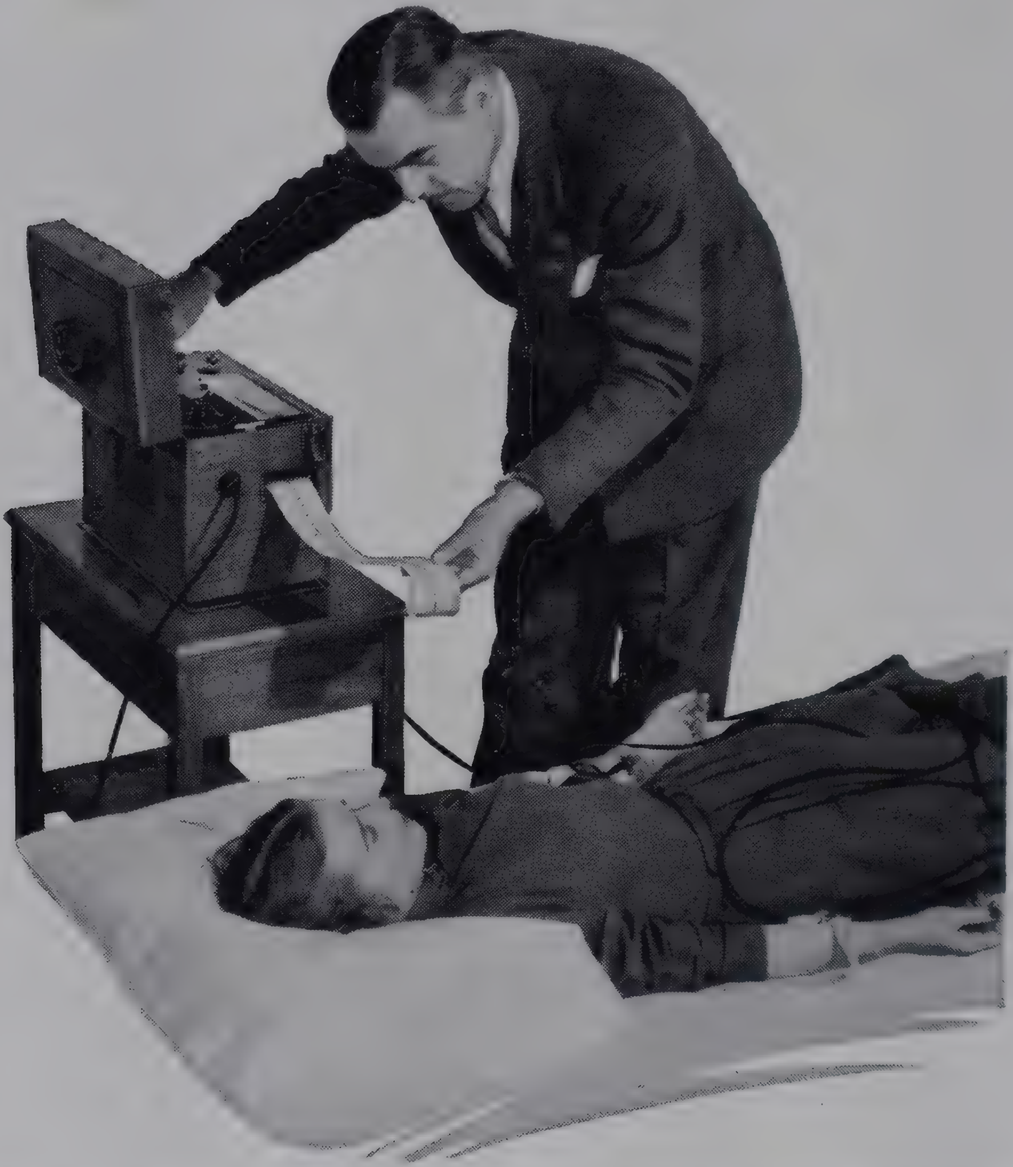

Fig. 730.—Sanborn Model 51 Viso-Cardiette in use. (Courtesy Sanborn Company, Cambridge, Mass.)

Observe the deflections of the writing arm through the observing window, and if they are of unusual amplitude, adjust the centering control so that the extreme deflections in the upward and downward directions are about equally distant from the margins of the graph. If the deflections are well within the ruled area of the paper, exact centering is unimportant.

If the stylus drifts or thrashes from side to side, or shows signs of tremor or of electrical interference, turn the selector switch back to "STD" and proceed as directed below under "remedies."

When the apparatus is in order, start the record by turning the power switch to "RUN."

Mark the lead being used by briefly pressing the lead-marking button at the center of the instrument panel, once for Lead I, twice for Lead II, etc.

Register the sensitivity as directed above. Depress the "1 mv" button briefly between two heartbeats. Repeat this in each lead.

Do not disturb the sensitivity control.

Permit the record to run about 8 to 10 seconds, giving 8 to 10 inches of record.

Stop the record by turning the power switch from "RUN" to "ON."

Proceed to Lead II.

Push and hold the Instomatic switch and turn lead switch to "2." In a second, release the switch.

Observe the writing arm movement.

Turn the power switch to "RUN." Mark the lead. Register the sensitivity. Run about 8 to 10 inches of record.

Repeat in the same manner for Lead III.

Continue for the AV lead if so directed. No change of electrodes or electrode connections is required to secure proper registration of the AV leads, except that a connection MUST be made to the patient's right leg, to properly ground the instrument.

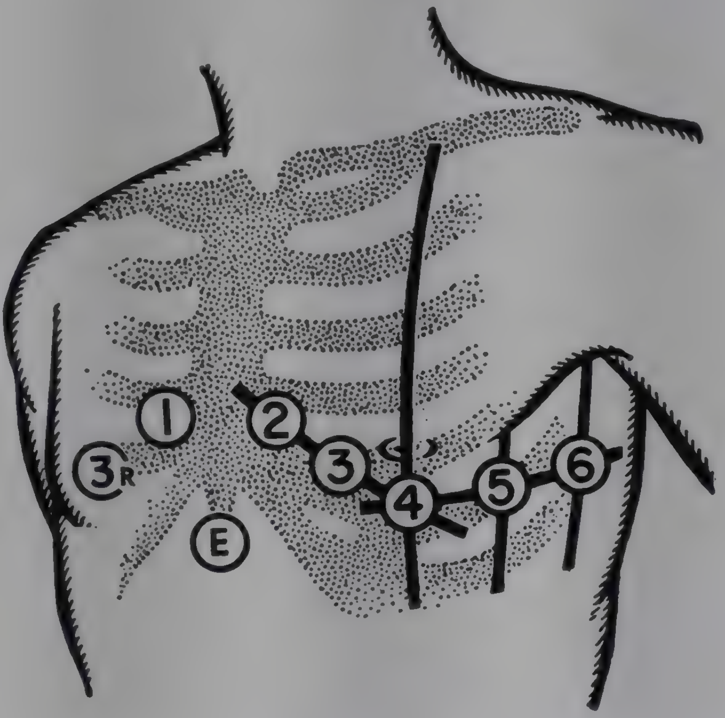

Fig. 731.—Position of electrodes for the chest leads. (Courtesy Sanborn Company, Cambridge, Mass.)

(4) **Chest Leads.**—(See pages 2407 ff. for Unipolar Leads.)

The physician determines and directs which chest leads are to be recorded, and in what sequence. He also determines how many electrode locations are to be recorded. Placing of these locations are shown in Fig. 731.

The Viso lead selector switch is provided with positions for taking both the conventional chest leads (CR, CF, and CL) and the Wilson or Vector return chest leads (V).

The "C" or chest connection must be attached to the chest electrode and placed and held on the chest wall. In addition the RL must be connected to the patient's right leg whenever V chest leads are to be taken, for the purpose of grounding the apparatus.

Before recording any chest lead, carefully observe deflections of the writing arm, and if necessary use the centering control to shift the base line to a position which will keep the deflection peaks approximately equidistant from the edges of the recording paper.

On positions CR, CF, and CL, the switch automatically connects the patient to the instrument for recording conventional chest leads. If the chest electrode has been placed at the apex, position CF will record chest (apex)-left arm, conventionally designated CF_4; CR would represent chest-right arm; and CL, chest-left arm.

The designation "V" is used with reference to the unipolar leads, which record the potential variations at any single point on the body, whether on a limb or at a chest-electrode site. An inactive or neutral reference point is obtained by connecting the three limbs RA, LA, and LL, each through a separate high resistance, to a common junction, which can then be regarded, without significant error, as a reference point of zero potential. This is the circuit suggested by Wilson and associates.[1] The lead selector switch automatically incorporates the ''Wilson circuit'' when turned to the V position.

Connect the exploring unipolar electrode to lead wire ''C'' of the patient cable, and then place at one or more of the chest locations. See Fig. 731. The recordings obtained represent the potentials present at the selected numbered sites, and are customarily referred to as V_1, V_2, etc.

(5) **Special Leads.—**

For esophageal or other special leads, the chest electrode connection is used for the ''exploring'' electrode, with the lead selector switch on ''V'' or on some other position, according to the technic being employed.

To mark these special leads, write directly on the record, designating the lead being taken. This may be done while each lead is being recorded, or on completion of the entire record strip.

In cases of amputations, use the remaining stump if it is long enough to allow the rubber electrode strap to take hold. The right leg may legitimately be subsituted for the left, although the two arms are not interchangeable. In difficult cases, fasten an electrode with adhesive tape on the shoulder or hip where the limb was formerly attached. If the Wilson circuit is to be used with one leg absent, put both the ''RL'' and ''LL'' electrodes on the remaining leg, but at sites separated by six inches or more, and with no electrode paste on the skin between them.

(6) **Recording Chest Leads.—**

To record the various chest leads, after the electrodes have been attached, push the Instomatic switch, and turn the lead selector switch to the desired position.

Record the lead as outlined for limb leads.

While the chest electrode is being shifted, to avoid disturbing the Viso-Cardiette amplifier and thus keep it ready for immediate recording of each chest electrode location, the Instomatic switch is provided with a protective locking feature. Pull the switch toward the operator to the locking position, before moving the electrode, each time a new chest location is to be recorded.

(7) **Completing the Record.—**

Tear down on the record when complete. Return the lead selector switch to STD and turn the power switch to OFF.

Disconnect the patient and sponge off the electrode sites with a damp towel.

Wash the electrodes so the paste residues will not accumulate on them. DO NOT USE STEEL WOOL.

(8) **Cleaning Up.—**

Disconnect the patient from the apparatus and sponge off the electrode sites with a damp towel. Wash the paste residues off the electrodes, but DO NOT USE STEEL WOOL. Dry and store.

(9) **Maintenance of the Instrument.—**

When the Viso-Cardiette is not in use, keep the cover closed, and further protect it with the gabardine slip cover. The **electrodes** must be kept clean and ''shiny-bright.'' Wash thoroughly after each use in hot water, and make sure all the Redux paste has been removed. Dry and replace in the instrument. If necessary, scrub with a scrubbing brush, *NOT* steel wool, using strong soap. Polish with a little Redux paste, wash *thoroughly*, and dry. Clean sandpaper may also be used.

Keep the **patient cable tips** clean in the same manner as the electrodes. Clean periodically with a strip of sandpaper but *NEVER* with steel wool.

No oiling of the instrument is ever required.

---

[1] Am. Heart J. 9: 447, 1933.

To clean the **stylus ribbon**, connect the instrument to power, turn the power switch to *ON* and the lead selector switch to *STD*. Open the paper supply door, lift the stylus off the paper by turning the galvanometer tilting lever counterclockwise, turn the heat control to maximum, and the power switch to *RUN*. Let the paper run through for 10 seconds, holding the stylus off the paper. The excess heat will melt off the plastic accumulation on the ribbon, and a clear, sharp base line will result.

If the base line is poorly defined, this might be due to several factors. (1) Insufficient heat. If the stylus temperature has inadvertently been moved, determine this by running some paper through, while turning the control left and right until the desired blackness is secured. (2) Clean the stylus as directed above. (3) Insufficient pressure. Remove the chassis from the cabinet, turn the knurled thumbscrew, which controls the pressure of the stylus, clockwise until the stylus ribbon clears the paper, then turn it counterclockwise until the ribbon just meets the paper. Place a pencil mark on the thumbscrew to note position and then turn the screw 1¼ additional turns, counterclockwise. (4) If the ribbon is slightly bent, the writing arm must be removed. After removal, place the arm, held near the base, on a flat surface, and *gently* smooth its upper surface to make it evenly flat. Then replace the arm.

To change the recording paper, open the galvanometer viewing window, open the paper drive door in front of the cabinet, swing the galvanometer tilt handle a half turn counterclockwise, and remove spool support bracket by pulling up and out. Raise the tension plate by lifting on the thumb latch until the black roller guide plate can be seen and heard to "snap up." Remove the remaining paper, while still lifting on the thumblatch, by rotating the spool counterclockwise and sliding out the spool with shaft and core. Grasp the core and shaft in one hand, and with the other turn the spool clockwise, and at the same time pull out.

To install new paper, remove the wrapping from the roll of Permapaper. Grasp the roll with one hand and the spool with the other. Push the shaft into the core of the paper roll, at the same time turning the spool clockwise. Continue until the paper is flush against the spool. Lift the tension plate slightly and slide the shaft, with the roll of paper, onto its spindle, pushing in as far as the roll will go. Then turn the spool clockwise so that about an inch or two of paper (no more) with the *unprinted* side *up* projects beyond the tension plate, toward the galvanometer magnets. Using the left hand, rotate the roll of paper on the spindle clockwise while, at the same time, the right hand holds the end of the paper, and guide the paper up and over the horizontal writing paten. Hold the right hand on the paten, and, with the left hand, place the edge of the paper underneath the roller guide plate, working from the top through the open viewing window. Obtain additional slack by rotating the roll of paper clockwise, or by pulling the edge or end gently. If too much slack is obtained, rotate the roll counterclockwise. Holding the roll in position, inspect the paper throughout its exposed length to make sure it is smooth and even. Still holding the paper in position, with the other hand press the roller guide bar down firmly until it snaps into position. Reinstall the proper spool support bracket by placing the slot over the rod in the base, at the same time raising the tension plate slightly. Turn the power switch to ON. While the paper is moving, press and hold the forefinger against the roll of paper. Any slack will now be taken up automatically. If necessary, use the fingers to guide the paper through and out the discharge slot. If the paper does not feed through automatically repeat the process from the beginning. Finally rotate the galvanometer tilting handle counterclockwise one-half turn, and close the viewing window.

UNIPOLAR LEAD ELECTROCARDIOGRAPHY

In the last ten years, there has been a steadily increasing interest in and awareness of the important unipolar lead electrocardiography so that at present this method has been universally adopted. These leads have been shown to be advantageous for a number of reasons. Among the most important is the light that they have thrown on the significance of abnormalities of the Q waves, particularly in Lead III in the diagnosis of posterior wall infarction, the differentiation of pulmonary artery obstruction from posterior myocardial infarction, the diagnosis of bundle branch block, right ventricular hypertrophy, and the detection of abnormalities when the standard lead electrocardiogram is normal or shows questionable changes. The effect of changes in position of the heart are particularly demonstrable with these leads.

Method of Taking Unipolar Leads.*—

A unipolar lead is one which represents the heart voltages present at *one* particular spot on the body with respect to a nonfluctuating reference point. This reference point is secured by connecting the limb electrodes together through three equal resistances of 5,000 ohms or more; the junction is the reference point, or central terminal, which is usually embodied in the lead selector of the electrocardiograph, or in a special switching box.

The electrodes placed on the body are then paired, in turn, with this reference point or central terminal, to secure the unipolar leads which represent the actual voltages present at these single points on the body.

With limb leads, however, these voltages may be rather small, so that special steps must be taken to secure a record with complexes of sufficient height or amplitude for easy and accurate measurement.

Leads V_R, V_L, V_F:

Leads V_R, V_L, and V_F are unipolar limb leads, in which the pairing is achieved by placing an additional ''exploring'' electrode (normally attached to the ''C'' wire of the patient cable) on the limb being measured, slightly removed from the electrode already in place. Do not allow electrode jelly to communicate between electrodes.

With the lead selector switch placed on V, a unipolar limb lead will be secured. Special steps must be taken to produce a record with complexes of ''readable'' amplitude. Therefore, in taking these leads, it is customary to increase the sensitivity of the electrocardiograph by 50%, or from 1 cm./mv. to 1.5 cm./mv. Allowance must be made for this increase, since the amplitude of the waves will show a voltage of 1.5 times that which is actually present at the location being recorded.

''R'' designates the right arm, ''L'' the left arm, and ''F'' the left leg (or foot).

Leads aV_R, aV_L, aV_F:

Leads aV_R, aV_L, and aV_F are also unipolar limb leads, and now are the ones most widely used. They are referred to as ''augmented'' unipolar limb leads.

No special placement of electrodes is required, nor is it necessary to change the sensitivity of the electrocardiograph to secure the increased or ''augmented'' height of the complexes. All necessary functions are performed automatically within the instrument, or within a special lead selector box, interposed between the patient and the electrocardiograph.

Turn the switch to the desired position—aV_R, aV_L, aV_F—to obtain the augmented unipolar limb leads.

The terminal letters designate the extremity, and are paired with the central terminal or reference point.

Allowance must be made in measurement and interpretation for the 1.5 cm./mv. increased sensitivity.

---

*With permission of Sanborn Company, Cambridge 39, Mass. From a bulletin entitled "Nomenclature and Derivation of All Presently-Used Leads" (1953).

Leads V_1, V_2, etc.:

Leads V_1, V_2, etc., are unipolar chest leads. They are achieved by pairing a point on the chest wall (see Fig. 731) with a neutral of zero reference point.

The subordinate numerals—V_1, V_2—are used to designate the position of the chest or exploring electrode.

Leads V_{3R}, V_{4R}, etc.:

Leads V_{3R} and V_{4R} are unipolar chest leads, as described above, but taken from positions on the chest wall to the right (R) of the sternum.

High V Leads:

High V leads are unipolar chest leads, taken with the chest or exploring electrode at positions on the chest wall one interspace above positions V_{1-6} and designated as high V_3, high V_4, etc.

V_E or V Ensiform Lead:

V_E or V ensiform lead is a unipolar chest lead, taken with the exploring electrode placed on the chest wall at the ensiform (base of sternum) position.

Because of the method by which unipolar leads are obtained, their patterns can be explained in terms of easily understandable principles.

Since the indifferent electrode (of Wilson) is for practical purposes zero (though not absolutely so), the actual values of the potentials at each extremity can be determined with unipolar leads. This is in contrast to the conventional bipolar leads (the Leads I, II, III, and the conventional chest leads), in which the potential recorded is the *difference* in the potential generated at each of the two electrodes in the bipolar leads.

In general, the relationships of the standard leads and the unipolar extremity leads are such that one type can be derived from the other as follows. The pattern of Lead I would be the potential values at the left arm (V_L) minus those at the right arm (V_R). The values of the potentials in Lead II would be the potentials recorded at the left leg (V_F) minus those at the right arm (V_R). The potentials recorded from Lead III would be the values derived from the left leg (V_F) minus those from the left arm (V_L). Thus it can be seen that the three standard bipolar leads consist of the algebraic summation of the unipolar leads.

Unipolar limb leads localize the electrical activity of the various areas of heart muscle. Thus, a unipolar lead from the left arm (V_L) records the potentials generated in the left lateral wall of the heart; a unipolar lead from the left leg (V_F) records the potentials produced at the diaphragmatic surface; the unipolar lead from the right arm reflects the potential variations of the atrial and ventricular cavities. Change in position of the heart with consequent altered relationships of the positions of these various regions of the heart with respect to the unipolar electrodes would alter the configurations of the electrocardiographic patterns in certain well-defined ways according to whether the heart is vertical, horizontal, or rotated either clockwise, counterclockwise, or backward or forward. It is beyond the scope of this chapter to describe and illustrate the different patterns of the unipolar leads according to the various positions of the heart and the modifications of these patterns produced by disease processes. This phase of electrocardiography has been thoroughly described in many books devoted to this subject.

INTERPRETATION OF THE ELECTROCARDIOGRAM

THE NORMAL ELECTROCARDIOGRAM[1]

The electrical activity in the heart muscle which precedes each contraction of the heart produces deviations in the electrocardiogram which are in general similar for all normal electrocardiograms. Nevertheless the electrocardiogram of every individual exhibits minor variations which are almost as characteristic for that individual as are his fingerprints. This is true only in so far as no alteration in the physiologic or anatomic state of the heart has occurred. The many variations of the normal electrocardiogram must be studied in order that proper interpretation of tracings may be made. Not infrequently erroneous conclusions, with all their serious implications, have been drawn by inexperienced persons who attributed minor deviations within the normal limits to organic heart diseases. Mistakes have also been made in the improper differentiation of abnormal tracings due to altered physiologic states from those due to actual organic disease.

Waves.—The series of waves seen in electrocardiograms of normal heart cycles was arbitrarily named by Einthoven as the P, Q, R, S, T, and U waves. This is the conventional terminology which has been universally adopted.

The form, amplitude, and direction of the different waves vary in the different leads. The amplitude of the deflections in Lead II is equal to the sum of the amplitudes in Leads I and III. This knowledge is helpful in correcting errors which are sometimes made in labeling and mounting electrocardiograms of the conventional three leads.

The P wave is produced by electrical activity spreading through the auricles. It is a small, rounded deflection which varies in height from 0.5 to 3.0 millimeters, representing 0.05 to 0.3 millivolts. Duration or width of this deflection normally does not exceed 0.1 second. At the end of this deflection when the string shadow has returned to the baseline or isoelectric level, there is a period in which there is no deflection whatsoever from the isoelectric level until a group of sharper, taller waves, the QRS complex, appears.

The QRS deflections are due to the onset and spreading of electrical activity throughout the ventricles. The interval between the onset of the P wave and the onset of the QRS complex is called the P-R or P-Q interval. The Q wave is often absent normally; under these circumstances the P-R interval is measured from the onset of the P wave to the onset of the R wave. If the Q wave is present, this interval is called the P-Q interval and is measured to the onset of the Q wave.

During this P-R interval the impulse is traveling through the auricles to the ventricles along a set pathway known as the bundle of His and the A-V node. The P-R interval measures this time, which is normally from 0.12 to 0.20 second. The QRS complex varies normally in certain respects—whether the initial deflection is directed upward or downward, whether the terminal deflection is downward (invert), or whether there are several upward or downward deflections. By convention the first deflection, if upright, is known as the R wave; if downward, the initial deflection is known as the Q wave.

The downward deflection which follows the R wave is known as the S wave. The S wave may often be absent. Not infrequently a second upward deflection occurs following the S wave. It is known as the R prime (R′) wave. If there is still another downward deflection following the R wave it is called the S prime (S′) wave.

Since the QRS complex represents the *spread* of the action current throughout the ventricular musculature from start to finish, the time interval from the onset of QRS, whether it begins with a Q or with an R, to the end of its final deflection, either with an R or with an S, measures the speed of this electrical impulse through the ventricles. Normally this time interval does not exceed 0.10 second.

---

[1] Assemblage of tracings in this chapter by Margaret Peteler, Technician in Electrocardiographic Laboratory of Jewish Hospital of St. Louis.

The R wave normally varies in height from 5 to 15 millimeters. After the electrical disturbance represented by the QRS has subsided, there is a segment, known as the S-T segment, which is usually isoelectric and of rather variable length; it ends in a rounded wider deflection known as the T wave. The ventricles are depolarized for the duration of the S-T segment and have not begun to recover their state of electrical excitement. This duration varies greatly depending upon heart rate, age, and sex.

The interval from the beginning of the QRS complex to the end of the T wave is known as the Q-T interval. It represents the duration of the spread of the electrical excitation and then the recovery from this state of the ventricular musculature. This varies with heart rate, age, and sex, but for normal rates it is usually about 0.4 second. The T wave, which is the final evidence of electrical imbalance in the ventricles, represents the phase of recovery from electrical excitation in the ventricles. During the period of the T wave the musculature approaches and reaches the completely polarized state. At the point of complete polarization the T wave has receded to the isoelectric level, and there are no deflections because the electrical potential is equal throughout the ventricles. The T wave in normal electrocardiograms is upright in Leads I and II, but in Lead III (called the "lead of exceptions" because of its variability under normal conditions) it may be upright or inverted. The amplitude of the T wave for the conventional leads varies from 1 to 6 millimeters.

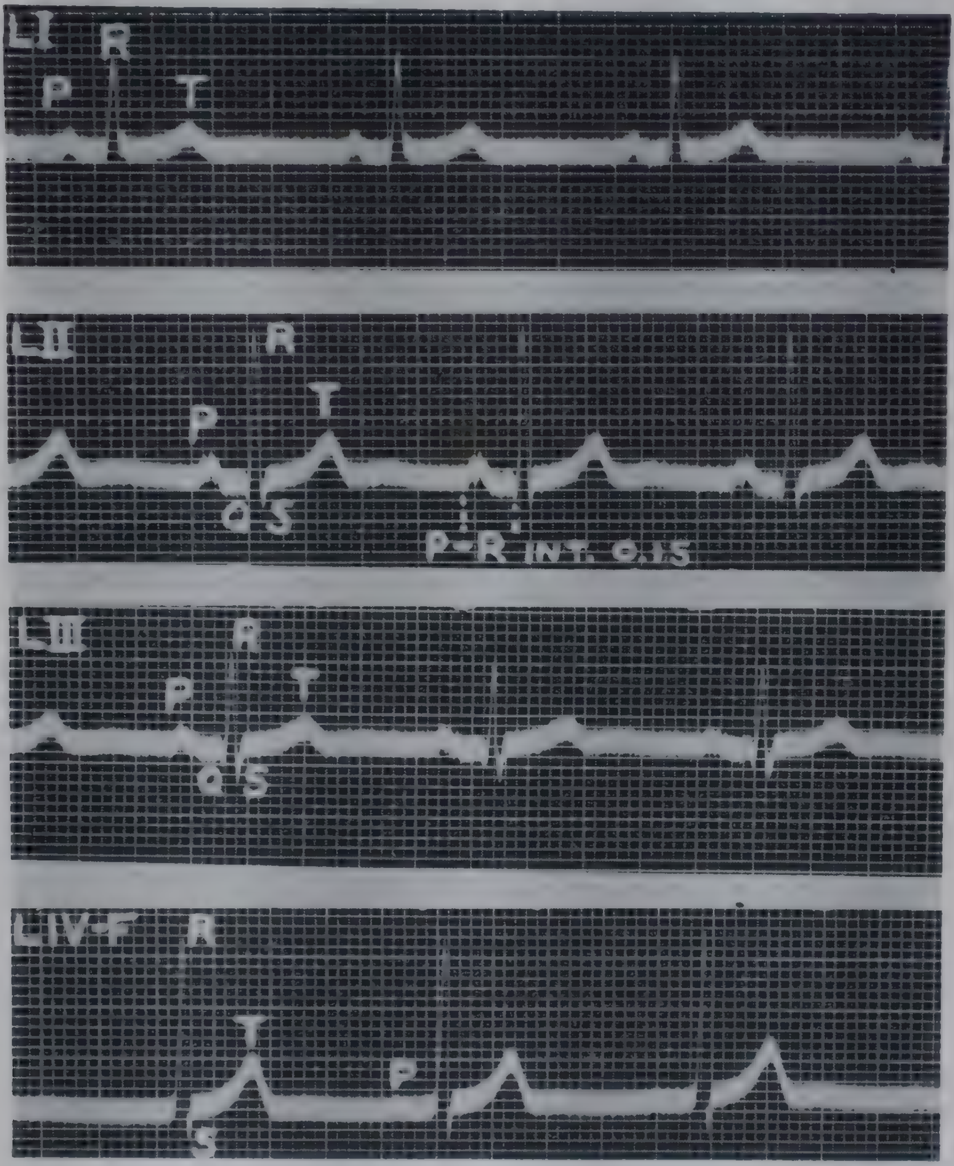

Fig. 732.—Normal electrocardiogram. P, Q, R, S, and T waves appear in proper relationship and are of normal configuration and amplitude. Note that the amplitude of T in Lead II approximates the sum of the amplitudes of T in Lead I and Lead III. Note the practically isoelectric P in Lead IV F which is a normal occurrence. Absence of Q in Lead IV F is normal. Presence of a QIV of 2 or more mm. is abnormal.

A low upward wave often shortly follows the T wave. This is known as the U wave. Thus far the cause of this deflection has not been definitely ascertained. The U wave occasionally is inverted. When large or asymmetrical, it is sometimes associated with myocardial damage.

The chest or standard bipolar and most recently unipolar precordial leads have come into common clinical usage since 1932. They have been invaluable in the diagnosis of myocardial infarction. Two electrodes are used to take bipolar precordial leads. One, the exploring or chest electrode, is placed in various positions to be described. The other, the indifferent electrode, is placed over a point distant from the heart.

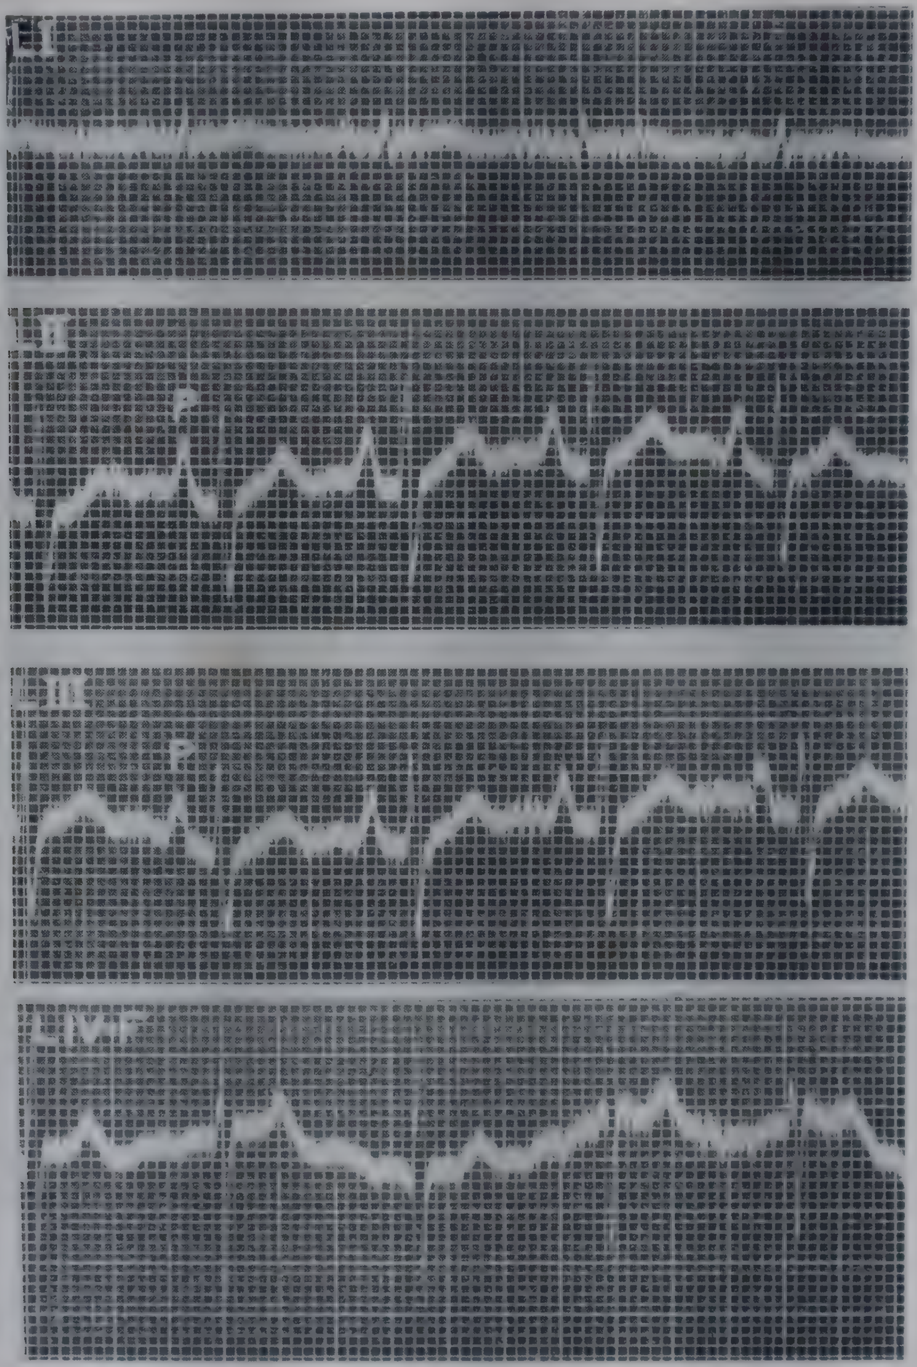

Fig. 733.—Artefacts due to muscular tremors. In addition to the artefact characterized by fuzziness of the tracing due to muscular tremor, note the prominent sharply peaked P waves in Leads II and III characteristic of the so-called P-pulmonale.

There are various types of bipolar chest leads each designated according to the position of the chest (exploring) electrode and the indifferent electrode. These various positions of the electrodes are designated as follows: The Roman numeral IV is used to indicate a chest lead, and a letter follows the numeral IV to indicate the position of the indifferent electrode. If the indifferent electrode is on the left leg, the lead is called IV F; if on the right arm, it is IV R; if on the left arm, IV L; and if on the back, IV B. Another type of lead which is most accurate is that advocated by Frank Wilson and his co-workers. It is a central terminal lead or V lead. In this lead the indifferent electrode is formed by connecting the right arm, left arm, and left leg electrodes together. This type of connection is advantageous in that the potential of this indifferent electrode is more nearly zero than when the indifferent electrodes are placed otherwise, where the current from the heart exerts some influence on the distant electrode though not nearly so much as on the exploring or chest electrode.

The chest lead may be recorded with the exploring electrode placed over different areas of the chest in relation to the heart. These positions on the chest are designated by numerals following the letters indicating the type of chest lead. They include the first letter C to indicate a chest lead, followed by the letters F, R, L, B, or V to indicate the position of the indifferent electrode as described above.

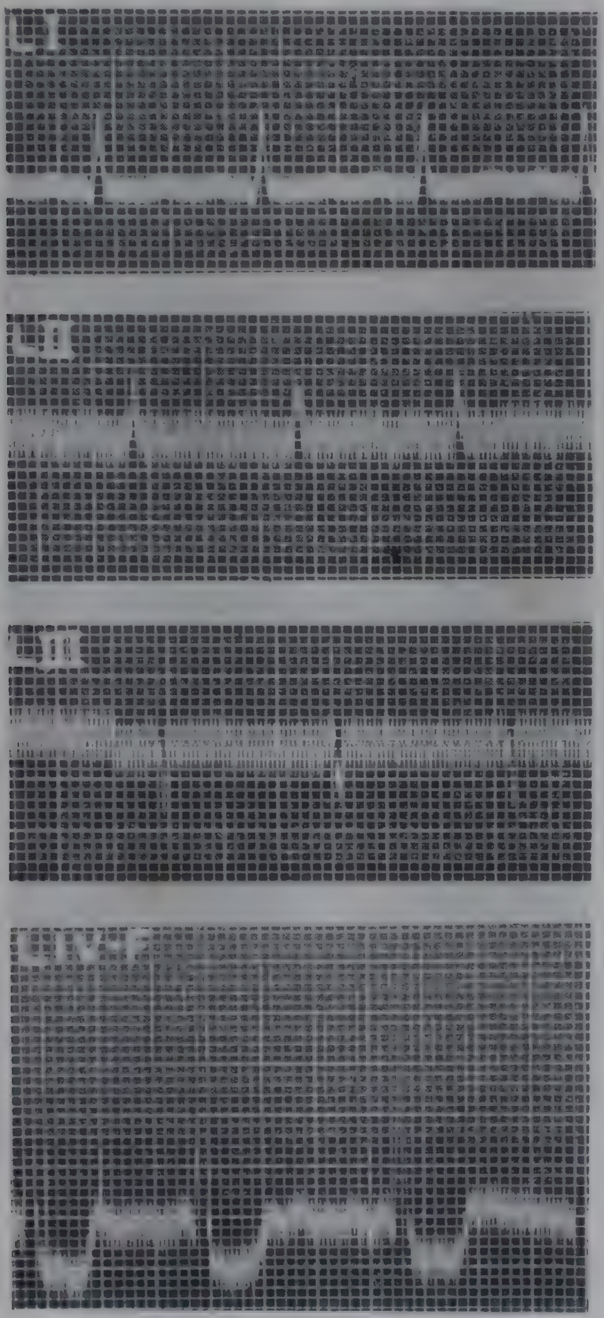

Fig. 734.—Artefacts due to interfering alternating current. This is evident chiefly in Leads II, III, and IV F.

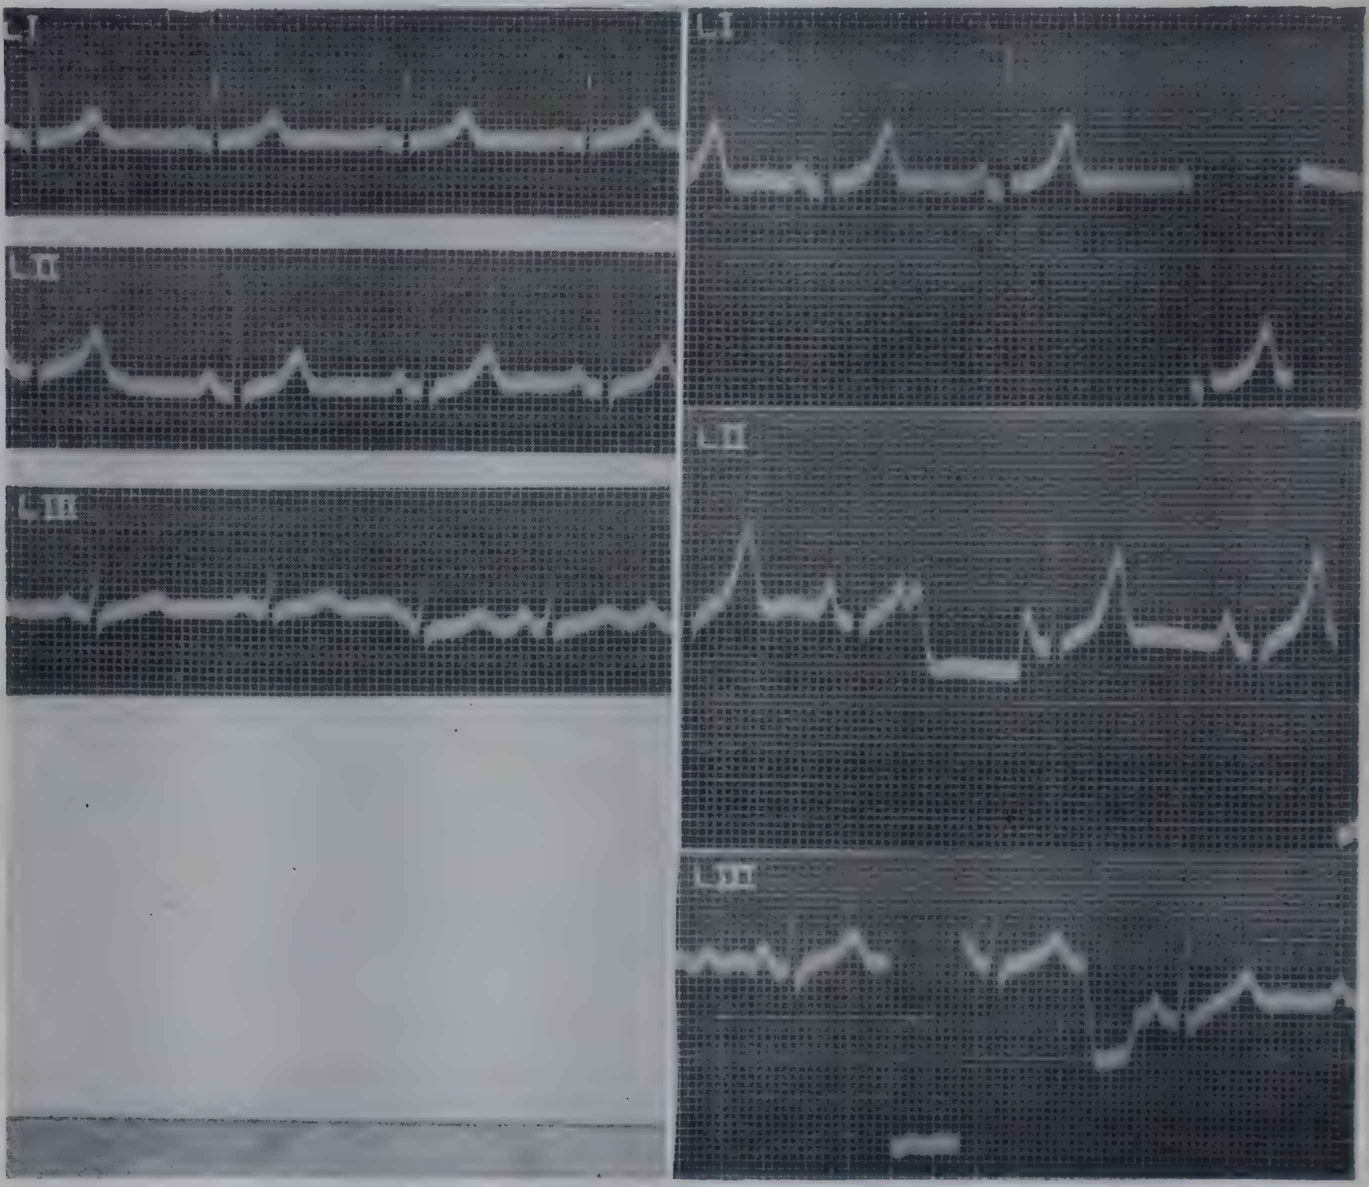
If the chest electrode is placed in the fourth intercostal space just to the right of the sternum, the numeral I then follows. If the position is the fourth interspace just to the left of the sternum, the numeral II is used. When the position of the chest electrode is midway between that of numeral II and the midclavicular line in the fifth interspace, it is designated as III. Position IV is the fifth interspace, midclavicular line; position V is at the same horizontal level in the left anterior axillary line; position VI, the same horizontal level as V, left midaxillary line.

If, for example, the indifferent electrode is placed on the left leg, the various chest lead positions are recorded as CF_I, CF_{II}, CF_{III}, CF_{IV}, CF_V, and CF_{VI}, respectively.

To clarify these designations, let us emphasize the distinction between the leads CF_{IV} and IV F. With the first designation, the chest electrode is always in the fifth interspace, left midclavicular line; with the latter the chest electrode is placed over the heart apex wherever it may happen to be.

Various positions on the chest are utilized because it has been found that some lesions of the myocardium are more apt to be reflected when the chest lead is placed in one position than when placed in another. Positions for the chest lead other than those previously described may sometimes be advisable when attempting to localize the site of the lesion or to determine the type of bundle branch block, if present.



A. *B.*

Fig. 735.—Artefacts due to a loose string. In *A* the electrocardiogram has been properly standardized. In *B* the string has been overstandardized, the string being much too loose. Note that the P, QRS, and T waves are altered in size and form.

As stated above, esophageal leads are sometimes desirable. In these instances a specially designed exploring electrode is swallowed until it reaches the level of the heart. The P waves are prominent in esophageal leads; for this reason this lead may be decisive in determining the nature of an arrhythmia in which P waves cannot be definitely identified in the conventional leads. This lead may also be of value in identifying posterior myocardial infarction, since the esophagus is more nearly in apposition to the posterior ventricular wall.

The appearance of the normal tracing taken with the chest leads varies in many details with the position of the electrodes. It is important, therefore, that the electrocardiographer familiarize himself with these normal variations. Since these variations are discussed in full in books devoted to electrocardiography they are not presented in this chapter. The characteristics of Lead IV F are briefly described because Lead IV F is the one that has been used in taking the electrocardiograms reproduced in this chapter. In the last several years the unipolar chest leads (V leads) have generally replaced Lead IV F in common usage. What is said in describing the characteristics of the IV F largely applies to the analogous unipolar chest leads (V_4).

Characteristics of Waves in Lead IV F.—The P wave is usually quite small and may be inverted, diphasic, or upright. In most instances it is inverted.

The P-R interval is as described for the conventional leads.

The QRS complex is usually of greater amplitude and tends to be slightly greater in duration than in the conventional leads. If R is less than 1 mm. in height, it is considered definitely pathologic. The S may be greater in amplitude than R, normally.

Q is usually absent but when present is not greater than 2 mm. in depth. A Q wave deeper than this is usually significant of myocardial damage as a result of coronary artery involvement. If a Q wave is present in Lead I, there tends to be a Q in Lead IV F.

The S-T segment may be short or absent, and normally is often elevated to a slight degree.

The T wave is characteristically larger than in the conventional leads, usually 5 to 7 mm., and is almost always upright in the adult. In young children the T wave is not infrequently inverted. Although it has been stated that the T wave is rarely notched or diphasic it has been Elson's experience on occasions to find notched and even slightly diphasic and inverted T waves in the absence of organic heart disease.

The U wave is often quite prominent in Lead IV and at times its appearance shortly after the T wave gives a simulation of a terminal diphasic tendency to the T wave.

In CF I, T is normally often inverted, R is usually of low amplitude, and S is relatively deep. In CF_4, which is taken with the electrode in the midclavicular line, fifth interspace, the appearance is the same as in IV F with the electrode over the apex, provided the apex is in its usual position in the midclavicular line, fifth interspace. Leads CF V and CF VI give an appearance similar to that of Lead I except that the amplitudes of R, S, and T tend to be smaller. The rule is that with the exploring electrode to the right of the sternum the tendency is for R to be small, S to be deep, and T to be inverted; and as the electrode is moved to the left axillary line the R becomes relatively tall, the S relatively small, and the T upright.

Common Technical Difficulties.—In order that a proper electrocardiogram be recorded it is necessary, when making the tracing, to understand some of the common technical difficulties which may cause artefacts or external deformities of the record, making proper interpretation difficult or impossible.

1. **Deformities due to muscular movement of the patient.** The movement of an arm or leg may cause slipping of the electrode over the skin, with sudden marked or slight shifting of the string from the base line. Slighter muscular contractions such as muscular tremor produce smaller, very irregular vibrations in the string shadow.

2. **Deformities due to changes in skin resistance and polarization of the electrodes.** These are characterized by a more gradual undulating shifting of the base line.

3. **Deformities due to improper grounding of the electrocardiograph and interfering induction currents.** These artefacts are characterized by regular vibrations due to 60 cycle alternating current at a rate of 60 times a second.

4. **Deformities due to a loose string.** If the resistance of the skin is too high, the string must be loosened to an unusual degree in order to standardize it. This prevents the string from stopping abruptly when a millivolt of current is added to the circuit so that the string ''overshoots'' or deviates above or below the proper amplitude. This would result in abnormally high amplitudes, slurring, and widening. When this occurs, the electrodes must be reapplied. The skin must be prepared more thoroughly, using electrode jelly to reduce skin resistance further. Overshooting must be watched for when taking each lead of the string galvanometer instrument.

5. **Deformities due to loose contacts.** Loose contacts at any place in the circuit may also cause sudden shifting of the base line.

Measurements of Amplitude, Heart Rate, Intervals, and Duration of Complexes

The duration of the P wave is measured from its convex surface at the instant it rises or falls from the base line to the moment it returns to this level. The duration of the QRS complex is measured from the beginning of the Q wave on its convex surface to the end of the R or S wave at its convex surface. The convex surface is used for making all other interval measurements such as P-R or P-Q, Q-T, and T.

The amplitudes of the upright deflections are measured from the upper surface of the base line to the upper surface of the topmost portion of that wave which is being measured. The inverted waves are measured from the lower surface of the isoelectric level to the apex at its lower surface. Duration and voltage of a complex are accepted as that measured in the lead in which they are the greatest.

Many ways of estimating the rates of the ventricles or auricles have been described. A convenient method is to count the number of time lines lying in the space of four cycles, either auricular or ventricular. Then 6000 is divided by this figure; the result gives the rate of the auricles or ventricles, according to which complexes were measured. Since the time lines are divided into groups of five by each heavy line (see above), it is convenient to begin measuring the four complexes where the first one falls on a heavy time line and then to count the heavy time lines, each representing groups of five, until the fourth complex is reached, and figure accordingly.

THE ELECTROCARDIOGRAM IN DISEASE AND IN DISORDERED PHYSIOLOGIC STATES

The electrocardiogram can be altered in many respects both by disease processes localized to the heart itself, and by general constitutional disorders. While many of these disease states cause electrocardiographic alterations which are nonspecific for that disease, there are others which are pathognomonic or highly suggestive of disease. The picture of acute myocardial infarction, for example, is usually characteristic. The location of this lesion can often be ascertained with a high degree of accuracy from the electrocardiogram alone. On the other hand, degenerative changes involving the myocardium, general constitutional disease, toxic agents, and even psychogenic factors may produce alterations in the electrocardiogram which are indistinguishable from each other.

The most significant changes in the electrocardiogram are those involving the QRS and T waves; in other words, those involving ventricular contraction. The size, shape, direction, and duration of the complexes depend on several factors. The relative thicknesses of the right and left ventricular muscles, for instance, determine whether the direction of the main deflection of QRS is up or down in Leads I or III. Certain diseases of the cardiovascular system alter the relative thickness of the right and left ventricles in characteristic fashion. The origin of the impulse which the muscle, auricular or ventricular, receives also determines the size, shape, and duration of the complexes. If, for instance, the impulse stimulating the auricles to contraction arises in the auricle in a point other than the normal location, the P wave will be altered in direction, size, or shape, and in its time relationship to QRS as well, since the time necessary for the impulse to reach the ventricles will be altered. It is normal for the impulse stimulating ventricular contraction to arise from a point above the ventricular musculature proper. As long as this obtains, the QRS and T complexes maintain a form, size, duration, and direction that is usual for this patient. If, however, a stimulus should arise in the ventricular muscle itself, the shape, size, duration, and direction are altered in a bizarre fashion, depending on the location of the exciting impulse in the ventricles. The T waves alone may be altered by multitudinous causes ranging from drinking cold water, psychogenic influences, or drug effects to serious organic disease involving the ventricular muscle. Any condition involving the pathway of conduction from the auricles to the ventricles may increase the duration of the P-R or P-Q interval.

In the same way, any disease or toxic process which impedes the conduction of the impulse as it spreads through the ventricles will cause increased duration of the QRS complex. The level and form of the S-T segments may be altered in certain characteristic respects by disease or toxic influences. Disordered rhythms of the heart, usually involving abnormal sites of impulse formation, and occurring as a result of a wide variety of organic and functional disturbances of the heart, give characteristic electrocardiographic patterns.

It is not our purpose here to give in detail the many patterns of electrocardiographic alterations that may occur. The electrocardiogram in the main types of cardiovascular diseases only will be discussed. An understanding of the pathologic physiology of disease is necessary in order to interpret abnormalities of the electrocardiogram.

Disturbances in depolarization and repolarization of heart muscle are caused by numerous factors both physiologic and pathologic; often these are manifested merely by lowering or inversion of the T wave. This change in T wave may not be specific for any type of lesion and may be caused by factors ranging from psychogenic influences to fibrosis resulting from long-standing and progressive coronary occlusion. In many cases it is possible to gain valuable clues to the nature of the disease by making serial electrocardiograms. With certain physiologic states, toxemias, and drugs, the T wave changes are reversible; with organic disease, such as fibrosis of the myocardium, the changes are permanent. Often when serial electrocardiograms are taken, the electrocardiograms undergo characteristic pattern changes which are pathognomonic of acute myocardial infarction. These changes involve the S-T segment and T wave primarily, and the QRS less strikingly.

Clues to the types of disease may be obtained if one understands the effects of disease in causing strain on the various chambers of the heart. Strain on the left ventricle, on the right ventricle, and on the auricles, with the consequent increase in muscle mass, produces characteristic evidence in the electrocardiogram. Some diseases or drugs are likely to exert their effects primarily on the conduction system, so that the presence of increased P-R conduction time will often give a clue to the disease or drug involved.

Axis Deviation.—Many cardiac diseases involve changes in relative size of the right and left ventricles with consequent effect on the electrical axis of the heart. This electrical axis may also be altered by changes in the position assumed by the heart in the chest cavity. Thick chested, sthenic individuals, with diaphragms that tend to be high, often have hearts that lie transversely in the thorax, whereas slender individuals with long chests often have hearts that assume a more nearly vertical position with consequently a different electrical axis with respect to the conventional leads. Since deep inspiration alters the position of the heart it therefore affects the electrical axis. This applies to changes in position of the heart occasioned by extracardiac lesions such as pneumothorax, fluid in the chest, pulmonary collapse, fibrosis with pull on the mediastinal structures, etc.

It thus becomes important to determine alterations in the normal electrical axis of the heart. When the largest deflection of QRS is upright (R) in Lead I and invert (S) in Lead III, this indicates the presence of left axis deviation. See Fig. 736. When the largest deflection of QRS is upright (R) in Lead III and invert (S) in Lead I, right axis deviation is present. See Fig. 737. Left axis deviation is present in any condition that causes relative enlargement of the left ventricle over the right.

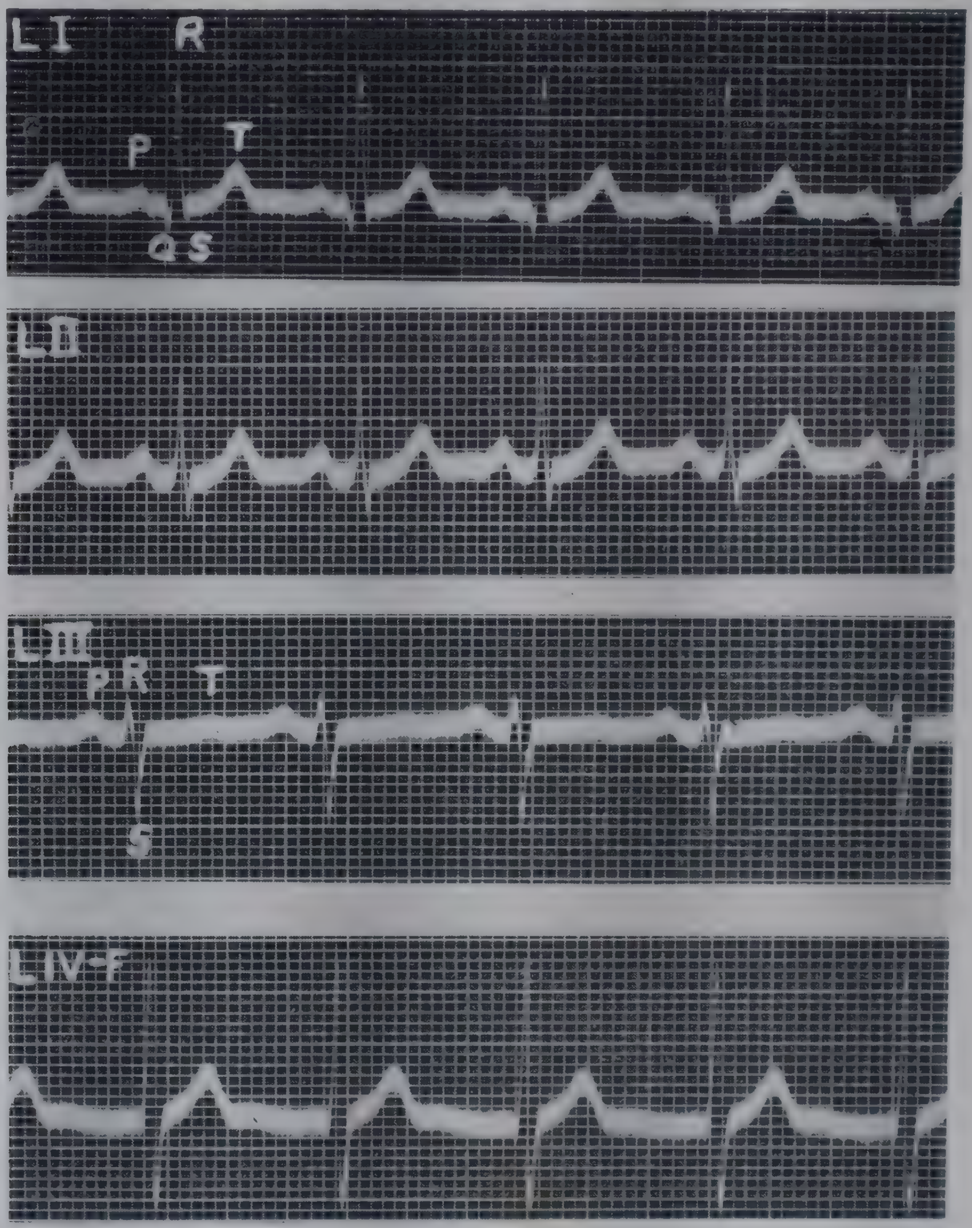


Fig. 736.—Left axis deviation. Note that the chief deflection in Lead I (R) is upright and the chief deflection in Lead III (S) is inverted. A small R is present in Lead III. In more marked degrees of left axis deviation R in Lead III may be entirely absent.

Right axis deviation occurs when there is relative enlargement of the right ventricle over the left. A transversely placed heart in which the apex lies more to the left produces the picture of left axis deviation. A vertically placed heart tends to produce a picture approaching right axis deviation. In young children, when the right ventricle is relatively thicker in relation to the left, the picture more nearly approaches right axis deviation, but, with age, as the left ventricle thickens, the picture of left axis deviation may finally be produced.

Deep inspiration will often cause a deeply inverted deflection (S) in Lead III to disappear, and abolish the picture of left axis deviation by producing a vertical position of the heart. If the right and left ventricles both enlarge and maintain their normal relationship with respect to size, then no change in electrical axis may occur. The occurrence of axis deviation can be helpful in determining the presence or absence, and the type, of valvular disease, since it is known that certain types of valvular disease tend to produce right axis deviation, whereas others tend to cause left axis deviation. The characteristic murmurs of these valvular deformities, or of congenital anomalies as well, may be absent or confusing; the finding of axis deviation suggestive of one or the other valvular condition may be decisive in the diagnosis. Changes in axis deviation associated with various types of cardiac pathology are mentioned in the discussion of electrocardiographic patterns found in the main classes of cardiac

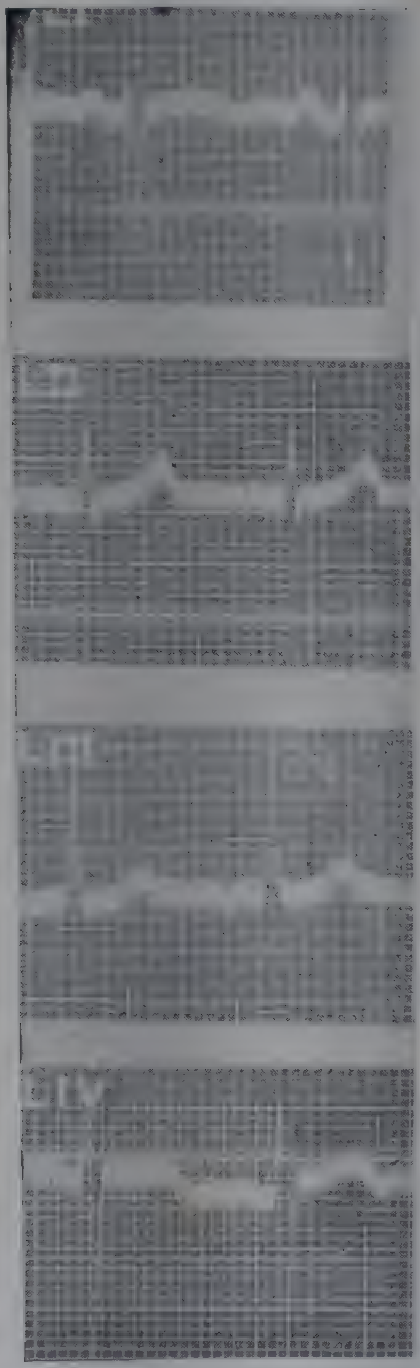

Fig. 737.—Right axis deviation. Note that the chief deflection (S) is down in Lead I and up (R) in Lead III. The R is small in Lead I but may be entirely absent.

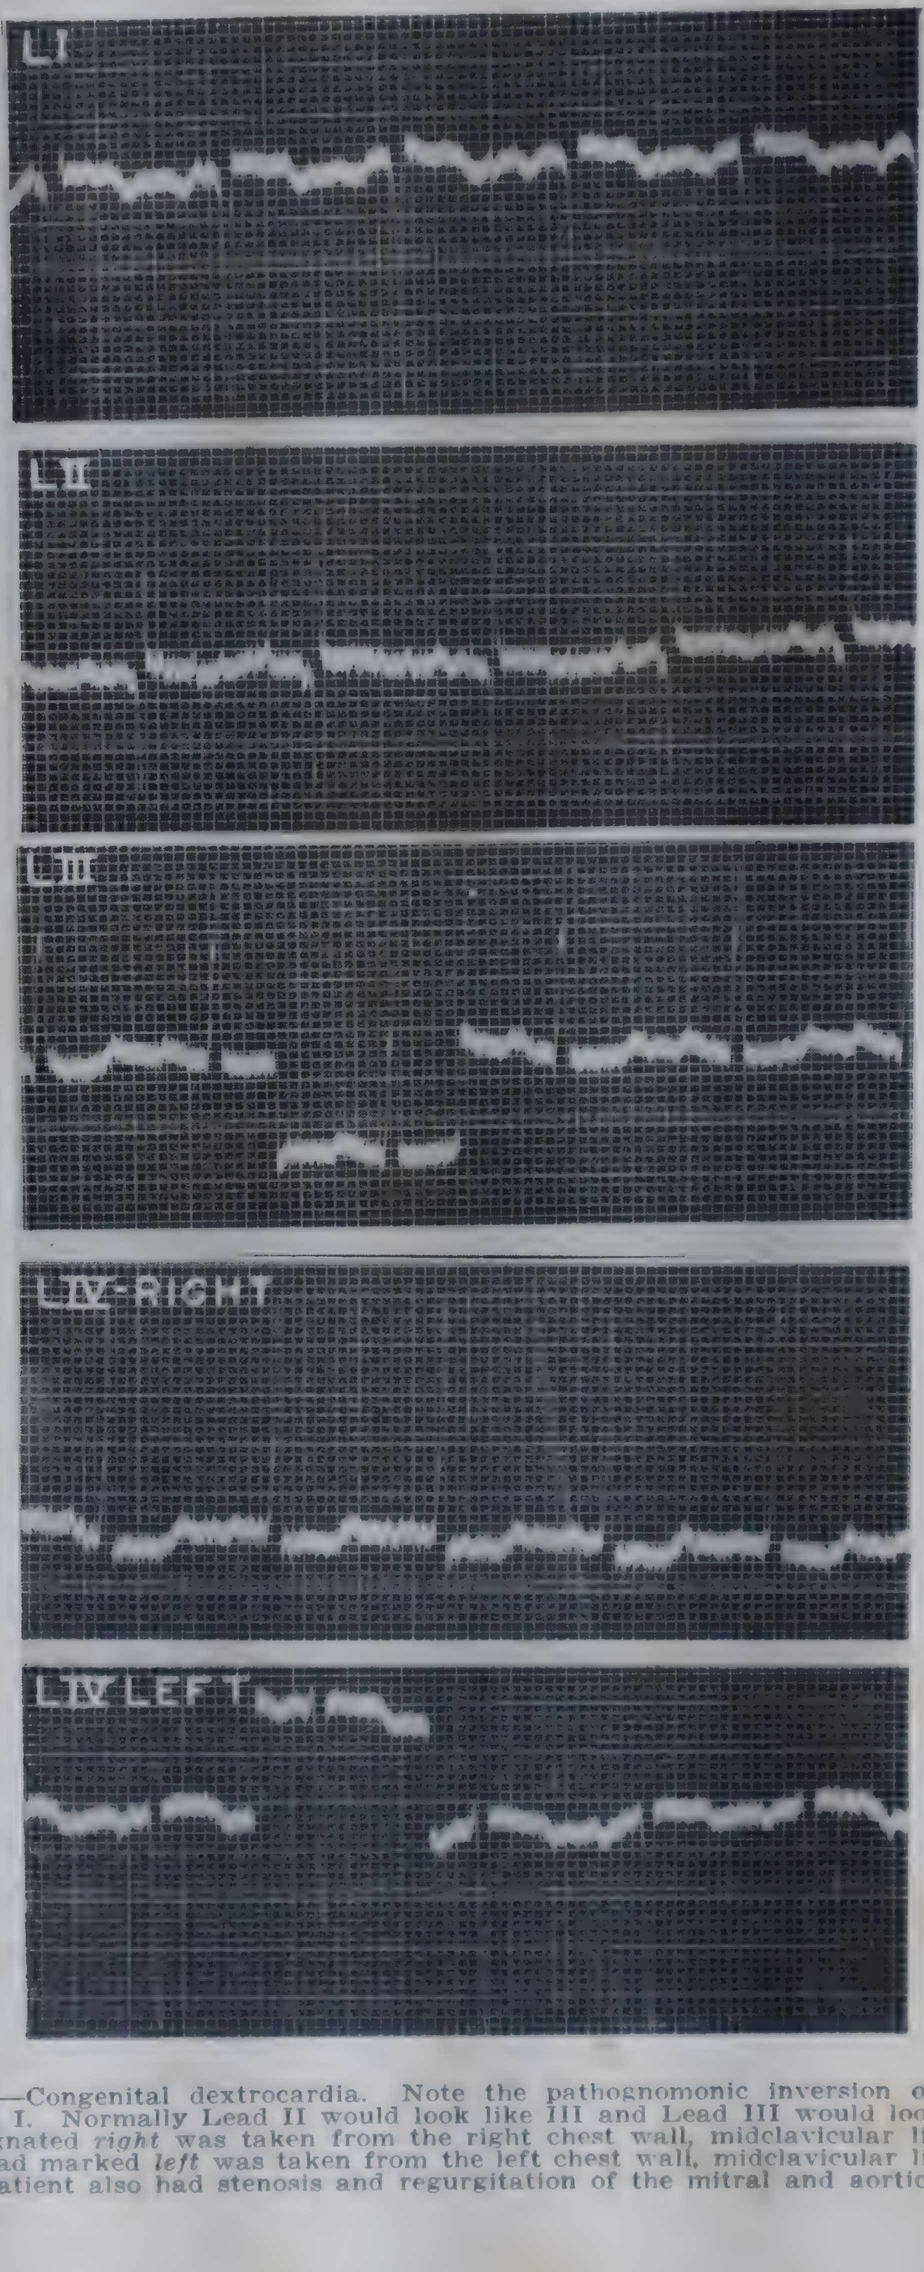

Fig. 738.—Congenital dextrocardia. Note the pathognomonic inversion of all the complexes in Lead I. Normally Lead II would look like III and Lead III would look like Lead II The lead designated *right* was taken from the right chest wall, midclavicular line—fifth interspace. The lead marked *left* was taken from the left chest wall, midclavicular line—fifth interspace. This patient also had stenosis and regurgitation of the mitral and aortic valves.

diseases. It is well to emphasize that left axis deviation may often be a normal occurrence. In these instances T_1 is upright, T_3 inverted, and S_{II} is absent or very small.

There are several methods for calculating the electrical axis of any electrocardiogram. The three most commonly used are: (1) Einthoven's triangle; (2) the triaxial reference system; and (3) Dieuaide's chart. These methods are well described in monographs devoted to electrocardiography and its underlying theories.

Congenital Heart Disease

The most striking and characteristic electrocardiographic changes occurring in congenital heart disease are those found in true congenital dextrocardia (right-sided heart). In this condition all the complexes in Lead I are inverted, Lead II resembles a normal Lead III, and Lead III resembles a normal Lead II.

Diagnosis of congenital dextrocardia may be made with absolute certainty from the electrocardiogram alone if the electrocardiographer can be sure that the technician who took the tracing did not reverse the arm leads, erroneously connecting the right arm lead wire to the left arm electrode, and the left arm lead wire to the right arm electrode. Unfortunately this careless technical error is by no means a rare occurrence. It behooves all those who are responsible for making electrocardiograms to check carefully all lead wires several times to make sure that no such errors will be made.

Other congenital anomalies which commonly result in electrocardiographic changes are congenital pulmonary stenosis and defective interventricular septum. These conditions cause well-marked right axis deviation. The QRS complexes are of much greater amplitude than usual. Congenital heart block may occur in which the auricular complexes (P) have no constant relationship whatsoever to the QRS complexes; in other words, the ventricles contract independently of the auricles because the stimulus from the auricles is blocked off somewhere in the conduction pathway from the auricles to the ventricles.

Rheumatic Heart Disease

Rheumatic fever may cause changes in the endocardium, chiefly the valves, the myocardium, or the pericardium; or changes may occur in all these structures at the same time. One of the most characteristic electrocardiographic effects of rheumatic fever in its acute stage is involvement by the acute inflammatory process of the auriculoventricular conduction system. This results in delay in auriculoventricular conduction with a subsequent increase in the P-R interval. This depression in conduction with consequent increase in P-R interval may be very slight; or it may become so marked that the ventricles do not receive any impulse at all from the auricles. Thus they do not contract in response to auricular stimulation so that one may see a P wave (auricular) without its corresponding QRS complex.

These varying degrees of increased P-R interval represent what is known as *heart block*. Heart block may be so marked as to be complete. If the block is complete, no ventricular complexes occur in response to the auricular wave. In complete heart block each of the ventricular complexes occurs independently of the auricular waves at a much slower rate than the latter. Milder degrees of heart block, in which each ventricular contraction responds to an auricular contraction, cannot be detected by ordinary clinical means. The electrocardiograph is invaluable in these conditions. It gives definite, objective, confirmatory evidence of the presence of acute rheumatic fever. Usually such P-R interval changes in acute rheumatic fever are transitory and disappear when the acute inflammation subsides.

The inflammatory changes of rheumatic fever which involve the myocardium proper cause alterations in the electrocardiogram not so specifically associated with rheumatic fever as the P-R interval changes. Other types of pathologic processes may also cause these patterns. Such manifestations may be characterized by slurring, or notching, lowering or widening of the QRS complex, lowering or inversion of the T waves, and changes in the Q-T intervals.

If the pericardium is involved by the rheumatic inflammatory process there will likely be elevation of the S-T segments in Leads I, II, and IV F. These changes are not specific for rheumatic fever, since any process which alters depolarization by involving the pericardium in this way can cause such electrocardiographic patterns.

The electrocardiographic pattern which develops with chronic endocarditis and consequent valvular involvement depends upon the valve involved. Since the mitral valve is frequently stenosed, increased strain is placed on the chambers behind this valve; namely, the left auricle, the right ventricle, and eventually the right auricle. The pattern of right axis deviation develops with increased right ventricular strain and increased muscle mass. Because the left auricular muscle so often becomes hypertrophied in mitral stenosis the P wave is altered, becoming prominent and notched. The auricular muscle is increased and a longer time is needed for the action current to traverse it; thus there is widening of the P wave. This type of P wave, characteristically present in Leads I and II, is quite suggestive of mitral stenosis.

A disorder of rhythm, known as auricular fibrillation, is very common in rheumatic heart disease with mitral stenosis because of the strain upon the left auricle.

If the mitral valve involvement is such that regurgitation is prominent and the stenosis is relatively minor or absent, strain is put upon the left ventricle, and left axis deviation occurs. This is not so suggestive of rheumatic heart disease since many more pathologic heart conditions other than rheumatic heart disease may give left axis rather than right axis deviation. If the aortic valve is involved and causes regurgitation or stenosis of that valve, a frequent occurrence in rheumatic heart disease, strain is put primarily on the left ventricle. This ventricle hypertrophies and left axis deviation develops. If both mitral stenosis and aortic stenosis or aortic regurgitation are present, and if both right and left ventricles hypertrophy, then the electrical effects of right and left ventricular hypertrophy may counterbalance each other and no axis deviation may result.

Hypertension

In hypertension, especially of a marked degree and of long standing, a rather typical electrocardiographic pattern of left ventricular strain develops. The R wave in Lead I is usually tall, the S-T segment becomes depressed and coved in Lead I and elevated in Lead III. The S wave is deep in Lead III, and the R wave is relatively small or absent in Lead III. The T waves in Leads I and III are in opposite direction to those of the main deflection of QRS in Leads I and III; that is, inverted in Lead I and upright in Lead III. The QRS may be slightly widened in some instances due to the additional time required for the action current to traverse the thickened ventricular muscle. Fig. 739 is an example of this type of pattern.

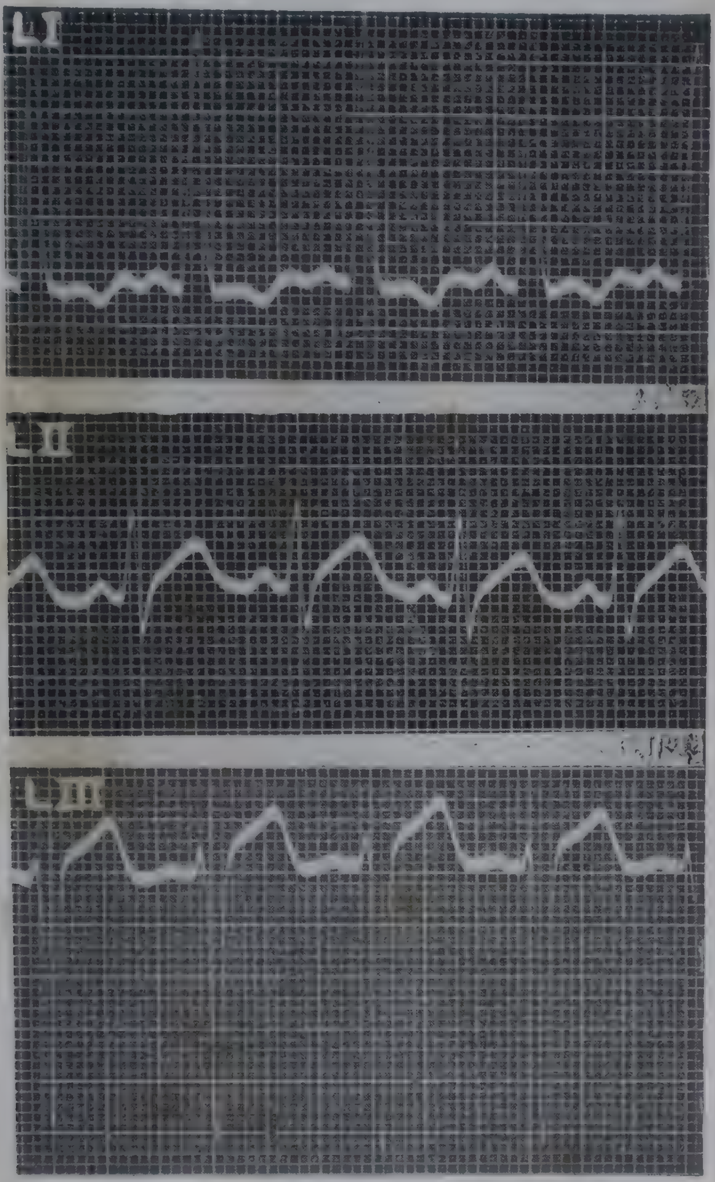

Fig. 739.—Left ventricular strain in hypertension. Note the tall R wave in Lead I, the deep S wave in Lead III; also the depression of the S-T segment in Lead I, and the elevation of this segment in Lead III. The T is inverted in Lead I and upright in Lead III. Note also the slightly increased duration of QRS which is due to the increased time necessary for the impulse to traverse the thickened ventricular muscle mass.

Myocardial Infarction

The electrocardiograph has been of great value in ascertaining definitely the presence of myocardial infarction. This condition is commonly referred to as **coronary thrombosis**. Since, however, the electrocardiographic patterns are caused directly by resulting actual necrosis of the heart muscle itself, that is, the infarction of the muscle, and not by the thrombus which obstructs the coronary artery, it is more correct to refer to these electrocardiographic changes as being due to myocardial infarction. This fact must be emphasized that, while most cases of myocardial infarction are due to coronary thrombosis, *occasionally myocardial infarction occurs in cases with extensive narrowing of the coronary arteries without thrombosis.*

The electrocardiographic picture of myocardial infarction varies according to the site and extent of the coronary artery obstruction. In general, there are two main varieties of coronary obstruction, anterior and posterior. These pictures may be modified by such factors as presence of previous infarctions, involvement of the conduction system, or involvement of the pericardium or endocardium.

Anterior Myocardial Infarction.—Most commonly the left anterior coronary artery is obtructed, with resultant infarction of the anterior apical portion of the left ventricle. If serial electrocardiograms are then taken, a characteristic series of changing electrocardiographic patterns will be produced. The QRS complexes in Lead I are frequently small, slurred, and W shaped. The earliest (within the first two days) and most characteristic change is an elevation and upward convexity of the R-ST segment in Lead I and a reciprocal depression of the same segment in Lead III. The T wave early has a high take-off from the S-T segment and may have merely a plateau type of configuration with perhaps a slight terminal dip. Later the S-T segment in Lead I drops steadily until it assumes a position at or slightly below the isoelectric level, maintaining a characteristically upward convexity.

The T wave in Lead I becomes completely inverted with a characteristic ''coved'' take-off from the S-T segment. The opposite changes occur in Lead III. The Q wave in Lead I, which has made its appearance early, will usually persist. The S-T segments and T waves very occasionally may eventually resume a completely normal pattern. The characteristic residual patterns of an anterior myocardial infarction are the prominent Q and inverted and coved T waves in Lead I, with opposite configuration (normal) in Lead III. This is known as the Q_IT_I pattern of anterior myocardial infarction.

Changes in the chest lead (IV F) in anterior infarction are quite characteristic, and frequently even more striking than in the other leads. Occasionally, in this type of infarction, Lead IV F may be the only lead which reveals the changes characteristic of anterior infarction, thus emphasizing the value of this lead in this condition. In general, the changes in Lead IV F parallel those in Lead I except that they are often more marked. In the early stages the S-T segment is displaced upward and the initial deflection of QRS may be only very slightly upright or deeply inverted (deep Q). A deep Q in Lead IV F is never normal and usually signifies coronary artery obstruction. The T in the early stages has an elevated take-off from the S-T segment which is short and abrupt, and often exhibits a slight terminal dip. Gradually, the S-T segment becomes depressed until it reaches the isoelectric level or a point slightly below it.

The T wave becomes sharply and deeply inverted. The Q wave is characteristically prominent and is more definitely indicative of the presence of anterior

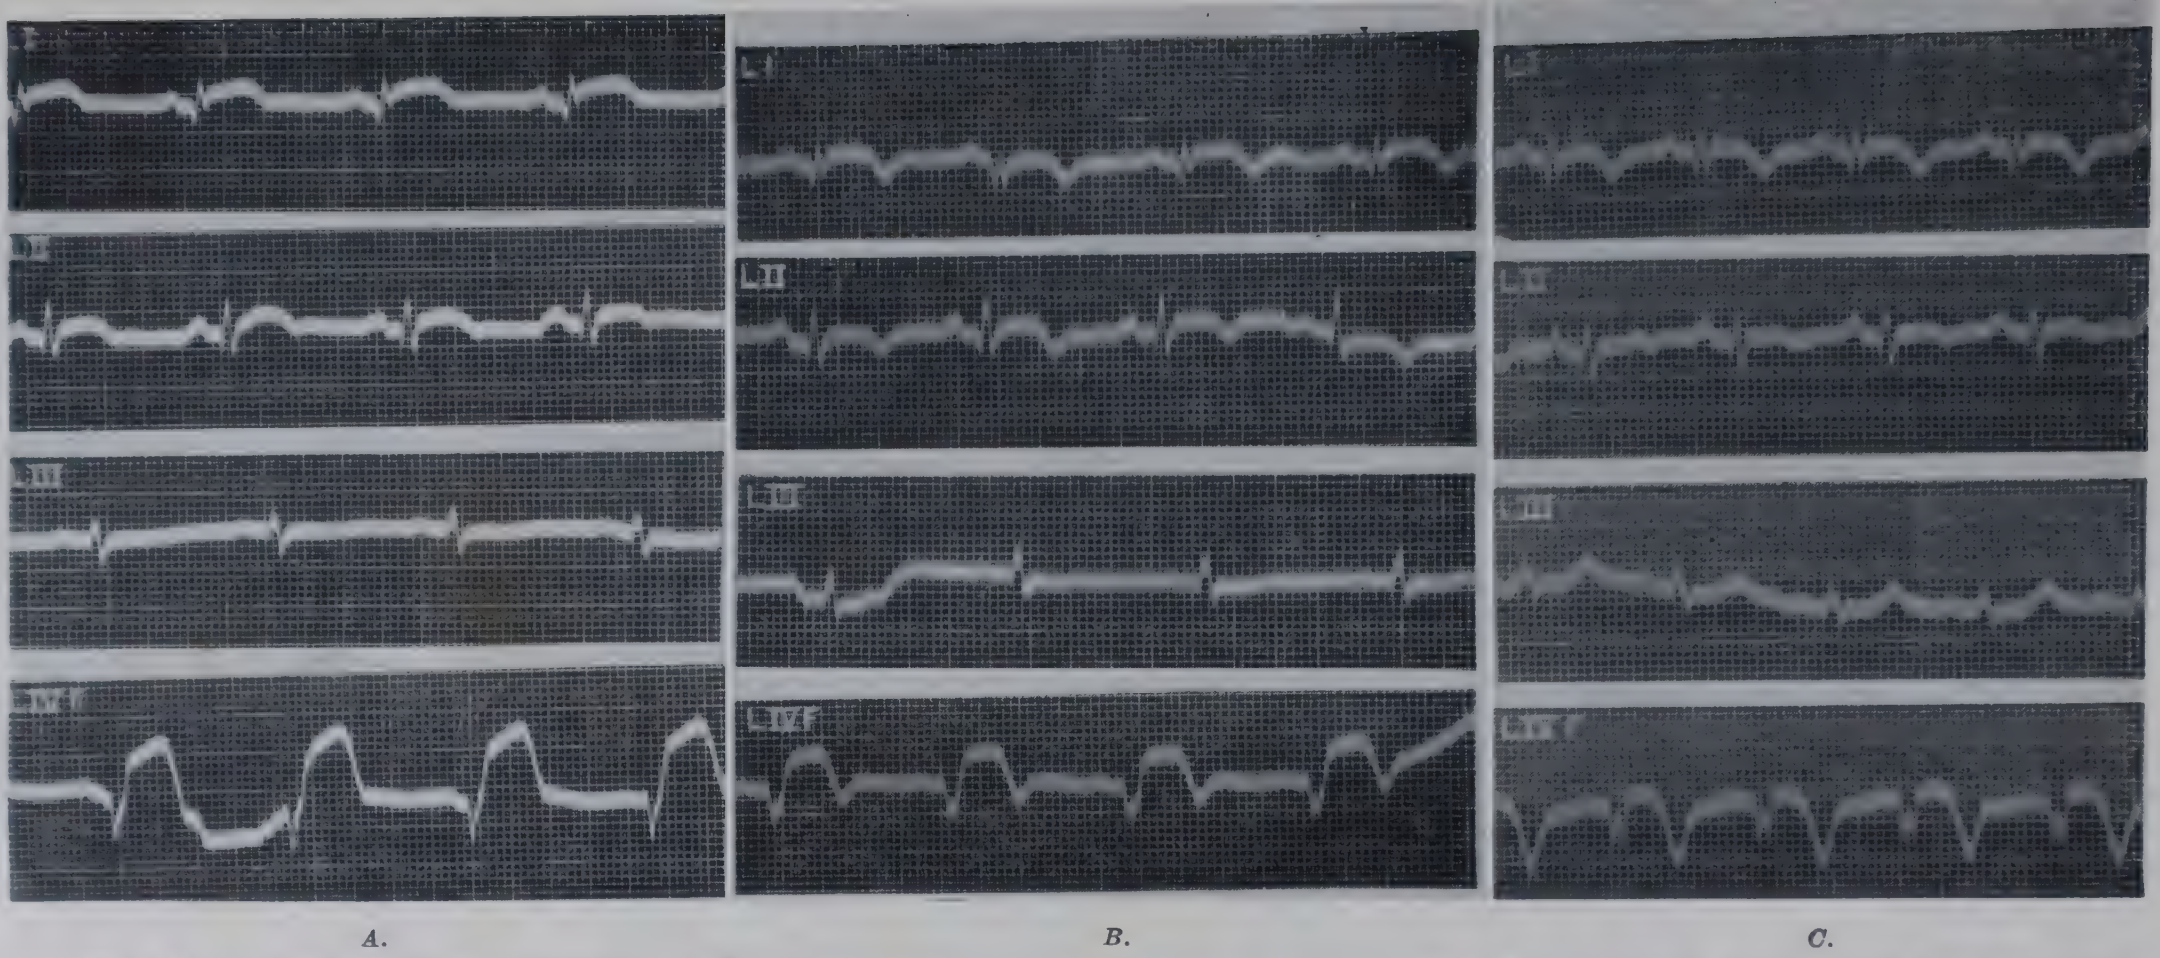

Fig. 740.—Anterior myocardial infarction. *A*, Electrocardiogram taken the day of the attack. The S-T segment is elevated and has an upward convexity in Leads I and II; in Lead III the S-T segment is slightly depressed, whereas in Lead IV F there is marked elevation and upward convexity of the S-T segment. A small Q wave is present in Leads I and II while in Lead IV F the entire QRS is inverted and notched—no R is present.

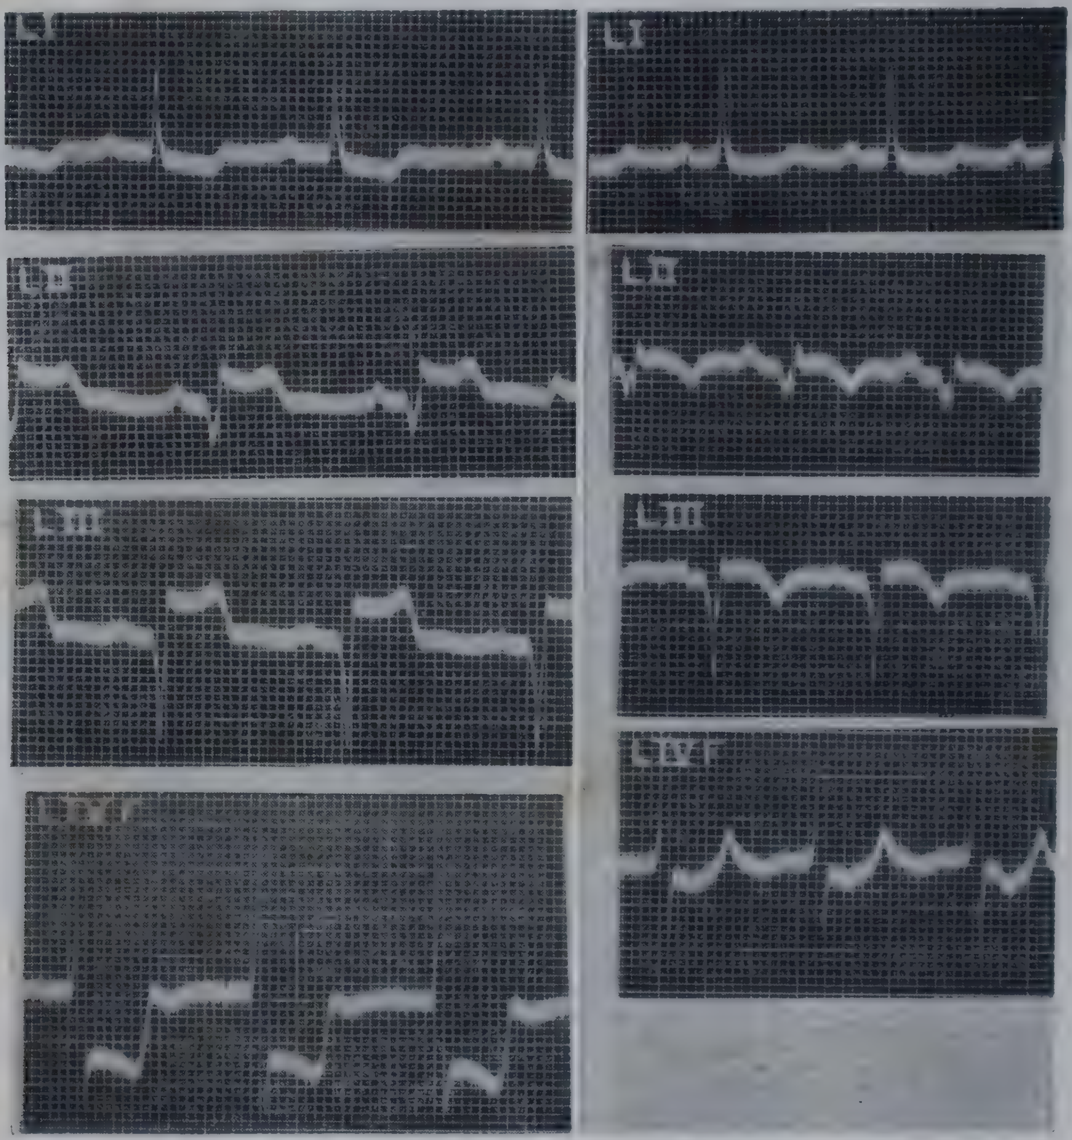
B, Taken four days after *A*. Note the lowering of the S-T segment with less upward convexity in Leads I, II, and IV F. The T waves in Leads I, II, and IV F are now definitely inverted. The Q waves in Leads I and II persist; R wave remains absent in Lead IV F.

C, Taken 28 days after *B*, 32 days after onset of illness. Note further lowering of the S-T segments in Leads I, II, and IV F almost to the isoelectric level. There is further deepening of the inverted T wave in Leads I and IV. T wave in Lead II is less inverted as would be expected with the appearance of the upright T wave in Lead III. Note also the sharply rounded convexity of the S-T segment in Lead IV F—the "coving" so characteristic of myocardial infarction. The QRS complex is W-shaped in Leads I, II, and IV; in Lead IV the entire QRS complex is below the isoelectric level.

infarction than an inverted T wave. Nevertheless a deep Q wave might never appear in Lead IV F, and an inverted T wave in Lead IV F may be the only evidence of an anterior myocardial infarction.

If the initial deflection in Lead IV F is upright (R IV) but is only 2 mm. or less in amplitude, it is quite suggestive of the presence of myocardial infarction. If an inverted T wave as well is found, then the evidence of myocardial infarction is more nearly conclusive. Fig. 740 shows the sequential changes, over a period of several weeks, in a case of acute anterior myocardial infarction.



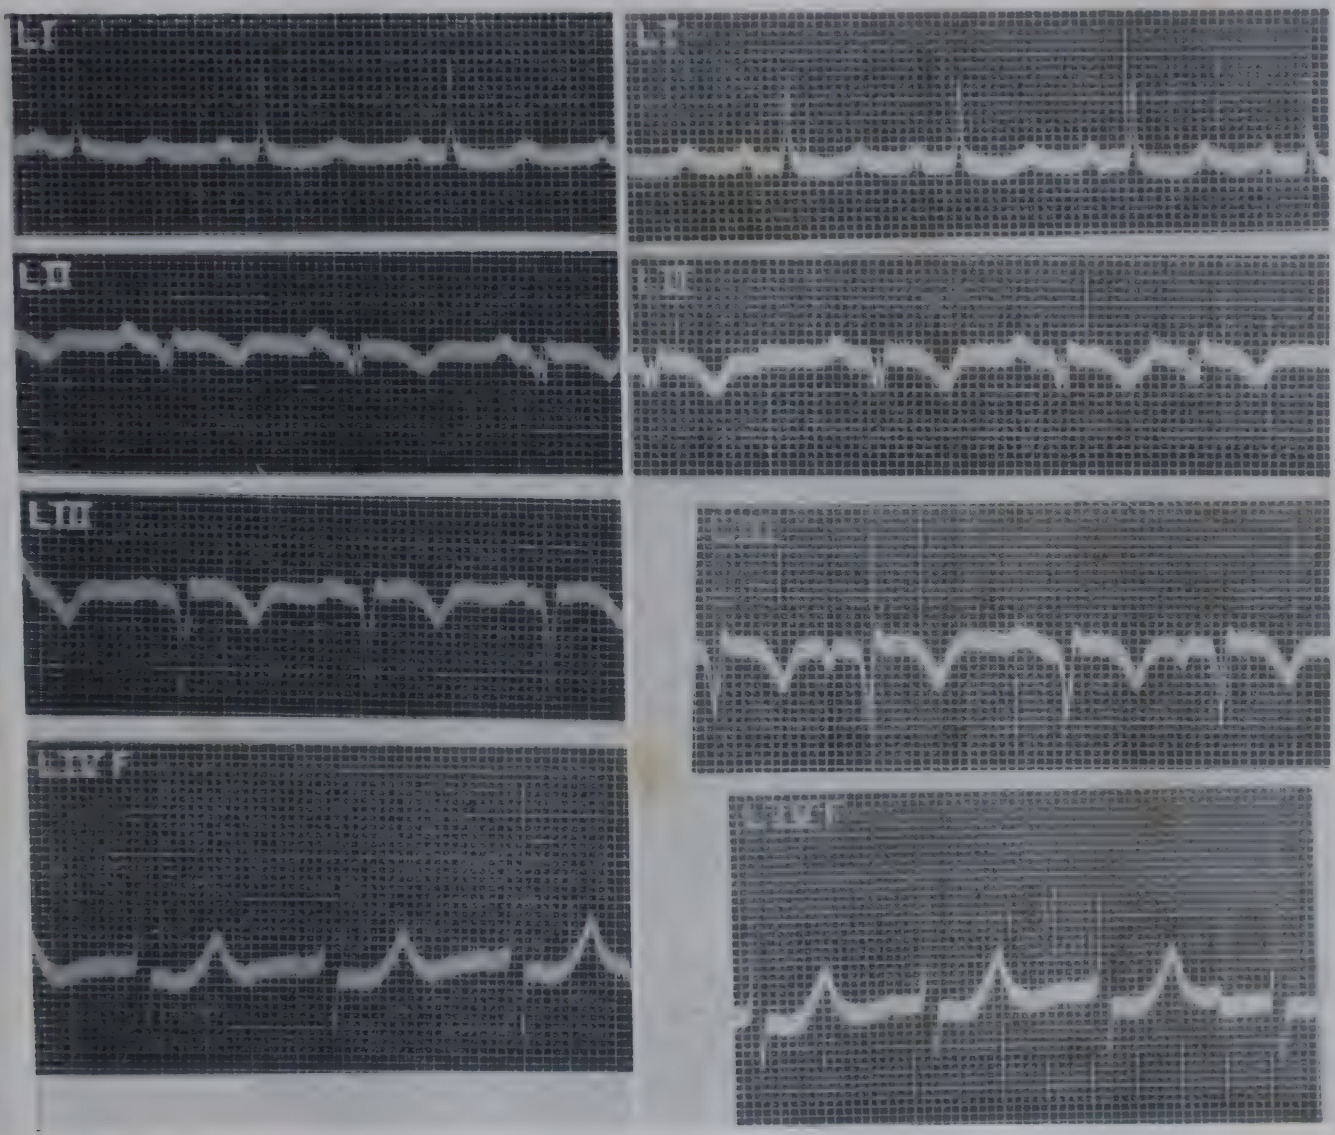
A. *B.*

Fig. 741.—Posterior wall myocardial infarction. Showing typical serial changes from the first day to the twenty-fifth day after the attack.

A, Shows most marked changes in Leads II, III, and CF_{IV}. In Lead I the S-T segment is slightly depressed whereas in Leads II and III the S-T segments are markedly elevated and plateau type. In Lead CF_{IV} the S-T segment is markedly depressed and has an upward convexity. The T wave in Lead I is diphasic and in Leads II and III has a high take-off with a slight upright direction. In Lead CF_{IV} the T wave has a low take-off and is diphasic. Note the characteristically prominent Q waves in Leads II and III.

B, Taken 15 days after onset. Note that the S-T segments in all the leads are returning toward the isoelectric level. The S-T segments in Leads II and III show a characteristic upward convexity, "coving." The T waves are now completely inverted and still show a slightly elevated take-off from the S-T segments. The Q waves remain prominent and notched in Leads II and III. The T wave in Lead CF_{IV}, while still showing a rather low take-off, is now almost completely upright.

Posterior Myocardial Infarction.—Posterior myocardial infarction shows changes similar to those of anterior infarction in Leads I and III except that the patterns are reversed. The characteristic rise in the R-S-T level takes place in Lead III and usually in Lead II, while reciprocal depression occurs in Lead I and often in Lead IV. A prominent Q wave in Lead III and often in Lead II becomes evident just as in anterior infarction a Q_I makes its appearance. There is the same upward rounding or convexity of the S-T segment, together with the elevation of this segment, the same stages of progressive lowering of S-T segment and inversion of T wave in Lead III as a result of acute posterior infarction as are found in Lead I in cases of anterior infarction. Variations from these classical patterns are seen. These depend upon the presence of the infarction in locations other than those described above; or they may be due to the fact that an old lesion has preceded the fresh lesion.



C. *D.*

Fig. 741.—*C*, Taken 18 days after onset. No significant change over the electrocardiogram taken three days earlier.

D, Taken 25 days after onset. Still shows no further significant change over the tracing taken one week before. The electrocardiogram has become stabilized in the typical pattern of posterior wall infarction characterized by prominent Q_{II} and Q_{III}, and inverted and coved T_{II} and T_{III}. Alterations in Leads I and IV often are not present or when present are minimal and in opposite direction to those of Leads II and III.

In the chest lead (IV F) changes with posterior infarction are not striking. The S-T segment may be depressed to varying degrees and may gradually rise to the isoelectric level. The T wave is normal or is occasionally unusually tall. Fig. 741 shows the serial changes occurring in a case of acute posterior myocardial infarction.

More information relative to posterior infarction may be obtained by using esophageal leads since this lead is placed as near the posterior surface of the heart as it is possible to place a lead in a living subject.

Syphilitic Heart Disease

The characteristic lesion of syphilitic heart disease is aortic regurgitation. Since changes in an electrocardiogram depend on muscular involvement and not on valvular defects, the effect of aortic regurgitation on the electrocardiogram will be caused by secondary results of this valve lesion, namely, left ventricular enlargement. As stated above, increase in size of the left ventricular muscle causes left axis deviation. It is thus evident that the electrocardiographic pattern which one expects for the usual syphilitic involvement of the cardiovascular apparatus is not specific for that condition. It may occur as well in any other condition causing left ventricular enlargement. If the syphilitic aortic regurgitation is early or is only slight, and no significant left ventricular enlargement has occurred, the electrocardiogram may then show a normal axis. Other changes (nonspecific) in the electrocardiogram may occur if the mouths of the coronary arteries are obstructed by a syphilitic lesion of the aorta with resultant fibrosis of the myocardium. The electrocardiographic effects will then be not unlike those of chronic coronary obstruction from other causes—inversions of T waves, alterations in conduction, spread and notching of QRS complexes, and increased P-R interval.

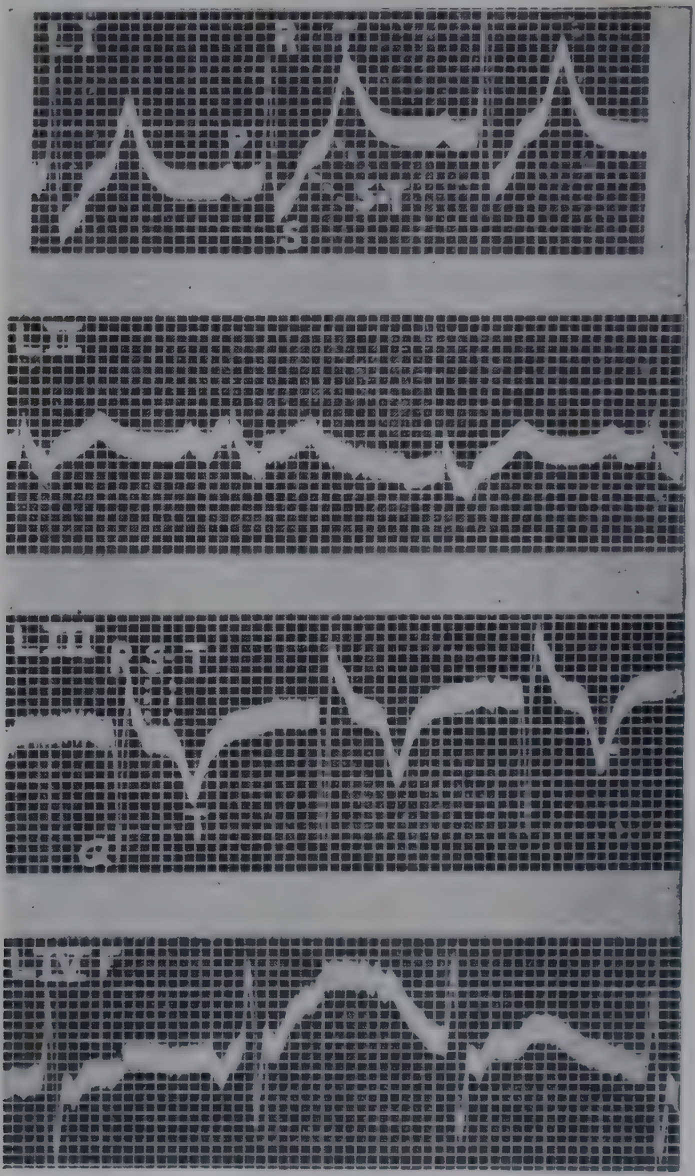


Fig. 742.—Acute massive pulmonary artery obstruction. Note the prominent wide and slurred S wave and the short steplike S-T segment in Lead I. The deep Q wave and inverted T wave in Lead III resemble those of posterior wall myocardial infarction.

Acute Pulmonary Artery Obstruction

Acute pulmonary artery obstruction is a condition which is often catastrophic and may cause death instantly or within a short period of time. The electrocardiogram often gives characteristic patterns which will fortify the physician in his decision to take heroic measures for treatment. It should be emphasized, however, that the electrocardiogram may be entirely normal in this condition.

The S wave in Lead I is prominent and wide, and leads rather abruptly and by a steplike configuration of the shortened S-T segment into the T wave. Q waves are often present in Leads II and III, and T_{II} and T_{III} are inverted Note that the pattern of Q_{III} and inverted T_{III} is that described for posterior infarction. The prominent, wide S_I and the characteristic S-T segment in Lead I, as well as the much more transitory nature of the picture in acute pulmonary artery obstruction, all help to differentiate it from posterior infarction where the changes endure for months and are usually permanent. The electrocardiogram of acute pulmonary artery obstruction often, though not necessarily, reveals right axis deviation because of the strain on the right heart.

Pulmonary Emphysema and Pulmonary Artery Sclerosis

Pulmonary emphysema and pulmonary artery sclerosis may cause changes in the electrocardiogram by increasing the strain on the right ventricle and thus result in right axis deviation. The P wave is often characteristically altered in pulmonary emphysema. It becomes tall and sharply peaked in Leads II and III (the P pulmonale) in contrast to the P wave of mitral stenosis, which is broad, prominent, and notched in Leads I and II. The T waves not infrequently may be low or inverted. Fig. 733 shows example of P pulmonale.

Any other conditions which affect oxygenation of the heart muscle, such as anemias, can be expected to cause lowering or inversion of T waves.

Thyroid Disturbances

Thyrotoxicosis is commonly associated with an electrocardiogram which shows merely normal complexes occurring at a faster than normal rate; that is, sinus tachycardia. Occasionally the QRS and T waves may show greater voltage than usual. One common abnormality of rhythm, which is manifested by hearts exhibiting the effects of the increased cardiovascular strain of thyrotoxicosis, is auricular fibrillation which is described below under "abnormal rhythms."

The opposite picture of thyrotoxicosis, myxedema, is often associated with electrocardiographic changes revealing low QRS and low or inverted T waves as well as slow rates (sinus bradycardia).

Deficiency Diseases

Deficiency diseases, of which beriberi is an outstanding example, often show electrocardiographic evidences of myocardial involvement such as low ventricular complexes (QRS and T).

Toxic States

Acute toxic conditions such as diphtheria and scarlet fever are examples of toxic diseases which may cause changes in T waves—flattening or inversion—and varying degrees of heart block—increase in P-R interval.

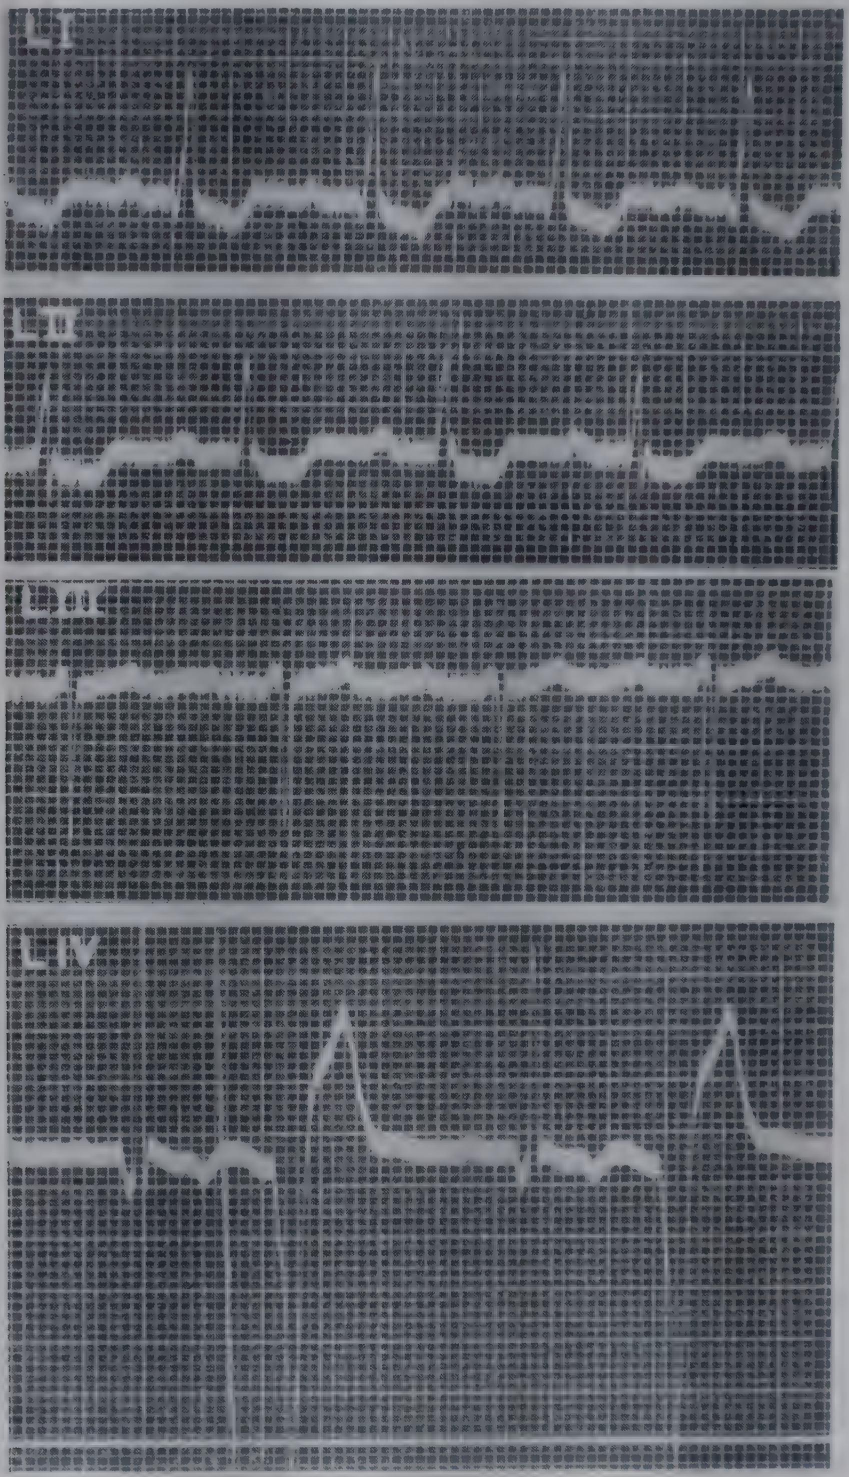

Fig. 743.—Digitalis effect. The R-T segments are depressed with abruptly downward deviation and no convexity upward. The T waves have become inverted in Leads I, II, and IV. The characteristic changes are here most typically shown in Leads I and II. In Lead IV are seen ventricular premature beats occurring every second cycle (pulsus bigeminus), a toxic manifestation of digitalis. The P-R interval is increased to 0.23 second, this being also a toxic effect of digitalis.

Chronic toxemias, such as uremia, often exhibit effects on the electrocardiogram. The QRS interval is often increased, the T waves inverted, the S-T segment depressed, and the Q-T interval increased as well. Pericarditis, a complication of uremia, may superimpose its effect upon the electrocardiogram.

Drug Effects

It is important to consider the effects of certain drugs on the electrocardiogram. Digitalis, which is the most important drug used in the treatment of heart disease, exerts certain characteristic effects. The most characteristic effect is on the S-T segment which descends abruptly without any tendency toward upward convexity as in the coronary S-T segments. The T waves are also depressed and eventually become inverted with full digitalis effect.

Digitalis also manifests an effect on auriculoventricular conduction so that the P-R interval is increased to the extent that even marked degrees of heart block are produced. In toxic effects many different types of disturbances of rhythm, most often extrasystoles, are produced. Fig. 743 shows the effect of digitalis on the electrocardiogram. Quinidine, another drug commonly used especially in certain arrhythmias, manifested by increased irritability of the heart muscle, depresses conduction and may produce spreading of the QRS, lengthening of the Q-T interval, and notching of the T wave. Morphine sometimes produces flattening or inversion of T waves.

Neurocirculatory Asthenia

The importance of distinguishing psychogenic effects on the electrocardiogram from those of organic diseases has been pointed out. These psychogenic effects are manifested by flattening, notching, or inversion of the T waves usually in Leads II, III, or IV, and very occasionally in Lead I. They have been often mistaken for organic effects. The importance of distinguishing between the changes in the electrocardiogram caused by neurocirculatory asthenia and those caused by organic heart disease is obvious since it involves matters affecting the happiness of the patient—prognosis, insurability, physical activity, desirability of marriage, etc. That such distinction can often be made has been pointed out by Wendkos, who restored abnormal T waves to normal by the use of certain drugs which act upon the autonomic nervous system.

In many patients either with or without organic heart disease, a great variety of disturbances in rate, rhythm, and conduction may occur. It is important to remember that these abnormalities in many instances do not necessarily indicate the presence of organic heart disease, but that, on the other hand, some are more likely to be associated with serious heart disease than others. It is not our purpose here to describe these clinical correlations, but rather to describe briefly those disorders in mechanism which are more commonly seen. Such uncommon mechanisms as parasystole and interference dissociation will not be discussed in this chapter.

NORMAL VARIATION IN RATE AND RHYTHM

In a normal electrocardiogram, the normal sequence of complexes, P, QRS, and T occurring in their correct relationships with each other and at a rate of 60 to 100 per minute, is known as a normal sinus mechanism. The impulse starts in its normal place in the sinus node and passes through the auricles down the A-V node, the bundle of His, the right and left bundle branches, and throughout the ventricle in a normal manner.

Sinus Tachycardia.—Impulses emanating from the sinus node occur at a rate exceeding 100 per minute. Because the impulse follows the normal conduction pathways the complexes are situated normally with respect to each other. The increased rate results in varying degrees of shortening of the T-P interval. If the rate is fast enough the T-P interval may be so shortened that P waves are superimposed upon the preceding T waves. Fig. 744 shows sinus tachycardia.

Sinus Bradycardia.—Here again the mechanism of conduction is normal and consequently the relationships of the complexes are normal. The rate, however, is below 60 per minute. Fig. 745 shows sinus bradycardia.

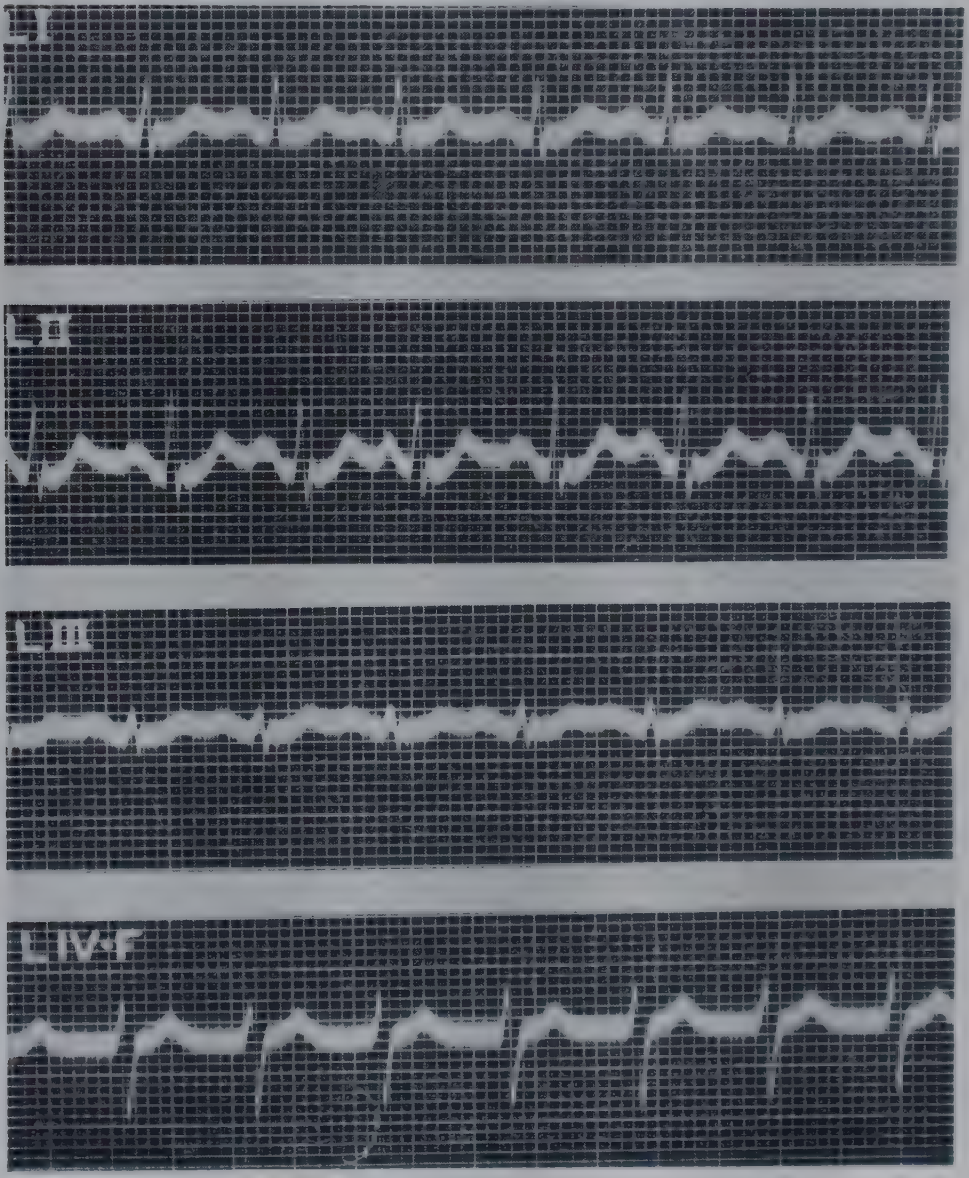

Fig. 744.—Sinus tachycardia. The configuration and duration of the complexes are within normal limits. The heart rate is increased to 139 per minute.

Sinus Arrhythmia.—The impulse for cardiac contraction originates in the normal place in the sinus node. However, because of variations in vagus nerve tone affecting the speed of impulse formation in the sinus node, the rhythm varies, with regularly recurring faster and slower cycles. The configuration of the complexes and the relationships between the auricular and the ventricular complexes are normal; the only variation is a regularly recurring increase and decrease of the T-P intervals with the slower and faster cycles. This mechanism is considered a normal alteration in rhythm. It depends, as a rule, upon the phase of respiration, an increase in rate occurring with inspiration and a decrease with expiration.

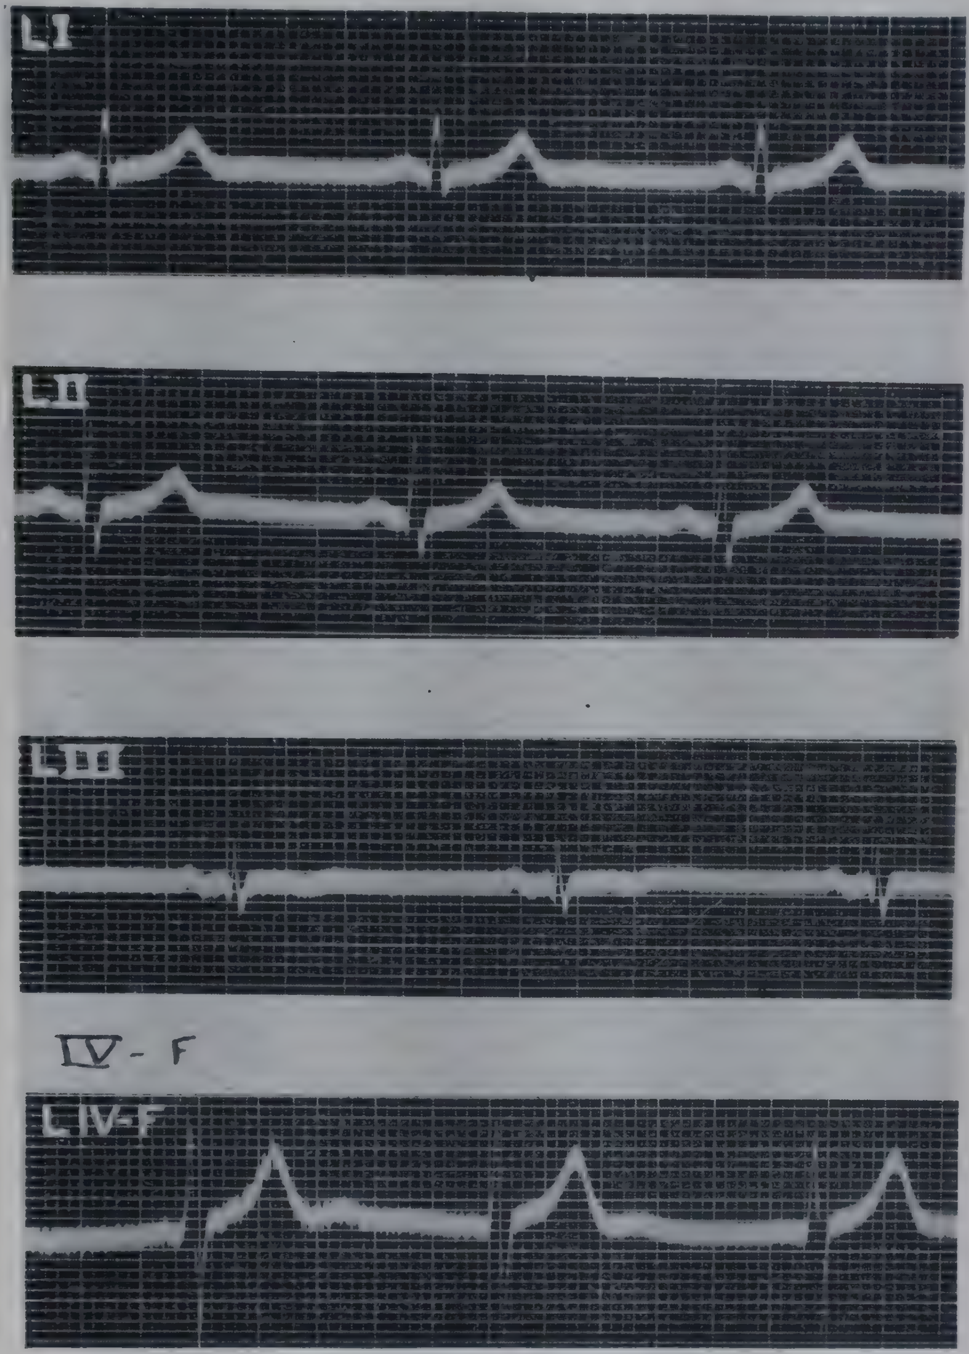

Fig. 745.—Sinus bradycardia. The configuration and duration of the complexes are within normal limits. The heart rate is 54 per minute.

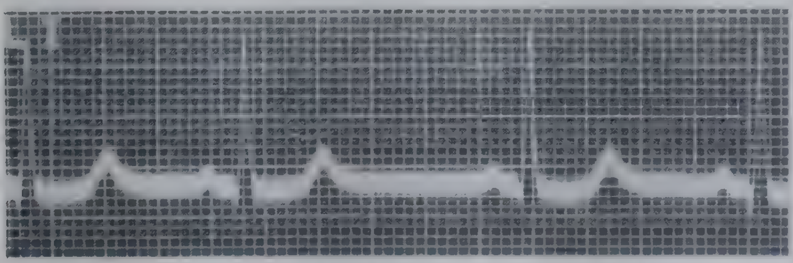

Fig. 746.—Sinus arrhythmia. Note that the auricular and ventricular complexes are of normal configuration and have normal time relationships. The only alteration is the shortening and lengthening of the T-P intervals.

ABNORMAL VARIATION IN MECHANISM

Disturbances in the Pacemaker.—Since the impulse which originates cardiac contractions normally starts in the sinus node, this node is known as the pacemaker. The site of origin may shift from its normal place and occur anywhere along the conduction system from the auricles to the ventricles. This abnormal disturbance in site of the pacemaker may occur as a result of functional or nervous influences, of toxic effects such as those due to drugs, and of organic disease involving the conduction system.

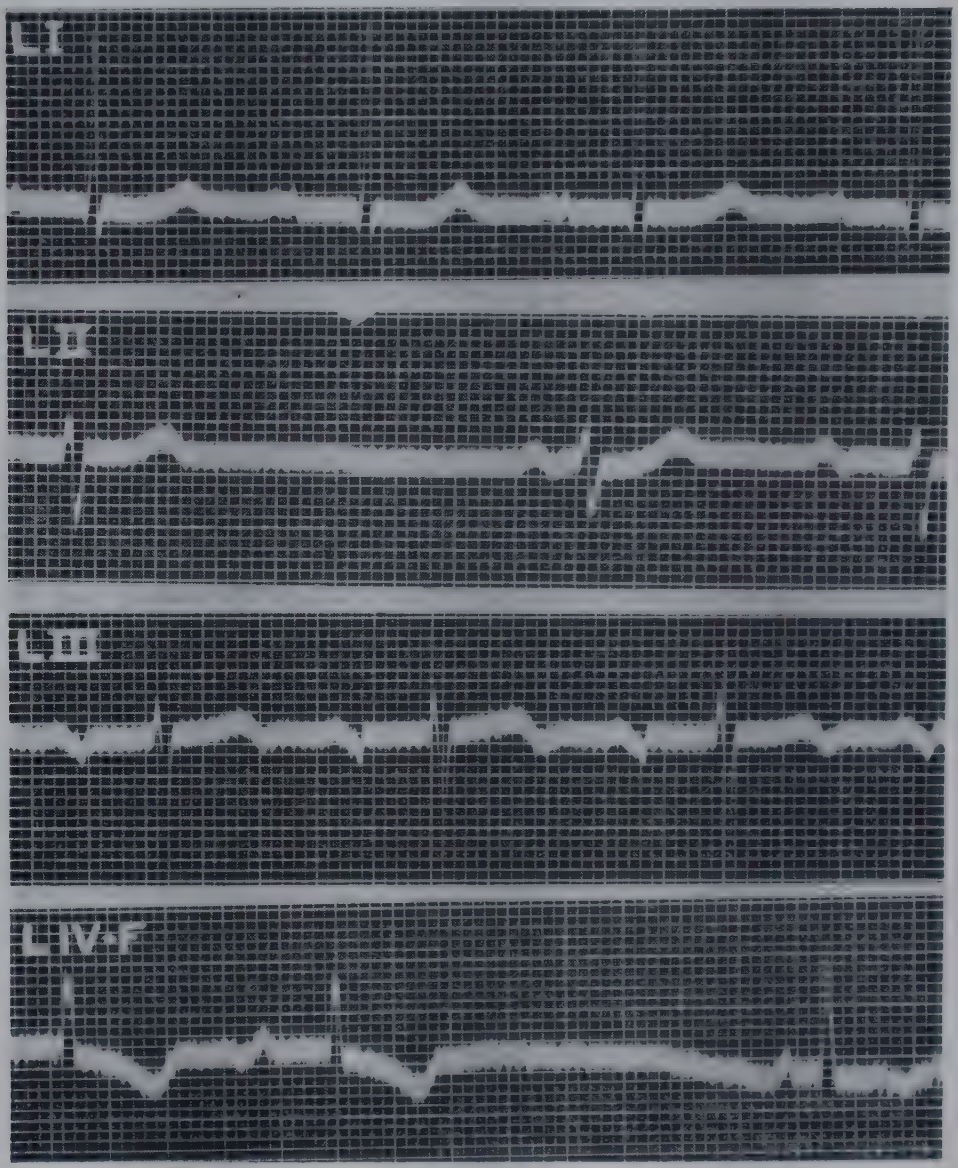

Fig. 747.—Sinus arrest (sinoauricular block), also delayed A-V conduction. Note dropping out of a complete heart cycle including P and QRS and T waves in Lead II.

Sinus Arrest (Sinoauricular Block).—In this mechanism there is a dropping out of a complete auricular cycle together with its accompanying ventricular cycle, which results in a pause usually almost the length of two normal cycles. The impulse at the sinus node has either not occurred at all, or it has been blocked from reaching the auricular muscle. Fig. 747 shows sinoauricular block.

Ventricular Escape.—In ventricular escape the impulse emanates in the bundle of His or on rare occasions below the bifurcation of the bundle. This occasionally occurs in sinus arrest when there is depression of the higher centers of impulse formation with rising degree of irritability of the lower centers, to a point where the lower center "escapes" from the control of the higher center (sinus node) and originates an impulse of its own. In this pattern a ventricular complex is seen after a long pause. This complex is normal because the impulse is supraventricular in origin but no P wave precedes it. If, as rarely happens, the focus originates below the bifurcation of the bundle, the form of the ventricular complex becomes distorted (aberrant). Fig. 748 shows ventricular escape.

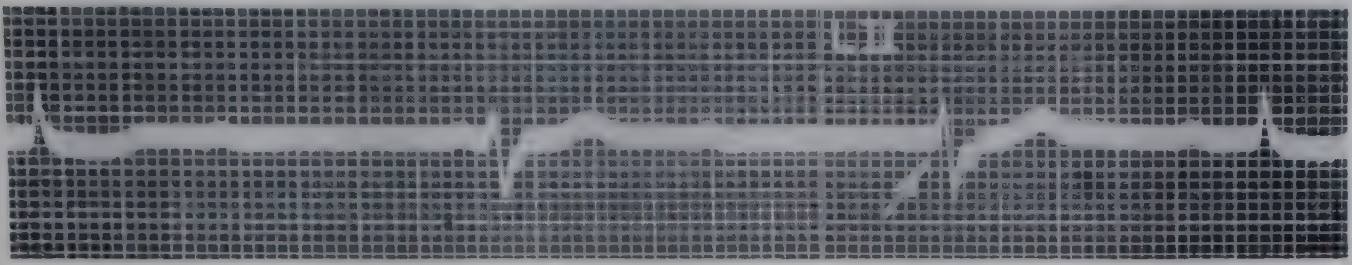

Fig. 748.—Ventricular escape. Note that the "escaping" ventricular complex is not preceded by a P wave and is of similar configuration to the preceding one except for the slight distortion of the S limb due to a superimposed P wave. The electrocardiogram also shows 2:1 heart block.

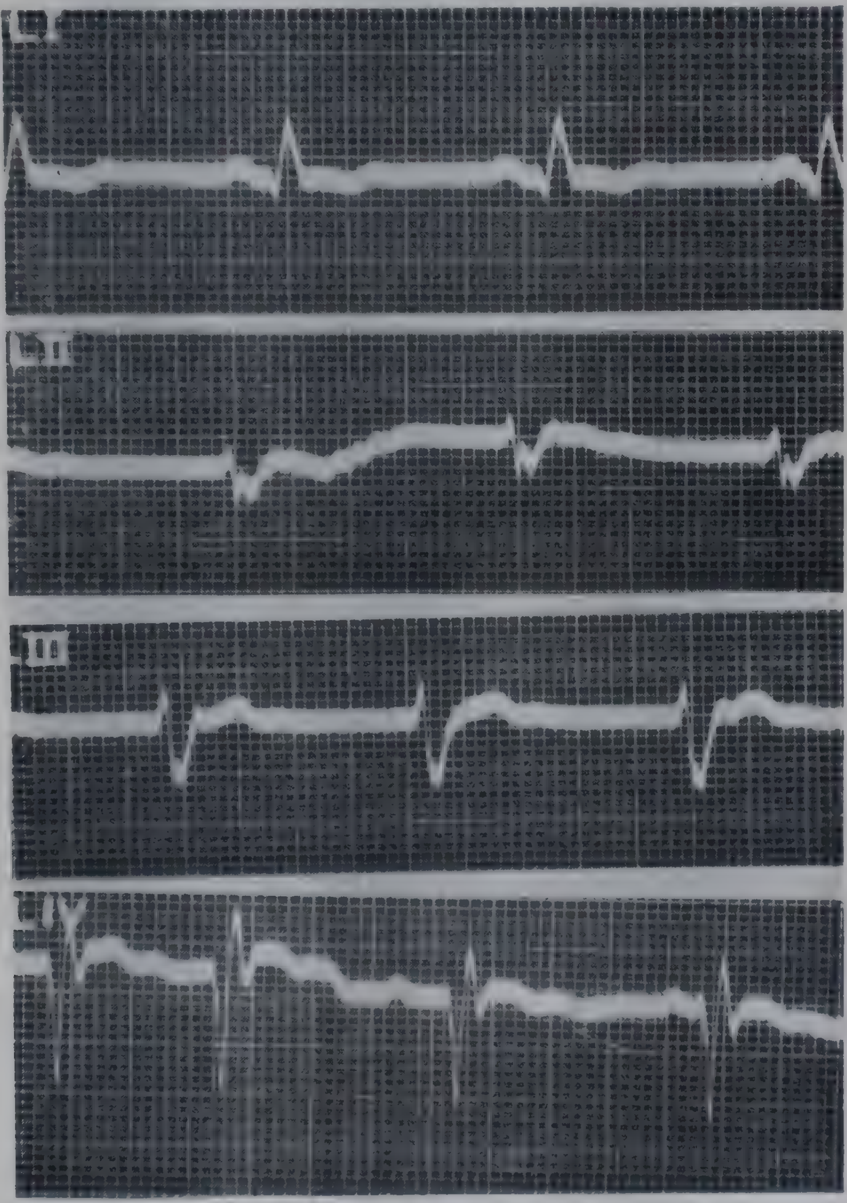

Fig. 749.—Shifting pacemaker. In Leads I and IV F, the time relationship of P to QRS varies, with slight variation in form of P especially evident in Lead IV F.

Shifting Pacemaker.—In this mechanism the site of impulse formation may wander anywhere from the sinoauricular node to the auriculoventricular node. The further the impulse occurs from its normal origin in the sinoauricular node the greater the alteration in the P wave. These alterations vary from only minor changes in the shape of the P wave to inversion of this wave. The relationship of P to QRS changes, so that the P may precede the QRS by a much shortened P-R interval or the P may be buried in or may even follow the QRS. Contour of the QRS does not change since the site of impulse formation is supraventricular. There is sometimes slight arrhythmia, as may be expected.

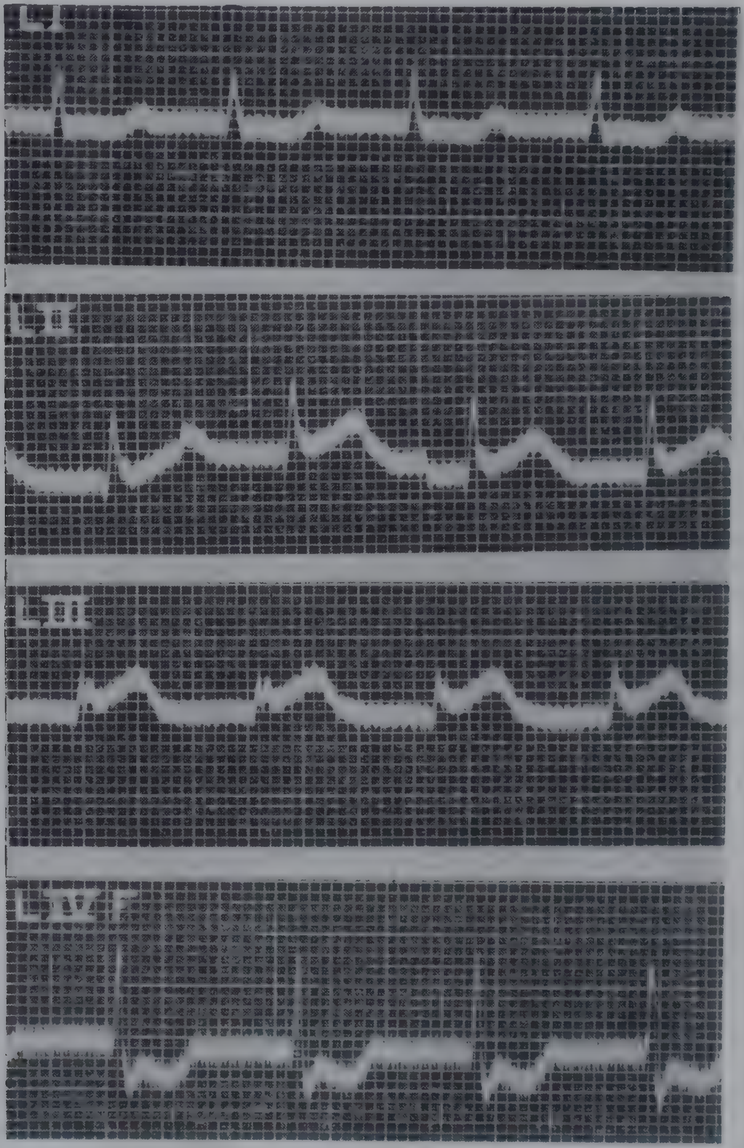

Fig. 750.—Nodal rhythm. The rhythm is regular and the rate is 100. The P waves cannot be seen and are buried in the QRS complexes. The ventricular complexes are supraventricular in form. The impulse has probably originated in the middle of the A-V node. If it had originated in the lower portion of the node, P waves would be visible following the QRS and would be of abnormal contour; if it had originated in the upper portion of the A-V node, the P would have preceded QRS with a very short P-R interval. In all these types, P waves may be absent. Note that the ventricular complexes in this electrocardiogram indicate that posterior wall myocardial infarction is present.

Nodal Rhythm.—Here the site of pacemaking impulse formation is in the auriculoventricular (A-V) node. Since this is a supraventricular site the ventricular complexes are of normal contour. The rhythm is regular. The P wave might not be seen; it may be buried in the QRS or it may occur immediately before or after the QRS depending upon whether the impulse reaches the auricles or the ventricles first. The rate is usually between 50 and 60 per minute.

Premature Contractions (Extrasystoles).—The existing rhythms may at times be interrupted by a contraction of the heart caused by an irritable focus which may arise elsewhere than in the sinus node—in the auricles, in the A-V node, in the bundle of His, or in the right or left ventricle. These contractions occur early after the normal cycle, some time before the next normal contraction is ordinarily expected to appear. The site of origin of these contractions can be detected by the characteristic alterations of the electrocardiographic complexes and their time relationships. Premature contractions are usually followed by a pause which, in the case of auricular extrasystoles, is longer than the normal pause between two cycles but is not equal to the sum of two cycles. The pause following extrasystoles arising in the ventricles is *compensatory;* that is, the length of the two cycles is equal to two normal cycles. There is an exception to this. Occasionally a ventricular extrasystole occurs without interrupting the regularity of the rhythm. No compensatory pause occurs, and in this case the extrasystolic beat may be followed by a pause shorter than the normal interval. Such ventricular extrasystoles are termed *interpolated.*

The greater the distance from the normal site that the premature focus arises, the greater is the change in appearance of the extrasystolic complex from that of the usual one for the patient.

Premature systoles may occur with varying frequency. The rhythm is termed *bigeminy* when they occur every second cycle, *trigeminy* if they occur every third cycle, and *quadrigeminy* if they occur every fourth cycle. It is possible to see numerous extrasystoles of variable origin in the same electrocardiogram.

Premature Auricular Systole (Auricular Extrasystole).—When an irritable focus in the auricle other than the sinoauricular node gives rise to an auricular contraction, a premature auricular systole results. It is characterized by a P wave which occurs before it is expected, sometimes superimposed upon the preceding T wave, but differing in form from the usual P waves for that particular record. This alteration in form may vary from only a slight degree to a marked degree characterized by a completely inverted P wave, depending upon the distance between the point of origin of the premature focus and the sinoauricular node. The P-R interval is increased or decreased and the QRS and T waves are unaltered in form, although these may occasionally be changed (aberrant). At times an extrasystolic P may occur without a corresponding QRS; that is, the ventricles may be refractory and do not respond to the extrasystolic impulse from the auricle, or the extrasystolic impulse from the auricle may be entirely blocked from reaching the ventricles. The pause which follows an auricular extrasystole is greater than the interval between two normal cycles, but the total time between the cycle preceding the premature systole and the one following it is less than the total of two normal cycles. In other words, the pause following a premature auricular systole is not usually compensatory.

Premature Nodal Contractions (Nodal Extrasystoles).—The impulse for this type of premature contraction arises in the auriculoventricular node or the bundle of His. This impulse travels downward to the ventricle and backward to the auricle, and produces both an auricular and a ventricular contraction.

If the backward-traveling impulse reaches the auricle at the time of the ventricular contraction, the P wave is concealed in the QRS complex. The P waves, when visible, are inverted, and may occur before or after the QRS depending on when the impulse has reached the auricles in relation to the time that the opposite traveling impulse has reached the ventricle. Since the impulse has reached the ventricles from above (supraventricular), the form of the ven-

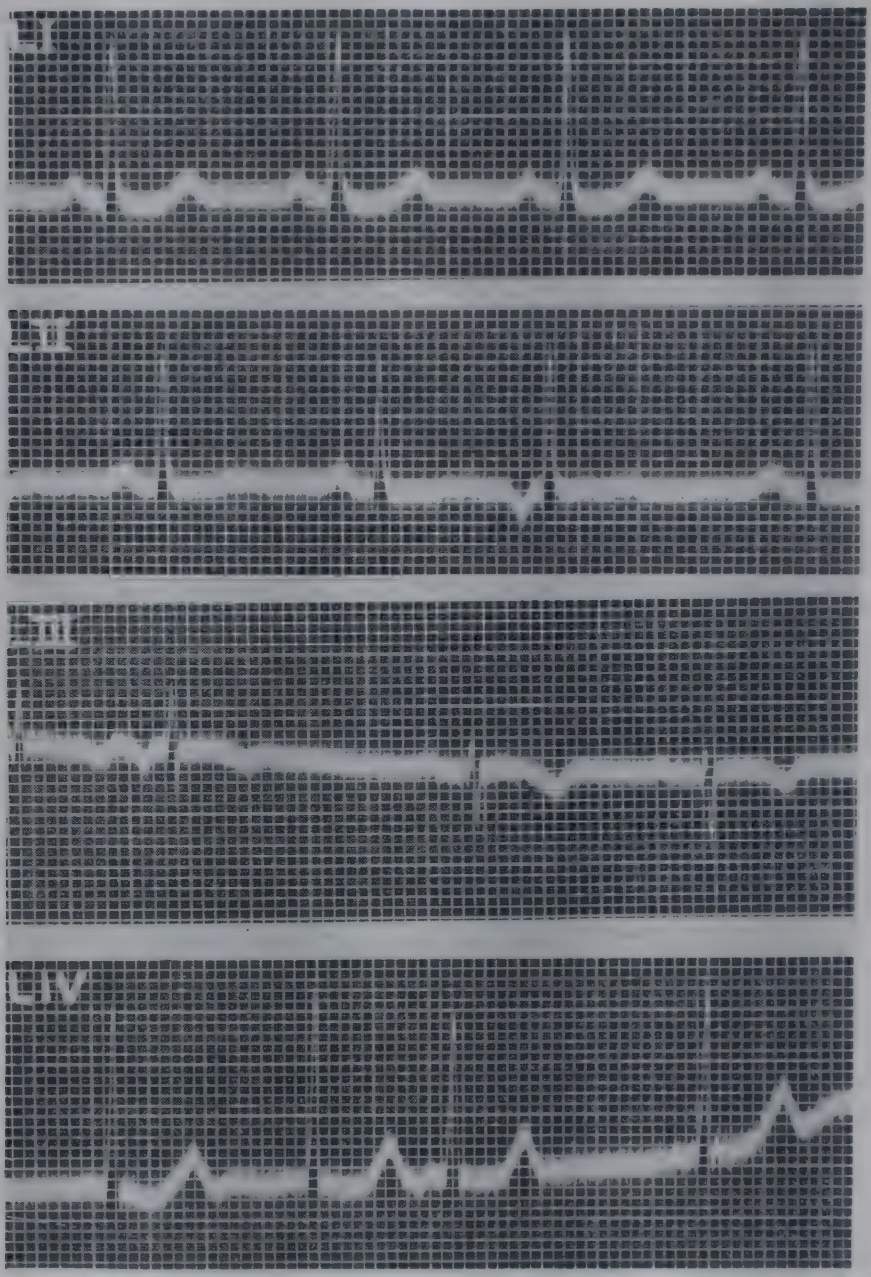

Fig. 751.—Premature auricular contraction. The premature beat comes earlier than anticipated. The P waves of the premature cycles in Leads II, III, and IV are inverted and are followed by ventricular complexes of normal configuration except in Lead III where the QRS and T are slightly altered (aberrant). The P-R interval of the regular cycle in Lead II is 0.15 second; that of the extrasystole is 0.11 second. Note that the pause following the premature auricular contraction is not compensatory.

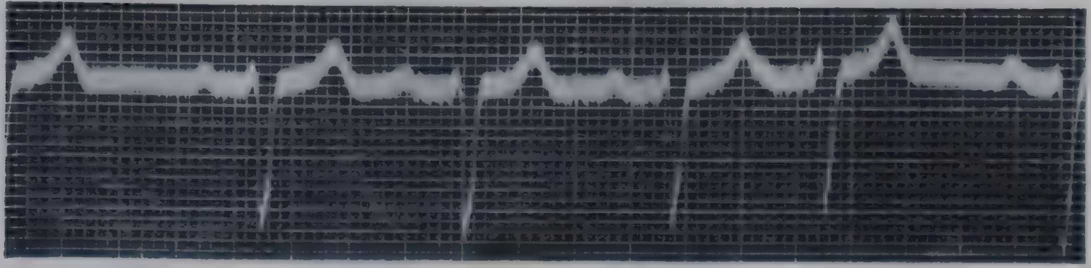

Fig. 752.—Premature nodal contraction (Lead III). The premature contraction occurs early. The ventricular waves of the nodal contraction are normal in configuration (supraventricular). The P wave is not visible.

tricular complexes will not be altered, or it will be altered only to a slight degree (slightly aberrant). The pause following this type of premature contraction may or may not be compensatory.

In rare instances the retrograde impulse does not reach the auricles, or the auricles are unresponsive (refractory) to the backward traveling impulse. The auricles, in such cases, continue to respond to the normally traveling impulses from the sinoauricular node, and the P waves are normal in shape and direction.

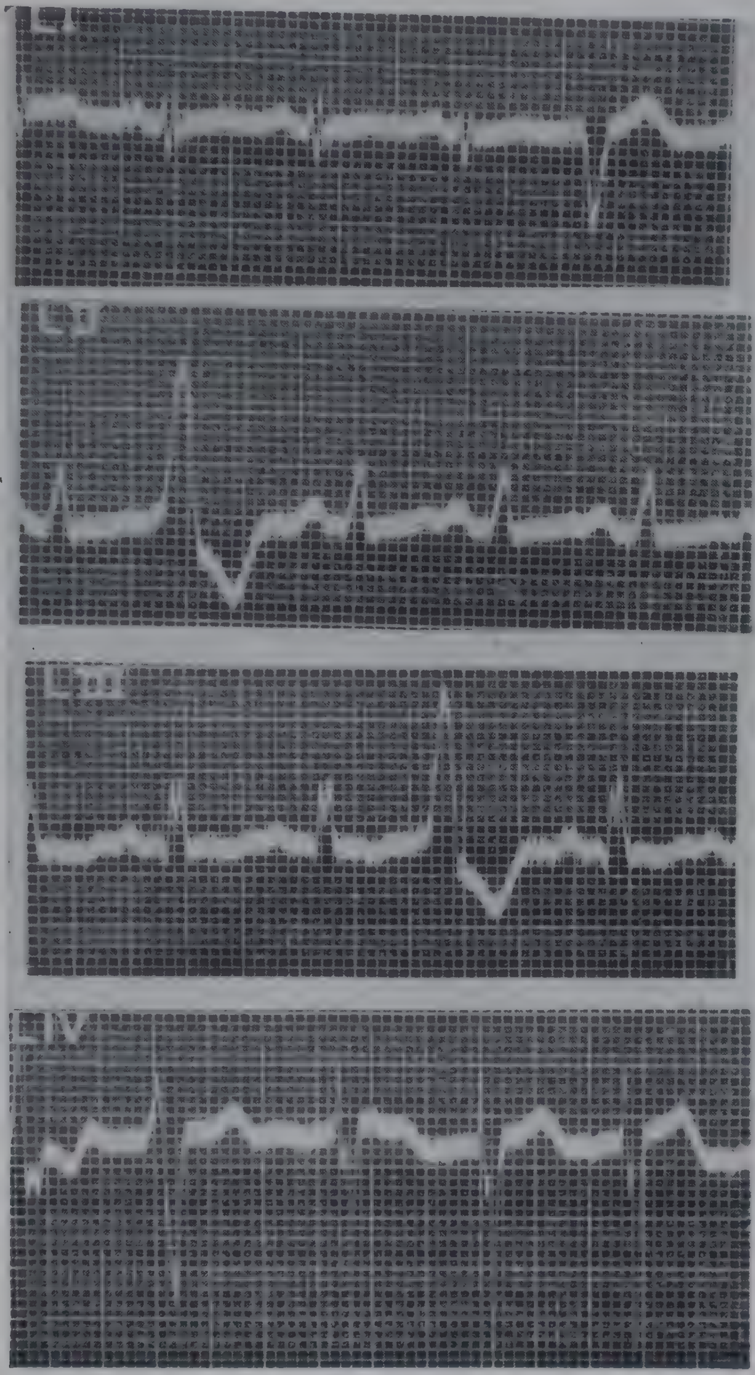

Fig. 753.—Left ventricular premature contraction. The QRS complexes are widened and slurred and the T waves are large and in opposite direction from the main deflection of QRS. The origin in the left ventricle is indicated by the fact that the main deflection is down in Lead I and up in Lead III.

Premature Ventricular Contraction (Ventricular Extrasystole).—In this type of premature contraction the focus arises either in the right or in the left ventricle below the bifurcation of the bundle of His. The ventricular complexes occur before the next regular complex. The QRS complex is characterized by increased width, notching, and slurring, and usually increased amplitude. The accompanying T is usually in a direction opposite to the main deflection of the QRS; it is of greater amplitude and width than the other T waves. The pause which follows the ventricular extrasystole is compensatory; that is, the sum of the duration of the preceding cycle and of the cycle following the extrasystole is equal to the duration of two normal cycles.

Auricular rhythm is not influenced, but the P waves are often lost in the premature ventricular complexes. The ventricles are refractory shortly after the extrasystolic contraction; thus they do not respond to auricular stimulus during this phase. Sometimes the refractory phase has passed before it is time for the next regular contraction. In such cases no dropping out of the regular cycle is evident, and the extrasystole is followed by a pause which is less than the interval between two successive normal cycles of the record. The extrasystole is then termed *interpolated.*

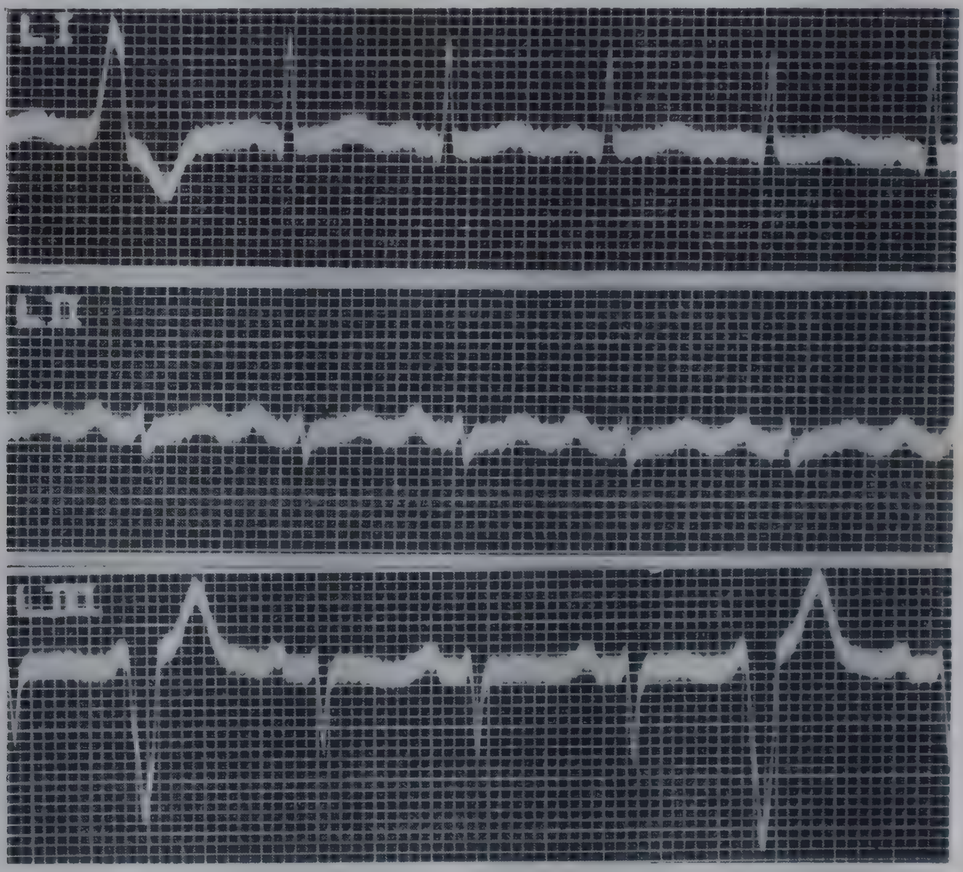

Fig. 754.—Right ventricular premature contraction. Note that the premature QRS complexes are widened and heavily slurred. The QRS is upright in Lead I and inverted in Lead III. The T waves are in opposite direction from the main deflection of QRS and are of unusual width and amplitude. Notice that the premature ventricular systoles are not preceded by P waves.

If the premature focus arises in the left ventricle the main deflection of QRS is down in Lead I (Fig. 753); if it arises in the right ventricle the main deflection is up in Lead I (Fig. 754). The main deflections of QRS in Leads II and III may be up or down in either left or right ventricular extrasystoles, although usually an upward main deflection of QRS in these leads indicates a left ventricular extrasystole and a downward main deflection indicates a right ventricular extrasystole.

Paroxysmal Tachycardia

Paroxysmal tachycardia is a term applied to a series of rapidly recurring heart cycles which have their origin in an abnormal focus in the auricles, auriculoventricular node or bundle, or in the ventricles. These episodes are characterized by the suddenness with which they start and stop; hence the term "paroxysmal." They may last from a minute or more to several days. The rate usually is quite constant, depending upon the origin of the impulse formation. The rate may be between 150 and 250 per minute. Because they originate in some abnormal irritable focus, these tachycardias may be regarded as a series of rapidly recurring premature systoles. These tachycardias are termed paroxysmal auricular, nodal, or ventricular tachycardia, deriving their names from the site of the abnormal focus.

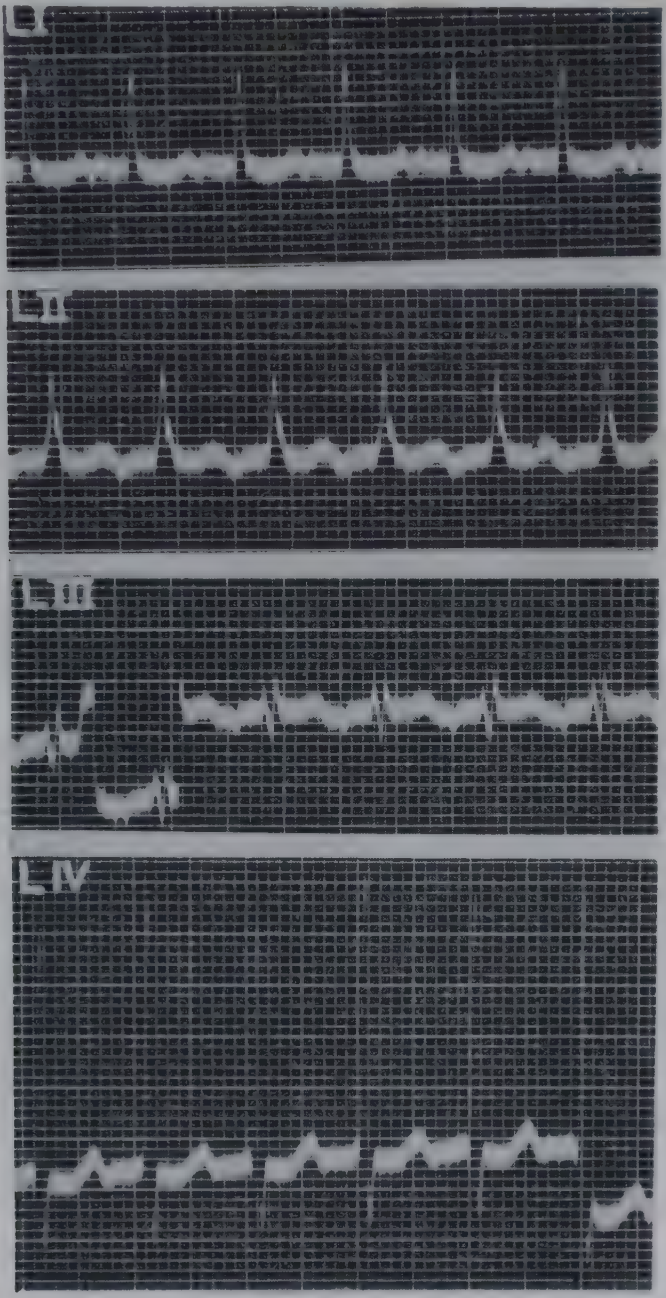

Fig. 755.—Paroxysmal auricular tachycardia. The rate is 157 and the rhythm is regular. The P waves in Lead I are tiny and follow immediately the preceding T waves. In Leads II and III the P waves are inverted. The P-R interval is 0.12 second. The QRS is of normal duration and of normal configuration.

Paroxysmal Auricular Tachycardia.—This type of mechanism is thought of as a series of rapidly recurring auricular extrasystoles. The P waves are different in form or in direction from P waves of a normal mechanism. The preceding T wave is often superimposed on the P wave so that identification of the P wave may be difficult or even impossible. In such instances differentiation of paroxysmal auricular tachycardia from paroxysmal nodal tachycardia cannot always be made. The QRS complexes are not usually altered in form, but they may be aberrant to varying degrees. Rate and rhythm are characteristically constant. Fig. 755 shows an example of paroxysmal auricular tachycardia.

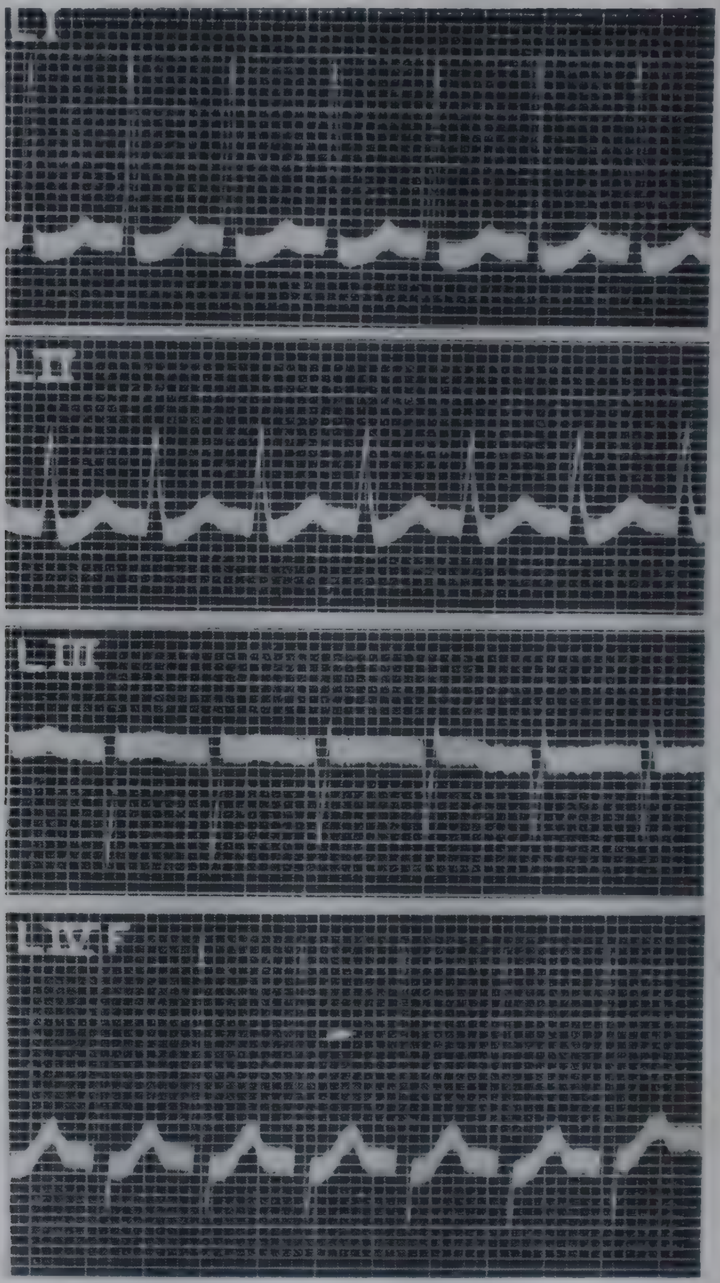

Fig. 756.—Paroxysmal nodal tachycardia. The appearance of the ventricular complexes is supraventricular and like that in nodal rhythm. However, the rate is much faster—171 per minute. The rhythm is perfectly regular. The P waves, as in the example of nodal rhythm, cannot be indentified.

Paroxysmal Nodal Tachycardia.—Here, too, rate and rhythm are absolutely constant. The P waves are usually hidden in the QRS complex but occasionally they occur before or after the QRS. Configuration of the QRS and T waves is not disturbed. The picture is one of nodal rhythm except for the rates which are much higher in paroxysmal nodal tachycardia. Fig. 756 shows an example of paroxysmal nodal tachycardia.

Paroxysmal Ventricular Tachycardia.—The rate in paroxysmal ventricular tachycardia, as in the other tachycardias, may be from 150 to 250 a minute. The appearance is that of a series of rapidly recurring ventricular extrasystoles. The P waves are usually not identifiable but, if seen, their rhythm is not altered. The rhythm is usually regular, although this type of tachycardia differs from nodal and auricular tachycardia in that the rhythm is often slightly irregular. This slight irregularity may at times offer a means of distinguishing auricular from ventricular tachycardia without the aid of the electrocardiograph. Fig. 757 is an example of paroxysmal ventricular tachycardia.

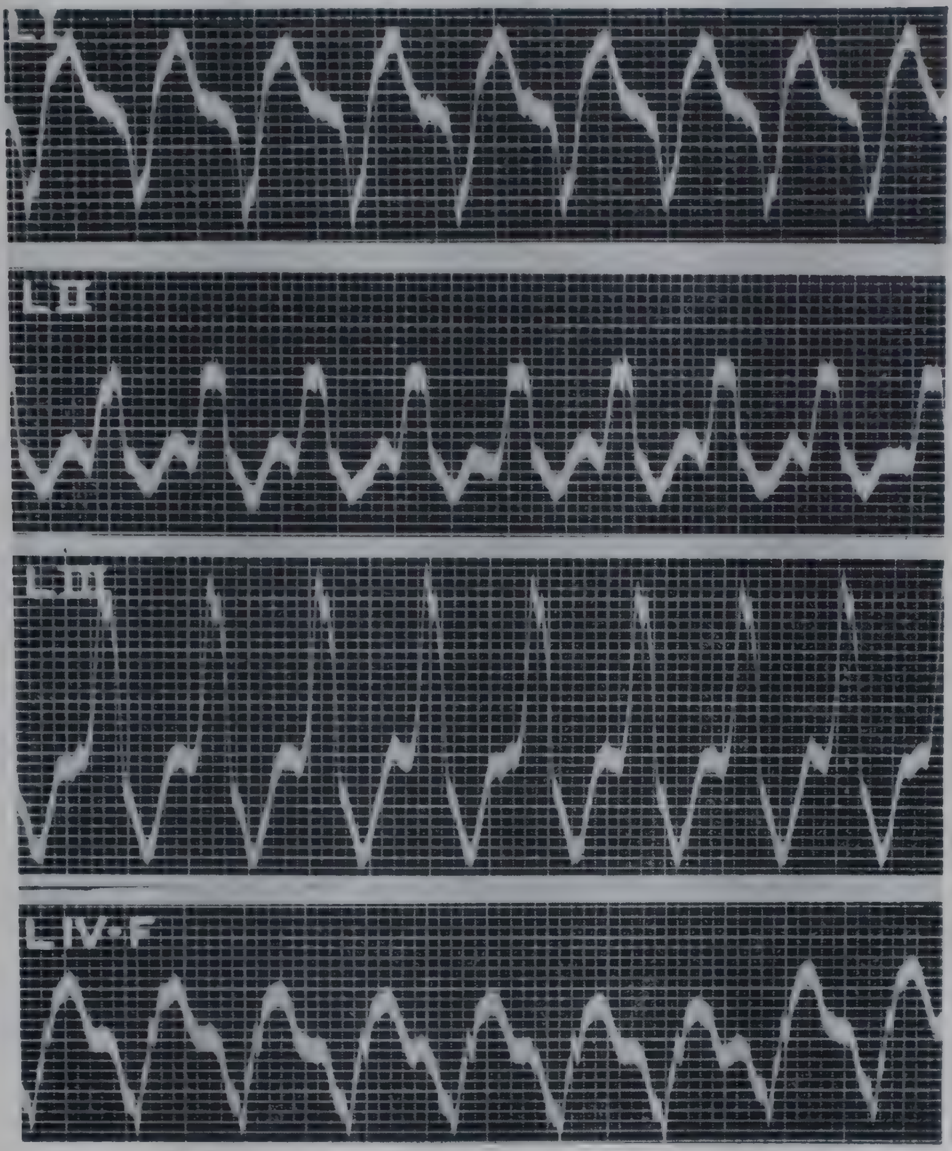

Fig. 757.—Paroxysmal ventricular tachycardia. Note that the rate is 171. The QRS complexes are widened, 0.16 second in duration, slurred and notched, with T waves in opposite direction from the main deflection of QRS. The ventricular complexes are regular in rhythm.

Auricular Flutter

This mechanism may be persistent or transitory. The sinoauricular node loses control of the dominant rhythm of the heart. The impulse travels a pathway about a ring of auricular musculature in a continuous cycle. This has been described as *circus movement.*

The electrocardiogram shows the auricular activity as regularly recurring sawtoothlike oscillations of the string shadow (flutter waves), interrupted by ventricular complexes at regular intervals in response to every second, third, or fourth auricular flutter waves. The form of the ventricular complexes is not altered except by the superimposition of the flutter waves themselves. The frequency of response by the ventricles to the flutter waves may vary in the same electrocardiogram so that the rhythm of the ventricular complexes becomes irregular.

Rarely ventricular complexes follow each auricular flutter wave (1:1 ratio). The flutter waves occur at rates of from 200 to 350 per minute. They are most clearly identified in Leads II and III. Not infrequently they cannot be seen at all, or they are much less obvious, in Lead I. Fig. 758 illustrates auricular flutter.

Auricular Fibrillation

Circus movements are also present in auricular fibrillation, but the pathway is shorter and irregular in its course by comparison with auricular flutter. This results in rapidly and irregularly recurring impulses which pass in an uncoordinated manner through the auricular muscle fibers. This is revealed in the electrocardiogram as absence of P waves as such. The P waves are replaced by small waves which are totally irregular in rhythm, size, and shape. These are termed fibrillary or "f" waves. These waves may at times be absent. They occur at rates of 350 to 500 per minute, but the rate is never constant. The ventricular complexes are not altered in form from the usual form for that patient. They occur in a completely irregular rhythm except in those rare instances where there is complete blocking of the impulses from the auricles to the ventricles. The less the degree of block in the bundle of His, the faster and more irregularly do the ventricular complexes occur. Auricular fibrillation may be permanent or paroxysmal. Fig. 759 illustrates auricular fibrillation.

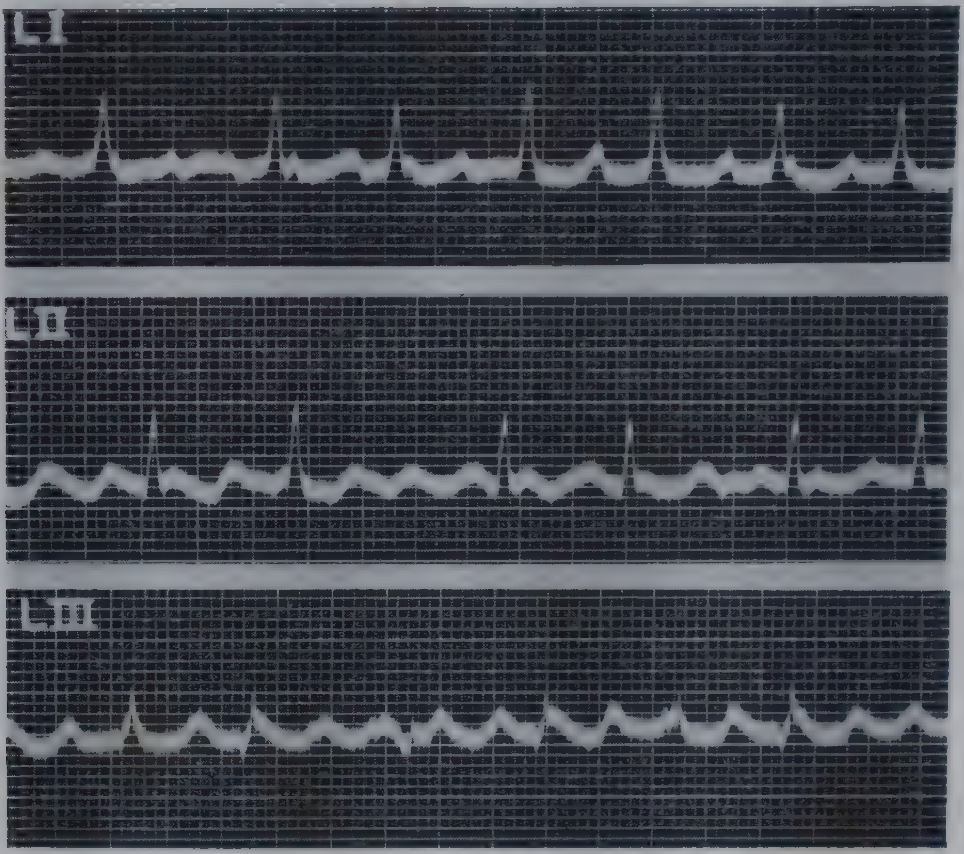

Fig. 758.—Auricular flutter. Note that the flutter waves appear as more or less regularly recurring, saw-toothed deflections, most prominent in Leads II and III. There is a varying rate of ventricular response, from 2 to 1 to 3 to 1. The rate of the flutter waves is 300 per minute.

Ventricular Fibrillation

The ventricles may fibrillate, as may the auricles, by virtue of the same type of mechanism. This mechanism, if continued for more than a minute or two, usually results in death. The electrocardiogram in ventricular fibrillation is characterized by large, bizarre oscillations of the string shadow. These are totally irregular in rhythm, in size, and in shape.

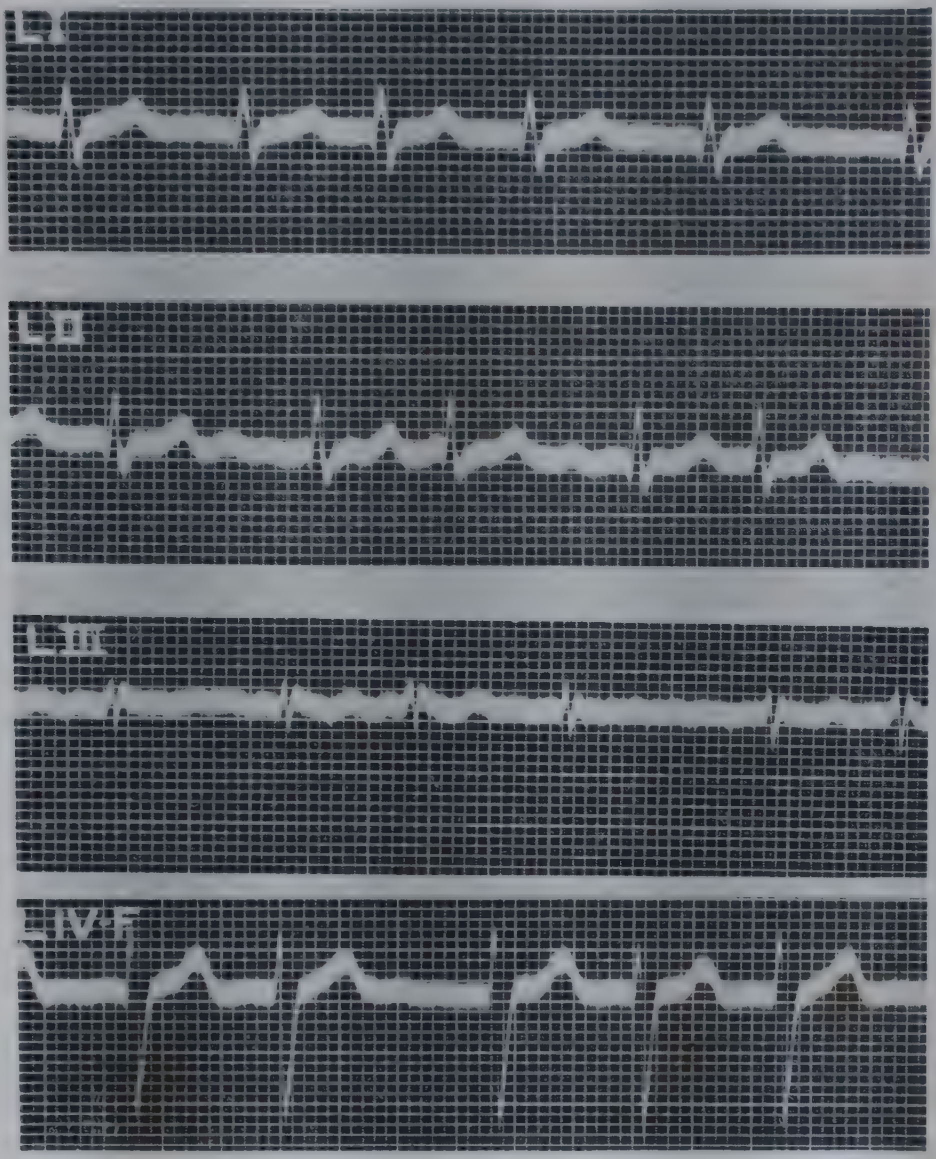

Fig. 759.—Auricular fibrillation. Note that the rhythm of the QRST complexes is totally irregular. The P waves are absent and are replaced by small, irregularly recurring waves which are unequal in amplitude and contour. These are the fibrillary waves and they are best seen in Leads II and III.

Bundle Branch Block

When conduction of the impulse is completely blocked in either the right or the left branches of the bundle of His, a characteristic electrocardiographic pattern results. The QRS duration is increased to more than 0.12 second. The deflections of the QRS are notched or slurred and are of large amplitude. The T wave is usually opposite in direction to the chief deflection of QRS, and is of increased size.

In **left bundle branch block** the chief deflection of QRS is up in Lead I (R), and usually down (discordant) in Lead III. See Fig. 760. Occasionally the chief deflection of QRS is up in Lead III; this is then known as the concordant type of left bundle branch block. The term ''chief deflection'' refers to the deflection of greatest duration or spread, which is not necessarily the deflection of greatest amplitude. The S-T segment is usually depressed in Lead I.

In **right bundle branch block** the chief deflection of QRS is directed downward (S) in Lead I and usually upward (R) in Lead III. See Fig. 761. Another type of right bundle branch block occurs in which the R is tall and narrow and is followed by a shallow but widened S wave in Lead I.

Partial bundle branch block is indicated when the QRS is widened, notched, and slurred only to a slight extent; the amplitude may be either large or small. The T waves may be directed upward or downward. The main deflection of QRS is often up in all leads. This type is often termed *defective intraventricular conduction* because it is difficult to determine with certainty whether the lesion has resulted in interference with conduction in the ventricular muscle itself or in the bundle branches.

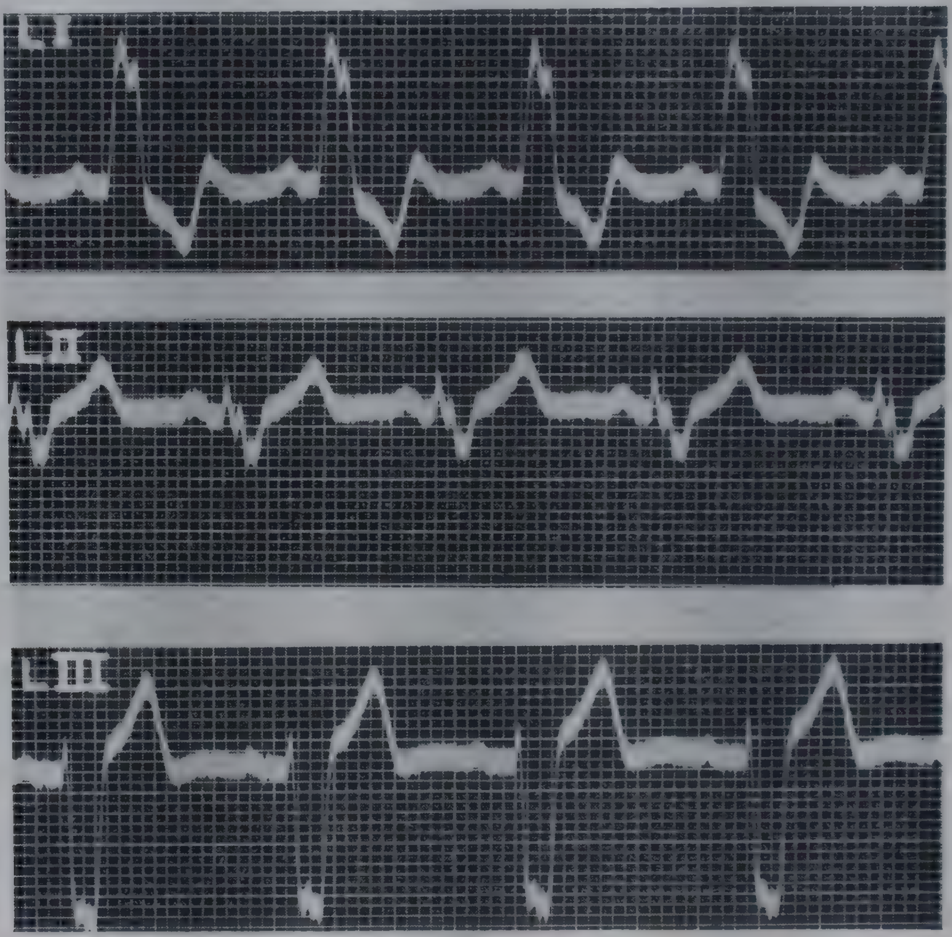

Fig. 760.—Left bundle branch block (common type of intraventricular block). The QRS complex in Lead I is upright, slurred, notched, and widened with duration 0.15 second. In Lead III the main deflection of QRS is down, slurred and notched, with duration 0.15 second. The S-T segment in Lead I is deflected downward and in Lead III is deflected upward. T in Lead I is inverted with slight diphasic terminal phase. In Lead III, T is upright. S in Lead II is widened, slurred, and heavily notched. P-R interval is normal, 0.15 second.

Atypical types of bundle branch block may occur in which QRS is very much widened, notched and slurred, and of high or low amplitude. The QRS is of rather bizarre configuration. The latter group includes the type known as ''arborization'' block. The T wave may be either of large or small amplitude, and may point in the same direction as, or in the opposite direction from the chief deflection of QRS.

Wolff-Parkinson-White Syndrome

This is an infrequently seen type of electrocardiographic picture which bears a superficial resemblance to bundle branch block. It is characterized by a *shortened P-R interval* in contrast to the other types of bundle branch block in which the P-R interval is normal or lengthened, especially if a lesion involves the bundle of His as well as the bundle branches. The QRS is only slightly widened, 0.10 to 0.12 second, and is relatively slightly notched and slurred. The diagnosis of Wolff-Parkinson-White syndrome is made only by means of the electrocardiograph.

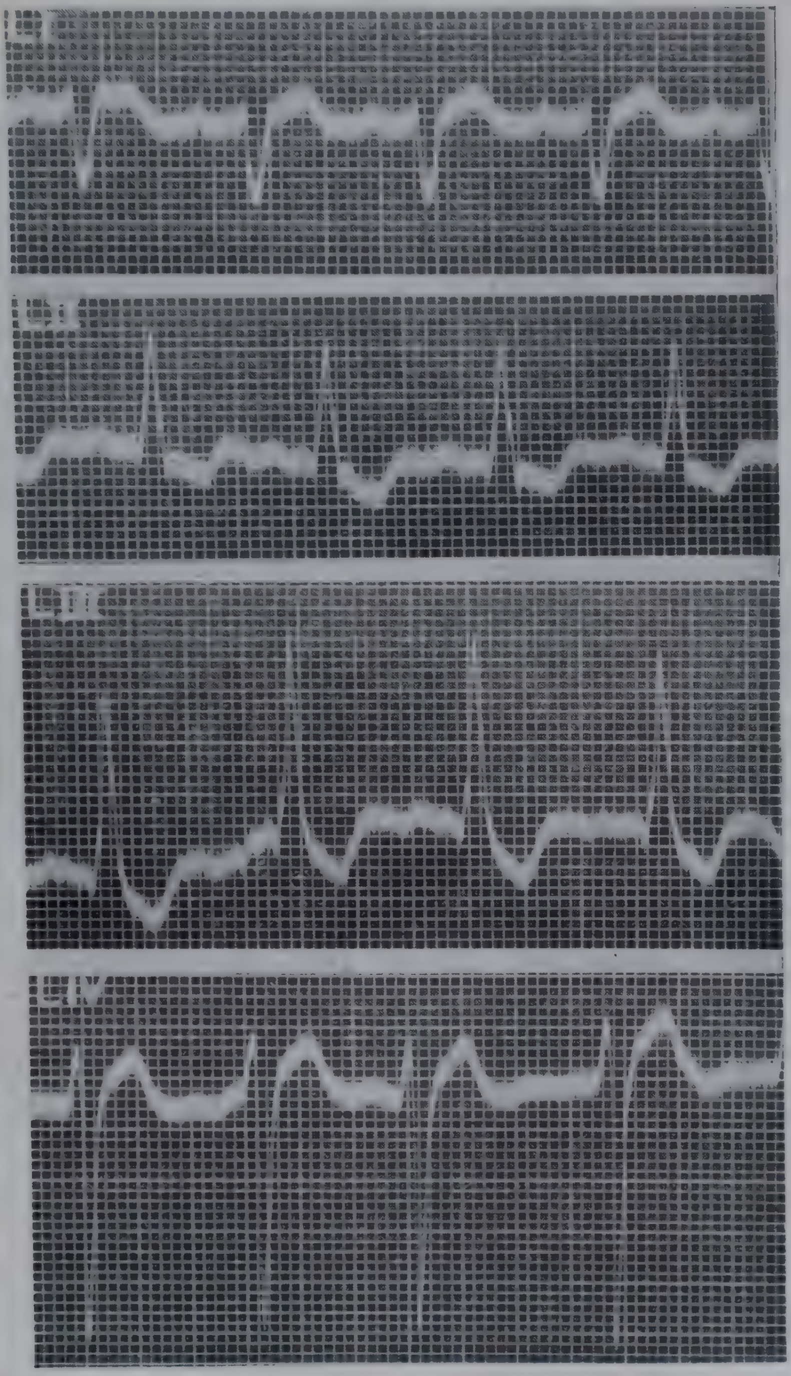

Fig. 761.—Right bundle branch block (uncommon type of intraventricular block). Duration of QRS is 0.12 second. In Lead I, R is minute and relatively short in duration whereas S is prominent, wide and heavily slurred. The main deflections are upright (R) with minute Q in Leads II and III. S-T in Lead II and S-T in Lead III are depressed and T in Lead II and T in Lead III are inverted. In Lead IV F, R is relatively small and short in duration while S is deep and widened.

That the patterns of the Wolff-Parkinson-White syndrome may vary widely has been pointed out by Burch and Kimball.[1] These authors classified the variations in these patterns into five groups ranging from QRS complexes which closely resembled those of complete left bundle branch block to those QRS complexes which were of normal duration in all the standard leads. However, the shortened P-R interval was present in all these groups and gave the clue to the true nature of the condition. Elson[2] has encountered a rare instance in which the type of Wolff-Parkinson-White syndrome characterized by shortened P-R interval and slurred basal portion of QRS complex with normal duration reverted spontaneously to normal patterns and then back to the Wolff-Parkinson-White patterns during the taking of the electrocardiogram.

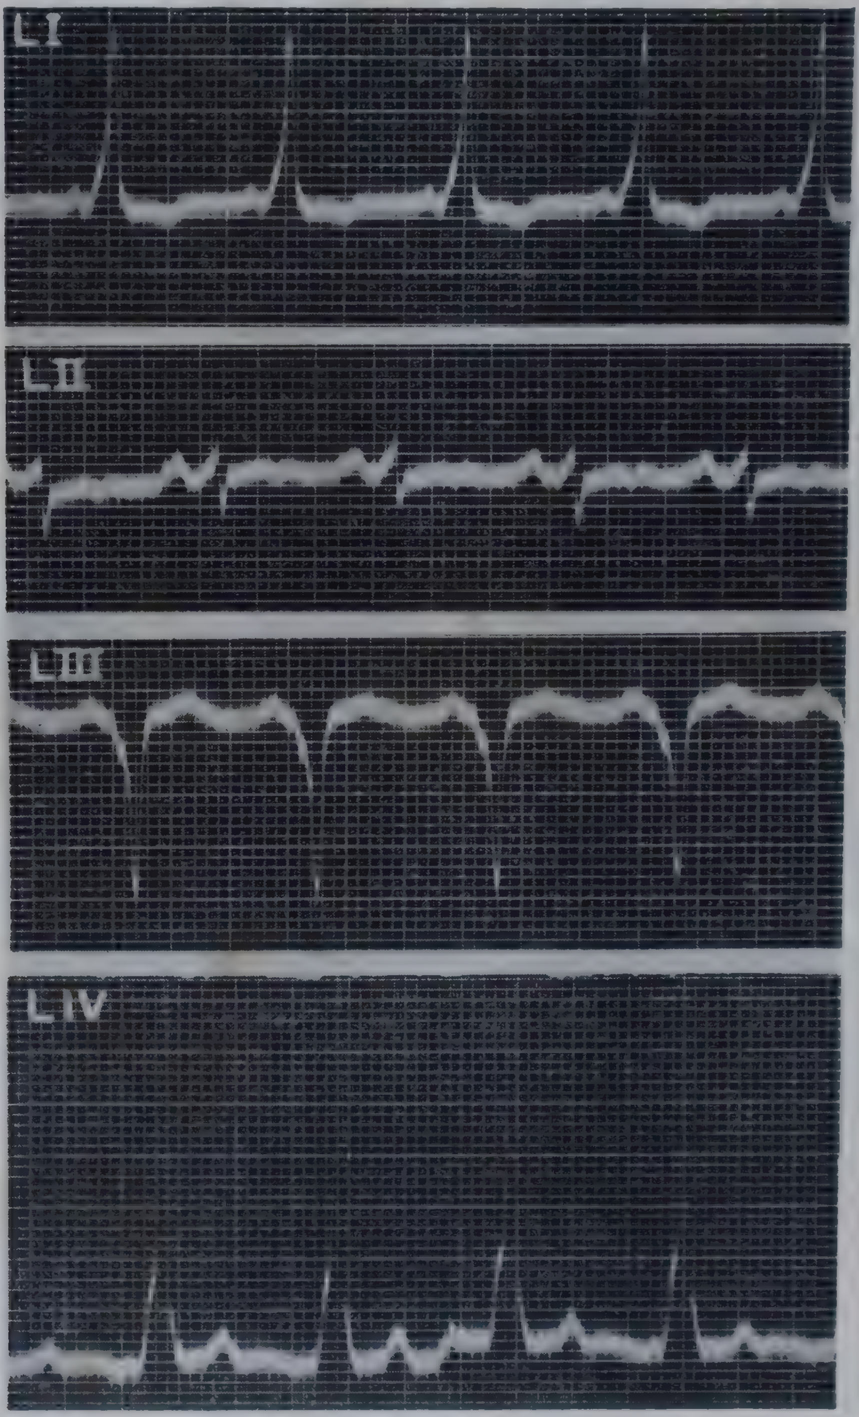

Fig. 762.—Wolff-Parkinson-White syndrome. (Short P-R, prolonged QRS combination.)

The Wolff-Parkinson-White syndrome is not ordinarily associated with organic heart disease. However, patients who exhibit this electrocardiographic manifestation are likely to have episodes of paroxysmal tachycardia. Fig. 762 is an example of this interesting type of electrocardiographic pattern.

Auriculoventricular Block

Mention was made, in discussing the effects of rheumatic fever on the heart, of the involvement of the junctional tissues, either at the A-V node or at the bundle of His, by disease processes. Not only rheumatic fever, but other types of disease as well, can inhibit conduction of the impulse in the junctional tissues. These are principally degenerative diseases, drugs such as digitalis, and neurogenic influences.

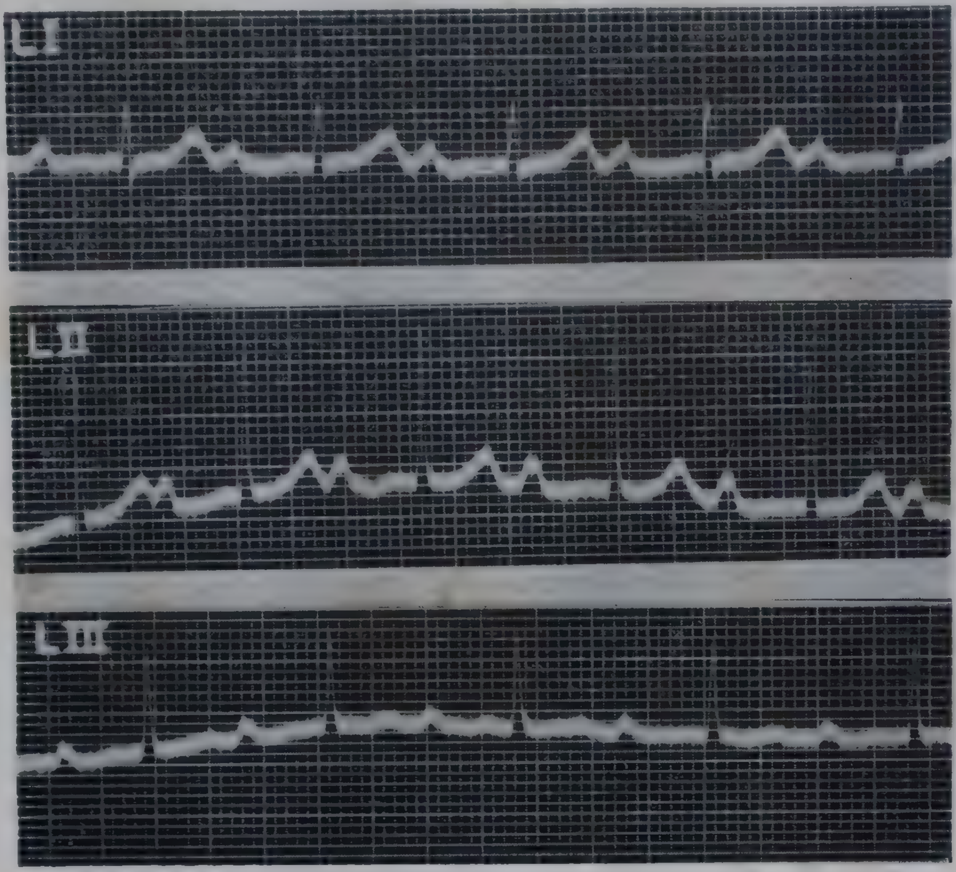

Fig. 763.—Delayed A-V conduction (first degree heart block). Each auricular complex (P) is followed by a ventricular complex QRST at an interval greater than the normal 0.20 second; in this instance 0.32 second.

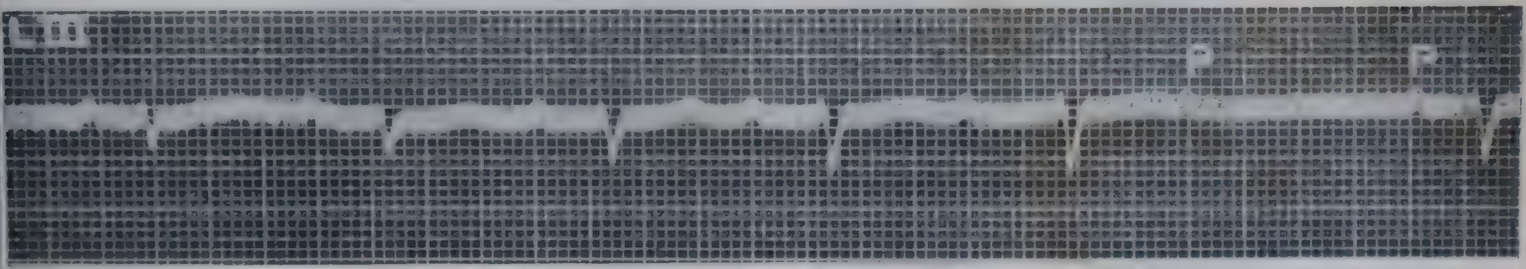

Fig. 764.—Second degree heart block (partial A-V block with dropped beats). Electrocardiogram shows dropped ventricular complexes preceded by progressively increasing P-R interval (Wenckebach phenomenon).

First Degree Heart Block.—Degree of interference with conduction varies widely. In the milder forms there is only a slight delay in the speed of conduction so that the impulse reaches the ventricle after a greater than normal interval. The rhythm of the heart is regular, with each QRS complex following each P wave, but with a P-R interval greater than 0.20 or 0.21 second. This degree of heart block is termed "first degree" heart block. First degree heart block is often referred to as "delayed auriculoventricular (A-V) conduction." An electrocardiogram is invaluable in ascertaining its presence, since it is usually impossible to recognize it clinically. Fig. 763 illustrates first degree heart block.

Second Degree Heart Block.—As interference in conduction of impulses from the auricles to the ventricles increases, some of the impulses may be completely blocked from reaching the ventricles so that the ventricles do not respond to certain of the auricular impulses, and a ventricular complex is dropped. These dropped beats may occur at infrequent intervals or as often as every other cycle. Frequently the P-R interval becomes steadily longer until eventually a ventricular complex is dropped. The P-R interval then again becomes relatively short, then progressively longer, until another ventricular complex is dropped. This is known as the "Wenckebach phenomenon." Fig. 764 illustrates second degree heart block and the Wenckebach phenomenon.

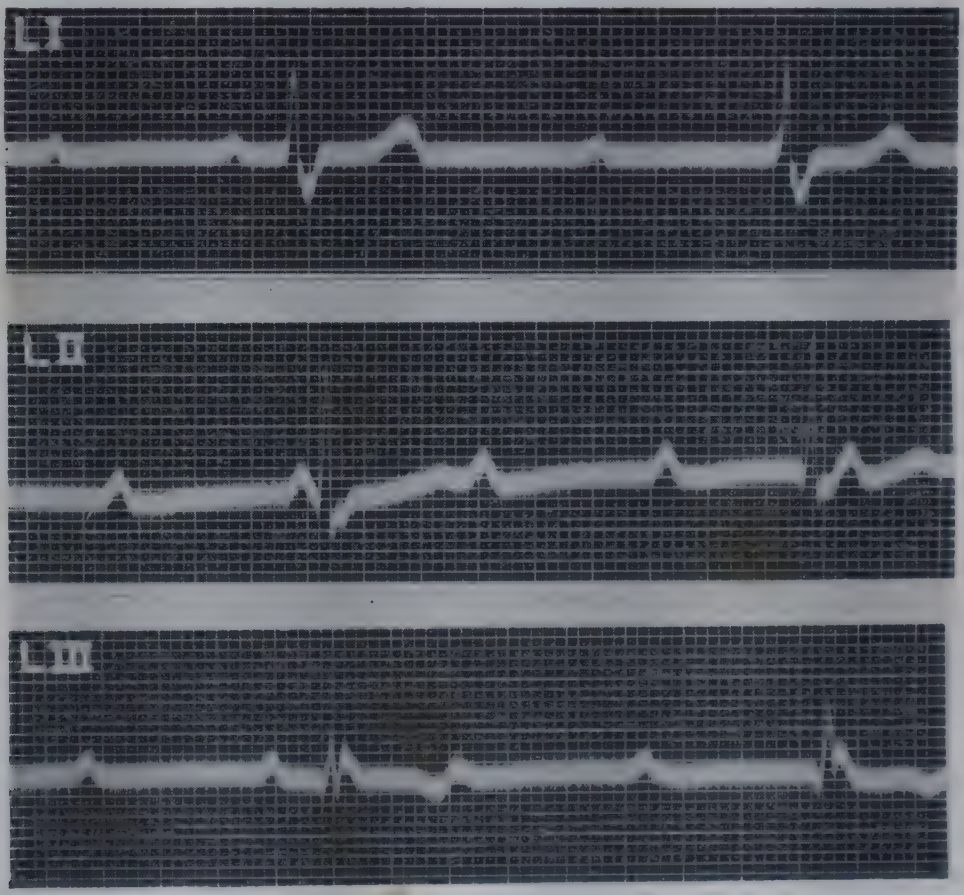

Fig. 765.—Third degree heart block (complete A-V block). There is no fixed relationship between the P and QRS complexes. The auricular rhythm is regular at a rate of 92 and the ventricular rhythm is likewise regular at a rate of 37. In Leads I and III the third P wave falls on the terminal portion of the T slightly distorting its configuration. In Lead III the second QRS is distorted by a P wave. Note also widening of QRS with slurring and notching in all leads indicating defective intraventricular conduction.

Third Degree Heart Block (Complete Heart Block).—In this type of auriculoventricular block, conduction in the auriculoventricular pathway is so markedly inhibited that all the impulses are prevented from reaching the ventricles. At the onset of this mechanism there is complete standstill of the ventricles for a variable length of time, ranging from a very few seconds to as much as a minute or even longer. During this time the ventricles respond to their own pacemaker just below the area of blocking, either in the lower part of the bundle of His or in the ventricles themselves.

It is during this period of standstill that patients are prone to lose consciousness (Adams-Stokes syndrome). If the pause is longer than a minute, death is likely to occur.

With the response of the ventricles to their own independent pacemaker, the ventricles contract at a much slower rate than formerly, usually 30 to 40 times a minute, or slower, and with a regular rhythm. The auricles continue to contract in response to their own pacemaker in the sinoauricular node but at a much faster rate than the ventricles. Thus in the electrocardiogram the P waves and the ventricular complexes will show no constant relationship with each other.

The form of the complexes will not vary from the usual form for the patient in heart block of any degree, since the manner of spread of the impulse through both the auricles and ventricles is normal. If the complete heart block has been caused by digitalis or is congenital in origin the ventricular rates are apt to be faster than 30 to 40 per minute. Fig. 765 is an example of complete heart block.

CONCLUSION

It must be emphasized that this chapter is intended to give the reader only an introduction to the subject of electrocardiography and its clinical and laboratory applications. The usefulness of the electrocardiograph in clinical medicine is established beyond question. This usefulness can, however, be impaired if one fails to recognize the many pitfalls in interpretation, such as the wide variation in normal patterns, changes due to artefacts and to faulty technic, and improper standardization of the instrument. It must be remembered that the electrocardiogram reflects changes in the myocardium which affect its electrical conductivity whatever the cause may be, and that these changes may be due to a great variety of causes, either organic or nonorganic. Such widely different causes as autonomic nervous system imbalance, position of the patient during the electrocardiographic recording, and actual degenerative changes in the myocardium may result in quite similar effects on the electrocardiogram. It is only after thorough familiarity with the theories and principles underlying electrocardiography, and after considerable experience in its clinical application, and recognition of its limitations, that one can realize the full usefulness of this instrument. As previously indicated, in only a relatively few instances does the electrocardiogram give pathognomonic information, and of these instances acute myocardial infarction is an outstanding example. Many arrythmias and conduction defects can be recognized only by the use of the electrocardiogram; these may be due to a wide variety of diseases or to functional causes. For correct clinical deductions from the electrocardiogram, the electrocardiographer should have as full a knowledge as possible of the clinical aspects of the patient's condition. It must again be emphasized that a normal electrocardiogram does not necessarily indicate the absence of heart disease; on the other hand the presence of a definitely abnormal electrocardiogram does not necessarily indicate the presence of organic heart disease. All electrocardiographic findings must be interpreted in the light of the clinical picture.

    serum, Leptospira, 1588
  reaction, 1422, 1423
    colorimetric method of adjusting, 1422, 1423
    hydrogen ion concentration, 1422, 1423
    testing, 1423
  Reed and Orr, anaerobic nitrate broth, 1437
      iron milk, 1437
  reheating, 1417
  Robertson chopped meat, 1426
  rope spore, 1695
  Row, 1868
  Rustigian and Stuart, urease broth, 1450
  Sabouraud, 1767
    agar, 1452
  Salmonella-Shigella agar, 1443
  Sanderson and Greenblatt, 1644
  Savino, 1588
  sea-salt water, 1451
  selenite F, Leifson, 1446
  semisolid, 1417
    enteric, 1448
    mannitol, Felsenfeld, 1449
      with H_2S indicator, 1449
  serum-ascitic fluid broth, 1425
    egg, ameba, 1830
    inspissation, 1395
    Loeffler, 1425
  S.F., Hajna and Perry, 1454
  Simmons citrate agar, 1450
  slants and butts, inoculation, 1469
  Snyder and Lichtenstein, 1428
  sodium azide agar, 1428
      chloral hydrate blood agar, 1428
  solid, 1417
    inoculating, 1463 ff, 1468, 1469
  soy, trypticase, 1427
  S.S. agar, 1443
  starch-serum, dextrose agar, 1456
  sterility test, 1420, 1701
      biologic, 1700, 1701
  sterilization, 1419
    inspissation, 1395
  stock cultures, 1455
  storage, 1417, 1420
  streptococcus, fecal, Hajna and Perry, 1454
  streptomycin fungi, 1767
    medium, Littman, 1453
  sugar broth, 1424
  taurochlolate, 1441, 1443
  Teague and Clurman buffered glycerol, 1451
  tellurite, 1434
    diphtheria, 1512
      types, 1510
    solution, 1435
    Whitney-Damon, 1435
  tetrathionate-brilliant green broth, 1446
  thioglycollate, 1436, 1437, 1438
    agar, Brewer, 1437, 1469
      Brewer-Vera, 1436
    base, 1438
    Brewer, 1437, 1469
    Brewer-Vera, 1436
    broth, 1436
    glycerol, 1438
    sterility tests, 1700, 1701
  thionin agar, 1429
  Tittsler and Sandholzer, motility, 1448
  transport, Hirschberg, 1432
  Treponema pallidum immobilization test, 2088
  Trichomonas vaginalis, 1865
  triple sugar iron, Hajna, 1447
  trypanosomes, 1868, 1869, 1873, 1874
  trypticase agar, 1427
    -cysteine-HCl-maltose agar, 1865
    lactose iron agar, 1438
    soy agar, 1427
      broth, 1424
  tryptophan, Braun, 1447
  tryptose agar, 1427
    citrate broth, 1428
  T.S.I. agar, 1447
  tuberculosis, evaluation, 1614
  tubing, 1419, 1420
  Ulrich milk, 1426
  urea, sterilization, 1418
  urease broth, Rustigian and Stuart, 1450
  Veervoort, 1588
  Venkatraman and Ramakrishnan, 1451
  Vera, eugonagar, 1427
  Voges-Proskauer methyl red, 1450

Culture media—Cont'd
  water for, 1418
    loss, restoring, 1417
  Wenyon and Noguchi, 1869
  Whalen charcoal agar, 1440
  Whitney-Damon, 1435

life cycle, 1937
embryos, 1935
span, 1936
male, 1934, 1935
microfilaria, 1935, 1936, 1939
identification, 1936
life span, 1936
Pandit and Iyer test, 1936
serologic test, 1936
symptoms, 1938
transmission, 1796
Wuchereria malayi, 1940
malayi, 1940
microfilaria, identification, 1936
urine, 101
Wuchereriasis, *see* Filariasis
malayan, diagnosis, 1940

X

"X" protein, 1038
fetus, 1073
Xanthine, calculi, identification, 139
Kamlet test, 138, 140
feces, 1294
Xanthochromia, spinal fluid, 1241
Xanthogranulomatosis, 951
Xanthomatoses, 954, 955
cholesterol, 372
classification, 952
nomenclature, 812
Xanthoproteic reaction, 175
Xanthydrol reaction, urea, Goldbaum, 259 ff
solution, 2162
Goldbaum, 259
X-B solutions, 298
Xenoculture, 1800
Xenopsylla cheopis, 1709, 1996
Hymenolepis diminuta, 1959, 1960
Xenopus laevis test for pregnancy, 1318
Xerophthalmia, vitamin A deficiency, 1380
Xerosis bacillus, 1513
vitamin A deficiency, 1380 ff
X-ray, blood picture, effect on, 867
crystals, analysis, 119
exposure, blood changes, 843
hemorrhagic diathesis, 902
therapy, leukemia, 893
leukopenia, 789
lymphoma, malignant, 893
nitrogen mustard, 891
polycythemia vera, 775
Xylol poisoning, blood changes, 764, 765
properties, 2370
Xylose fermentation, Salmonella, 1517
urine, 57

Y

Yates, bromine in blood, 496
Yaws, 1586, *see also* Treponema pertenue
diagnosis, 1586
distribution, 1586
immobilizing antibody, 2086
immunity, 1586
syphilis, 2019
differentiation, 1586
transmission, 1586
Treponema pertenue, 1585 ff
Wassermann test, 2019
Yeast, 1783, *see also* Fungi
beef agar, 1456
Blastomyces dermatitidis, 1787
blastomycosis, South American, 1788
blastospore, 1765
blood agar, 1426
Candida albicans, 1775
cells, gastric contents, 1208
culture media, honey, 1698
extract, 1426
agar, Chapman-Stone, 1436
Emerson, 1453
for culture media, 1418
mannitol-H_2S media, 1449
micromedium, Bertacchini, 1451
thioglycollate glycerol medium, 1438
Histoplasma capsulatum, 1785, 1786
intestinal, 1882, 1884
milk, 1678
myelin globules, 1787, 1788
peptone glucose extract agar, Jamieson, 1455
pyrogens, 1125
reproduction, 1764
skin, examination, for, 1622
spinal fluid, 1601
sputum, 1608
Yellow fever, 1734, 1735, 1748, 1749
antibody determination, 1734
blood picture, 841, 844
complement fixation, 1735
diagnosis, 1740, 1751
viscerotomy, 1874
distribution, 1734
hemoglobin in urine, 78
neutralization test, 1734
treatment, 1735
vaccine, virus hepatitis, 904
vector, 1734
virus, 1734
viscerotomy, 1735
Yohimbine, identification, 2322, 2323
reactions, 2306
Yolk sac antigen, Frei test, 1728
technic, 1730
inoculation, 1475, 1729, *see also* Egg inoculation
examination, 1476
Toxoplasma, 1887
tuberculosis, 1475

Z

"Z" streak, bacterial plating, 1465
Zaffaroni, Burton, and Keutmann iodoplatinate reagent, 2318
Zak, cholesterol, technic, 363
Zak-Leffler protein bound iodine, 491
Zeiss monocular microscope, 8
Zemansky criteria for neoplasma, 1226
Zenker's solution, 2096, 2115
    mercury removal, 2155
Ziegler-Heidenhain hematoxylin, 1824
Ziehl-Neelsen stain, 1411
    tissues, 2142 ff, *see also* Tissues, acid-fast stain
Zimmermann reaction, 1323, 1325
Zinc acetate test, bile, 1289
    uranyl, reagent, 423
  flotation method, concentration, feces, 1809
Zinc—Cont'd
  poisoning, symptoms, 2228
    treatment, 2242
  sulphate, 5%, Somogyi, 227
    reagent, Lauber and Mattice, 236
    solution, Barker, Humphrey, and Scoley, 486
    turbidity test, 319
  tests for, 2352
  water, 1674
Zirconyl chloride fixative, 1368
Zirkle, clarification of paraffin sections, 2172
Zizania aquatica, Fasciolopsis buski, 1992
Zondek, pregnancy test, rapid method, 1312
Zooparasites, definition, 1794
Zygosity, 1048
  Rh, anti-Hr serum, 1049
Zygospore, definition, 1765
Zygote, definition, 1146
  malaria, 1894
